Acute passive congestion occurs when the liver is suddenly engorged with blood as a result of anaphylaxis, shock, or other acute insult. In the early stages, the liver is swollen, dark, and bloody on section, and there is little accentuation of the acinar pattern. There is usually excessive blood-tinged abdominal fluid, because the congested liver elaborates lymph at an increased rate; this may be seen exuding from the capsule during life and distending hilar and gall-bladder lymphatics in fresh carcasses. Because this lymph is rich in most clotting factors, it tends to clot on the liver capsule, and the lobes may be stuck together by fibrin, which is often blood-tinged.

The microscopic picture in acute passive congestion is one of fairly uniform sinusoidal engorgement, with accompanying distension of lymphatics in the stroma of hepatic veins, portal triads, and capsule. There follows rapidly fatty change, trabecular atrophy, and necrosis of periacinar hepatocytes with retention of the perisinusoidal reticulum framework. Erythrocytes tend to move into the perisinusoidal spaces left by the lost hepatocytes, and may be seen trapped there when blood drains from sinusoids and veins in freshly fixed sections. The intrahepatic network of lymphatics at this stage becomes very distended and may form extensive cavernous channels about hepatic veins and venules, in portal triads, and just beneath the capsule. Distension of the space of Disse may be seen, but rarely, if ever, in tissue well fixed soon after death, and is best regarded as a postmortem artifact. By comparison, perisinusoidal edema is more obvious in hepatic congestion associated with shock or inflammatory conditions.

In **chronic passive congestion**, the amounts of fibrous connective tissue in the liver increase in various patterns that differ among species. The capsular surface becomes thicker and more opaque, and can develop a finely nodular texture with the formation of capsular plaques. In dogs and cats, the edges of the central lobes become rounded, whereas the margins of lateral and caudate lobes are sharpened by peripheral atrophy and fibrosis. If the cause of the congestion is still present, there is usually copious ascites at this stage. In species in which fibrosis is more pronounced, a chronically congested liver has a distinct reticulated acinar pattern, often more obvious beneath the capsule than in deeper parenchyma. This pattern is known as "**nutmeg liver**" and is *due to the contrast of red periacinar zones of congestion with loss of hepatocytes, among pale swollen periportal parenchyma composed of viable hepatocytes that are fatty* (see Fig. 2.28). This classical pattern of chronic passive congestion is most obvious in ruminants and horses. The "nutmeg" pattern can be mimicked by some forms of toxic periacinar necrosis or fatty change but should always be distinguishable from them by the presence of fibrous plaques in Glisson's capsule in the passively congested liver. The pale lobular pattern is less obvious in carnivores and should not be expected in animals that have insufficient adipose reserves for mobilization. Over longer periods, *periacinar fibrosis links hepatic venules with one another and with the larger portal triads in a pattern known as* **cardiac fibrosis** (Fig. 2.39B).

Inflammatory changes in the outflow veins are sometimes observed. Acute inflammation and thrombosis of sublobular veins are typical of acute salmonellosis in many species but these changes are terminal and not associated with hepatic dysfunction. Inflammatory cell infiltrates are occasionally observed in the larger hepatic veins, and have been described in dogs with parvoviral myocarditis. Muscular hypertrophy of walls of hepatic veins has been described in dogs with arteriovenous fistulae. Fibrous remodeling of these veins has been associated with nitrosamine intoxication in domestic animals.

The term **Budd–Chiari syndrome** is used to describe the clinical features associated with hepatic venous outflow obstruction caused by thrombosis of the main hepatic veins in humans. In veterinary medicine, the term **Budd–Chiari-like syndrome** has been applied more broadly to encompass the clinical signs and pathologic changes that develop in response to various mechanical causes of postsinusoidal obstruction of hepatic venous flow, resulting in development of *hepatomegaly, postsinusoidal portal hypertension, high-protein ascites, and acquired portosystemic collateral shunting*. The syndrome has been infrequently reported in dogs and cats. Causes include obstruction of flow due to tumors (e.g., intraluminal leiomyosarcoma, adrenal pheochromocytoma with extensive invasion into the caudal vena cava in the dog) or abscesses in the liver or caudal vena cava, hepatic venous or venal caval thrombosis, congenital malformation (fibrous web), kink or acquired stricture occluding the lumen of the vena cava or hepatic veins (intrahepatic postsinusoidal venous obstruction), or cardiac malformations impairing right atrial function (cor triatrium dexter, neoplasia). Histologic changes include distension of the hepatic veins and perivenous sinusoidal congestion, which, with chronicity, leads to perivenous fibrosis typical of chronic passive congestion.

Thrombosis of the caudal vena cava has been described in detail in cattle, where rupture of a hepatic abscess into the caudal vena cava is the most common etiology. Sequelae include pulmonary emboli, endoarteritis, multifocal pulmonary abscessation, and chronic suppurative bronchopneumonia. **Hepatic vein thrombosis**, associated in humans with polycythemia vera, pregnancy, and the postpartum state, oral contraceptive use and intra-abdominal cancers, is a rare occurrence in dogs.

Acquired portosystemic shunts

Congenital shunts have been described in the section on Developmental anomalies, above. *Acquired portosystemic shunts within and external to the liver can develop in association with various chronic liver diseases that lead to portal hypertension.* These shunts can be multiple, small, and may be difficult to identify postmortem. They are easily destroyed by routine dissection, so they must be noted before removal of the abdominal viscera. Acquired shunts can be associated with evidence of portal hypertension, such as distension of the portal veins and ascites, but when shunts are multiple and well established, portal hypertension is somewhat relieved. *It is important to distinguish these varicose dilations that develop in response to portal hypertension from true congenital portosystemic shunts.* Acquired shunts arise in vestigial nonfunctional portosystemic communications that dilate and become functional in response to portal hypertension. They tend to develop between mesenteric veins and the caudal vena cava, right renal vein, or gonadal veins, and are multiple, taking the form of a plexus of tortuous, thin-walled vessels (see Fig. 2.4). Esophageal shunts and varicosities are common in humans with cirrhosis, but are much less important in domestic animals. This may be related to postural differences such that shunts are more likely to enter the vena cava where central venous pressure is least. In dogs, acquired shunts are most numerous along the caudal mesentery.

Telangiectasis

Telangiectasis is cavernous ectasia of groups of sinusoids that occurs in all species, but is particularly common in cattle. The lesion is not functionally significant. Telangiectases occur throughout the liver as dark-red areas, irregular in shape but well circumscribed, and ranging from pinpoints to many centimeters in size. Sectioned or capsular surfaces are depressed after death, and on cutting they appear as cavities from which the blood drains to reveal a delicate network of residual stroma and strands of atrophic hepatocytes. The pathogenesis of telangiectasis remains uncertain; however, an ultrastructural study of pretelangiectasis (sinusoidal dilation) and telangiectasis (blood-filled cavities) in Holstein–Friesian steers demonstrated *sinusoidal barrier alterations*, leading to sinusoidal capillarization, with progressive formation of a true basement membrane and perisinusoidal fibrosis. A toxic or metabolic etiology has been suggested.

Telangiectasis in livers is quite common in older cats. As with the bovine lesion, there is no evidence clinically of related liver dysfunction. In cats, the cavities are rather more frequent in the subcapsular zone (Fig. 2.41) and rarely exceed 2–3 mm in size. There are often other senile changes in these livers, such as chronic fatty change, nodular hyperplasia, and chronic cholangiohepatitis, but there is no evidence that these changes have any causal relationship to the telangiectasis.

Peliosis hepatis

Peliosis hepatis is a term used to designate a hepatic vascular disorder characterized by cystic, blood-filled spaces in the liver. The histologic lesion is characterized by multiple, dilated, blood-filled spaces surrounded by fibromyxoid stroma containing inflammatory cells and dilated capillaries. The blood-filled cystic spaces may be partially lined by endothelium; some may merge directly with surrounding hepatic

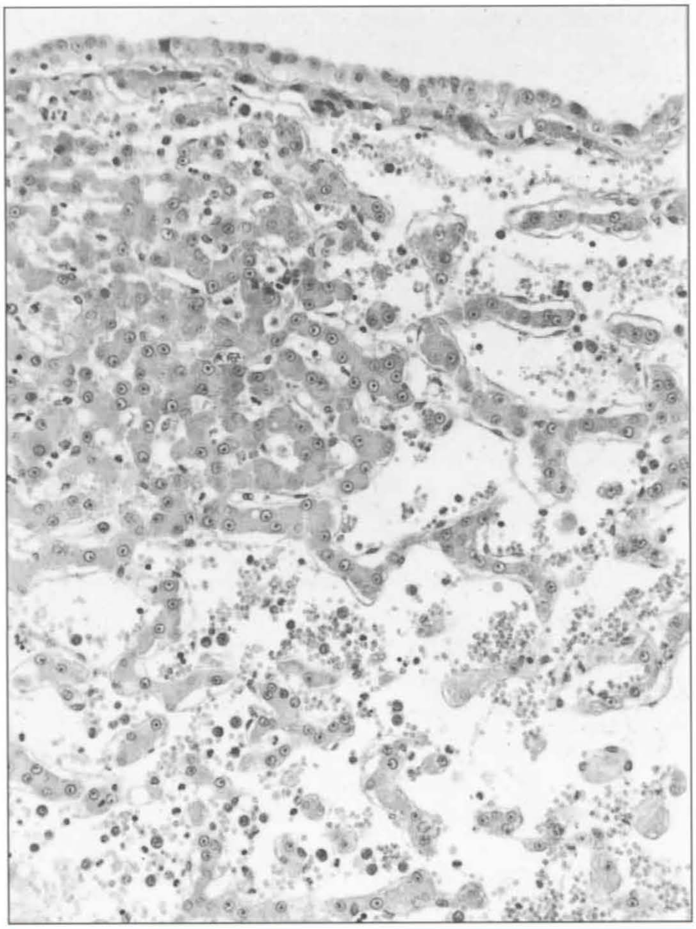

Figure 2.41 Subcapsular **telangiectasis** in a cat.

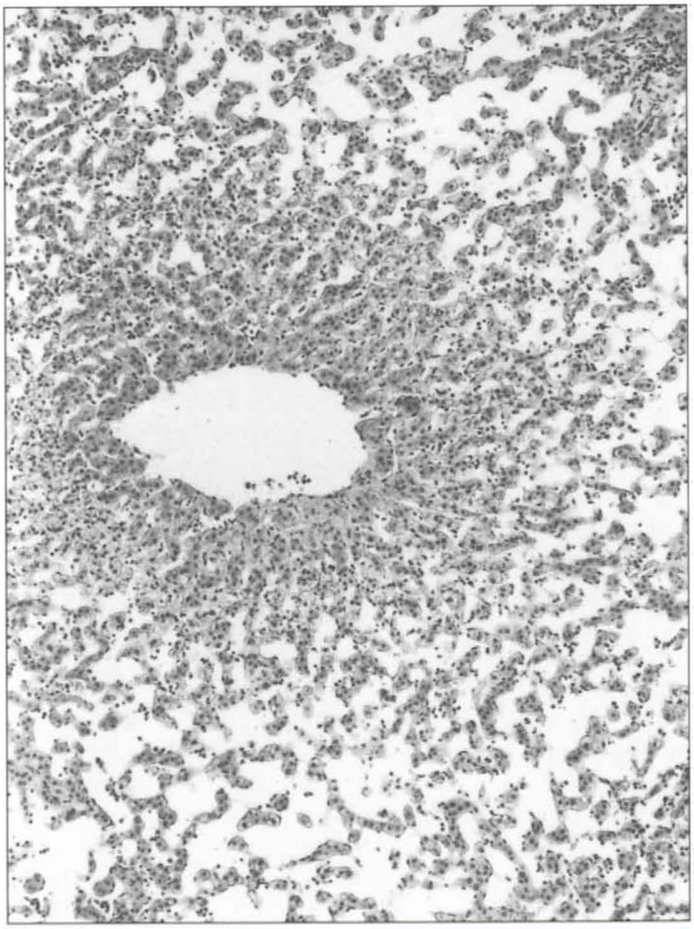

Figure 2.42 Periportal sinusoidal dilation due to chronic *Pimelea* poisoning in an ox.

sinusoids. These lesions were originally described in human patients with tuberculosis. More recently, it is described as an idiosyncratic association with administration of various drugs, including anabolic and contraceptive steroids. Infectious peliosis hepatis caused by *Bartonella henselae* or *B. quintana* infection has also been described in immunosuppressed human patients. *Peliosis hepatis has been reported in cattle, dogs, and cats, but the pathogenesis is unknown. B. henselae* DNA has been identified by polymerase chain reaction from the liver of a single canine case. Bovine hepatic telangiectasis and human peliosis hepatis have been suggested to share a similar pathogenesis. Primary alteration of the sinusoidal barrier, with increased deposition of basement membrane components in the perisinusoidal region and fibrosis, may alter oxygen and substrate exchange between hepatocytes and the blood, leading to hemodynamic imbalance, hepatocyte atrophy, and eventually to sinusoidal disruption.

A specific condition termed "*peliosis*" develops in cattle poisoned by plants of *Pimelea* spp. This form *begins as diffuse periportal sinusoidal dilation* (Fig. 2.42). Since these changes are also found in these animals in the spleen and in other organs with sinusoidal microcirculation, it seems that the lesions may be adaptive to progressive and dramatic increases in total blood volume. In the late stages of the intoxication by *Pimelea*, the liver may resemble a huge, blood-filled sponge. The animals eventually die of a combination of hemodilutional anemia and circulatory failure.

INFLAMMATORY DISEASES OF THE LIVER AND BILIARY TRACT

The inflammatory response in the liver is unusual for three main reasons. First, *hepatic microvasculature is structurally and functionally different from tissues with capillary vasculature.* Microvascular permeability to plasma proteins, a hallmark of acute inflammation in most tissues, is a normal property of the fenestrated sinusoidal endothelium of the liver. Thus, edema is not a prominent feature of acute parenchymal inflammation, although it can be observed in the capsule, biliary tracts, and gallbladder. Microvascular blood flow in hepatic sinusoids is also less responsive to the actions of various vasoactive mediators that alter blood flow in most other acutely inflamed tissues. Second, *hepatic Kupffer cells have some distinctive properties that enable them to deal with many potentially inflammatory insults in the portal circulation.* While they appear to have a higher threshold for activation, they can release large amounts of potent mediators such as nitric oxide, interleukin-6, and tumor necrosis factor-α that can influence cell populations in the liver and elsewhere. Third, *the liver has central regulatory influences on many proinflammatory insults and inflammatory mediators.* The liver produces most plasma proteins with anti-inflammatory functions, and is also the site of degradation of most soluble plasma proteins. Kupffer cells are the main site of clearance of immune complexes from the circulation, and they have an important role in the development of immunotolerance to potential antigenic substances absorbed from the intestine.

These unusual aspects of the inflammatory response in the liver can make it more difficult to differentiate some degenerative and inflammatory conditions in this organ. Ongoing cell death and repair can appear inflammatory and acute leukocyte responses can cause necrosis and apoptosis in the liver. *The term* "**necroinflammatory**" *is convenient when the underlying pathogenetic mechanisms of necrosis and inflammation are unknown.* Areas of focal hepatitis are commonly found in the liver, particularly in older animals. These usually reflect previous areas of focal infection or necrosis that are of little functional significance because the liver has so much functional reserve and regenerative capacity.

Increased numbers of leukocytes (**sinusoidal leukocytosis**) are observed in hepatic sinusoids in many acute or subacute bacteremias. These changes can be diagnostically useful but they do not constitute evidence of hepatitis unless there is obvious infiltration of granulocytes, monocytes, or lymphocytes into the perisinusoidal space. **Extramedullary hematopoiesis** can also appear as focal aggregates of myeloid cells in the perisinusoidal compartment. These changes (sometimes termed *myeloid metaplasia*) can be distinguished from inflammatory infiltrates by the presence of immature myeloid cells. Occasionally, hematopoietic cells from the splenic red pulp can be artifactually extruded into the portal vasculature and appear in the liver, usually as nucleated cell aggregates in the larger portal veins.

Infectious agents capable of causing hepatitis include viruses, bacteria, fungi, and helminths. Autoimmune and idiosyncratic drug responses are also observed in frequently, but often the etiology of acute or chronic hepatitis cannot be determined.

Acute hepatitis

The liver is subject to infectious and degenerative insults that elicit inflammatory responses in various patterns, for which the general term hepatitis is appropriate. **Cholangiohepatitis** *applies to hepatic inflammation centered on the biliary tract and extending into adjacent hepatic parenchyma.* The term **hepatitis** *is used for focal or diffuse hepatic conditions that are either caused by infectious agents or characterized by a leukocytic infiltrative inflammatory response, irrespective of the cause.* This definition allows us to include viral infections that are hepatotropic, even though the lesions are mainly characterized by hepatocellular necrosis or apoptosis rather than by the inflammatory response to the agent. Demonstration of sufficient amounts of injurious infectious agents within the lesions by inclusion bodies, antigens, or nucleic acids are important in making this diagnosis. The term hepatitis is also used for responses to some hepatic toxicants, metals, or drug metabolic idiosyncrasies in which there is a prominent leukocytic response to damaged cells. However, in responses in which single necrotic hepatocytes elicit a mild neutrophilic or histiocytic response, the term hepatitis is less appropriate because the pattern of injury is primarily degenerative.

Leukocyte infiltrates in diffuse hepatitis tend to accumulate mainly in the vicinity of the portal tracts, around major bile ducts, or sometimes in the capsule and around the central veins. Small but important numbers of neutrophils and mononuclear cells, including lymphocytes, are usually seen in the perisinusoidal space and among hepatocytes, and are often focally concentrated in sites of necrosis. Edema is an unusual feature of acute hepatitis, but is seen in severe injury, for example in infectious canine hepatitis. Grossly, hepatic edema is most obvious in the gallbladder, large extrahepatic bile ducts, hepatic lymph nodes, and sometimes in the capsule. Microscopically, edema is also evident in the portal triads and sometimes by an increase in the perisinusoidal space.

Kupffer cells are key participants in the acute inflammatory responses in the liver. They can enlarge and accumulate vacuoles and lysosomal debris during regular phagocytic removal of microorganisms, cell debris, and extravascular erythrocytes. They can also be activated to secretory histiocytes that release various cytokines and other mediators that induce hypertrophic or proliferative responses of hepatocytes, stellate cells, and endothelium. Activated Kupffer cells are larger and more prominent or numerous in sections, their nuclei are larger and vesicular, and their cytoplasm is basophilic and may contain vacuoles or ingested particulate matter. In overwhelming infections, many of the Kupffer cells and adjacent sinusoidal endothelial cells and hepatocytes undergo necrosis.

Patterns and character of inflammation in hepatitis vary according to causative agent, severity and stage of disease, the route of entry into the liver, and pathogenesis of liver injury. Some viral pathogens such as *Canine adenovirus 1* can cause acute and diffuse hepatitis, with widespread hepatocellular necrosis, mixed leukocyte infiltrates, sinusoidal congestion, and edema. By comparison, most infectious causes of hepatitis, for example toxoplasmosis, various herpesviruses, and various bacteria, produce a more patchy pattern of inflammation with focally intense leukocyte and Kupffer cell responses in the vicinity of areas of necrosis. The distribution, character, and chronicity of these focal lesions are important diagnostically, but they typically do not damage enough functional hepatic parenchyma, ducts, or vasculature to produce systemic signs of liver failure. Foci of hepatitis with necrosis are common incidental findings, and these are assumed to reflect localized responses to bacteria that arrive via the portal system. Occasionally such focal necroinflammatory lesions are large and numerous, for example in cattle with rumenitis.

Chronic hepatitis

Chronic liver disease in domestic animals has historically been classified into several different entities based on morphologic criteria. In human medicine, classification of chronic hepatitis has been simplified, and morphologic divisions such as chronic active hepatitis and chronic persistent hepatitis, originally defined in specific clinical contexts, have been abandoned due to problems of evolving definitions and application, and lack of correspondence with prognosis. The single designation "**chronic hepatitis**" is now used for *chronic necroinflammatory disease lasting more than 6 months*, further modified by specifying the etiology, type, and severity of inflammation and degree and distribution of necrosis (activity or grade), and the degree of fibrosis (chronicity or stage). Systems for *grading and staging chronic hepatitis* have been developed (Tables 2.1 and 2.2). More detailed *histological activity index* scoring systems have also been developed. In human medicine, chronic hepatitis is usually the result of chronic infection with hepatotropic viruses, and, less commonly, autoimmune, drug-induced or associated with inherited metabolic diseases such as Wilson disease. In veterinary medicine, chronic liver disease may develop following chronic bile duct obstruction, infection with hepatotropic infectious agents, familial or hereditary metabolic diseases, or may be toxic, drug-induced, or possibly autoimmune in origin. However, *the majority of chronic liver disease is idiopathic*, reflecting deficiencies in our current level of understanding of the etiological, pathophysiological, and clinical implications of the patterns of inflammation and necrosis seen in domestic animals.

Regardless of the etiology, *initial acute liver damage will not progress to fibrosis or cirrhosis unless the inflammation and damage are protracted*, for example, by ongoing hepatocellular injury mediated by immunological mechanisms, including antibody- and lymphocyte-mediated cytotoxicity, or ongoing oxidative damage. Clinical signs are nonspecific in the early stages, but as the disease progresses to involve more of the liver and impair regeneration, icterus, ascites, and hepatic encephalopathy may develop as typical correlates with hepatic insufficiency.

Chronic hepatitis of humans has several characteristic lesions. These are also evident in animals, although not to the same degree or frequency as described in the various forms of viral, immune-mediated, and idiosyncratic hepatitis in humans. The first is **periportal interface hepatitis**, sometimes referred to as "*piecemeal necrosis*" (Fig. 2.43). *This necroinflammatory change initially destroys the limiting plate of periportal hepatocytes, and may continue to erode into the hepatic parenchyma, expanding the portal areas.* Portal inflammation is variable in intensity, and includes infiltration by lymphocytes and plasma cells. Bridging necrosis, with tracts of necrosis dissecting across the hepatic lobule between portal triads or between portal areas and central veins, may also develop. Degenerative changes affecting hepatocytes in areas of interface hepatitis include cell swelling and apoptosis. Bile duct degeneration, multifocal necrosis, and hepatocellular regeneration in the form of increased numbers of binucleated and trinucleated cells and mitotic figures, may also be seen. Deposition of collagen and basement membrane material in the space of Disse leads to capillarization

Table 2.1 Grading the degree of disease activity in chronic hepatitis

	Lesions and degree of injury			
Category	Portal area inflammation	Periportal (piecemeal) necrosis	Nonzonal necrosis	Bridging and/or multiacinar necrosis
Mild	Mild, patchy	Absent or mild	Mild	Absent
Moderate	Moderate	Moderate	Moderate	Absent

Chronic hepatitis in dogs

Chronic hepatitis is a relatively common diagnosis in dogs. While infectious etiologies, and drug- and toxin-induced chronic hepatic disease have been described, *the majority remains idiopathic*, although some appear to be breed-associated or familial. *Breeds of dogs* reported to be at increased risk for chronic hepatitis include the Bedlington Terrier, West Highland White Terrier, Doberman Pinscher, American and English Cocker Spaniel, Skye Terrier, Labrador Retriever, and Standard Poodle. Apart from the hereditary hepatic copper accumulation in Bedlington Terriers, the etiology of the breed-related disorders remains unclear.

The pathophysiologic mechanisms of chronic hepatitis in dogs are poorly understood. Given the importance of autoimmune hepatitis in human medicine, several studies have evaluated the role of immune mechanisms in dogs. Peripheral blood mononuclear cell proliferation in response to liver membrane antigens was higher in dogs with chronic hepatitis, supporting the hypothesis of an immune-mediated process, although whether this is primary or secondary to hepatocyte destruction is not known. An immunohistochemical study of the inflammatory infiltrate in 16 dogs with chronic hepatitis identified CD3+ lymphocytes as the most numerous lymphoid cells in liver sections from affected animals. Degenerate hepatocytes were occasionally surrounded by these cells, and necrosis was positively correlated with the numbers of CD3+ lymphocytes, suggesting a role for an immune-mediated process in chronic hepatitis. The number of α-smooth-muscle actin-positive cells (periductular myofibroblasts and activated perisinusoidal stellate cells) in portal triads and fibrous septa was positively correlated with the stage of fibrosis, lending support to the role of these cells in fibrogenesis in the canine liver. Upregulation of major histocompatibility complex class II antigen expression in hepatocytes has been demonstrated in Doberman hepatitis in association with lymphocyte infiltration, and it has been suggested that hepatocytes presenting a putative major histocompatibility complex class II molecule-associated autoantigen could be targets for T-cell-mediated immune attack. However, a primary autoimmune pathogenesis has yet to be demonstrated.

Liver disease associated with increased hepatic **copper** *occurs in various breeds of dogs that develop acute hepatic necrosis, subacute hepatitis, chronic hepatitis, and cirrhosis.* Copper is an essential metal cofactor for cuproenzymes, acting as a redox catalyst for a number of cellular oxidases. However, interaction with cellular hydrogen peroxide can yield highly reactive hydroxyl radicals. Hepatic copper accumulation may result from a primary metabolic defect in hepatic copper metabolism, or possibly as a secondary event resulting from abnormal hepatic function, cholestasis, and altered biliary excretion, a mechanism described in the human literature but not conclusively demonstrated in dogs. *A hereditary, autosomal recessive copper-associated hepatopathy associated with impaired biliary copper excretion and progressive accumulation of copper within hepatocytes has been well documented in Bedlington Terriers, and postulated in other breeds, including West Highland White Terriers and Skye Terriers.* The chromosomal locus of the gene in affected Bedlingtons has been mapped and a mutation in the *MURR1* gene identified, while other defects in the canine homologs of human genes for the copper-transporting ATPase, *ATP7B*, defective in Wilson disease in humans, and *ATOX1*, the copper chaperone delivering copper to *ATP7B*, have been excluded as possible candidates. While its function is unknown, the protein Murr1 has been shown to interact with the copper transporter ATP7B, and may be a copper chaperone involved in directing copper to biliary excretion. The human *MURR1* gene is also polymorphic and one mutation is believed to contribute to the pathogenesis of Wilson disease in a minority of human patients.

The role of copper in the pathogenesis of hepatic disease is less clear in breeds of dogs other than the Bedlington Terrier. Elevated hepatic copper (>400 μg/g dry weight) has been reported in clinically normal dogs, as well as in diseased liver from other breeds. Liver disease with concurrent copper accumulation has been reported in the Doberman Pinscher, West Highland White Terrier, Skye Terrier, Dalmatian, Keeshond, and Poodle, as well as others. *Chronic cholestasis, hepatitis, and cirrhosis of any etiology could increase liver copper concentrations;* secondary copper accumulation occurs in the majority of human patients with primary biliary cirrhosis, prolonged extrahepatic bile duct obstruction, or chronic liver disease. When the hepatic concentration of copper surpasses 400 μg/g dry weight, the excess begins to accumulate within lysosomes in all breeds of dogs, first demonstrable in the hepatocytes of zone 3, later in zone 2, and finally in zone 1 at the highest copper concentrations, a distribution that differs from that of other copper-loaded animal species. At levels exceeding 400 μg/g dry weight, copper-loaded lysosomes become demonstrable by the histochemical stains, rubeanic acid and rhodanine, allowing a qualitative assessment of copper storage. Regardless of the reasons for copper accumulation, lysosomal copper can exceed a threshold or be released when hepatocytes die, and thereby contribute to the development of hepatitis. *Hepatic pathology does not typically occur at concentrations less than 2000 μg/g dry weight*, although higher values can still be found in some dogs with normal liver histology.

Bedlington Terriers *are the only breed to date shown to accumulate copper continuously throughout life,* and hepatic copper concentrations in these animals may be very high; as much as 12 000 μg/g dry weight has been recorded, and levels higher than 5000 μg/g are common. Affected Bedlingtons are usually presented with signs of progressive liver failure, including ill-thrift, wasting, ascites, and signs of encephalopathy. An acute form may occur in some dogs, with acute hepatic necrosis and release of copper into the systemic circulation, where it provokes a hemolytic crisis and rapidly developing anemia and icterus. The most characteristic feature of the histology is the presence of numerous golden-brown refractile granules in hepatocytes, and darker pigment in Kupffer cells. The hepatocellular granules are copper-engorged lysosomes, which preferentially

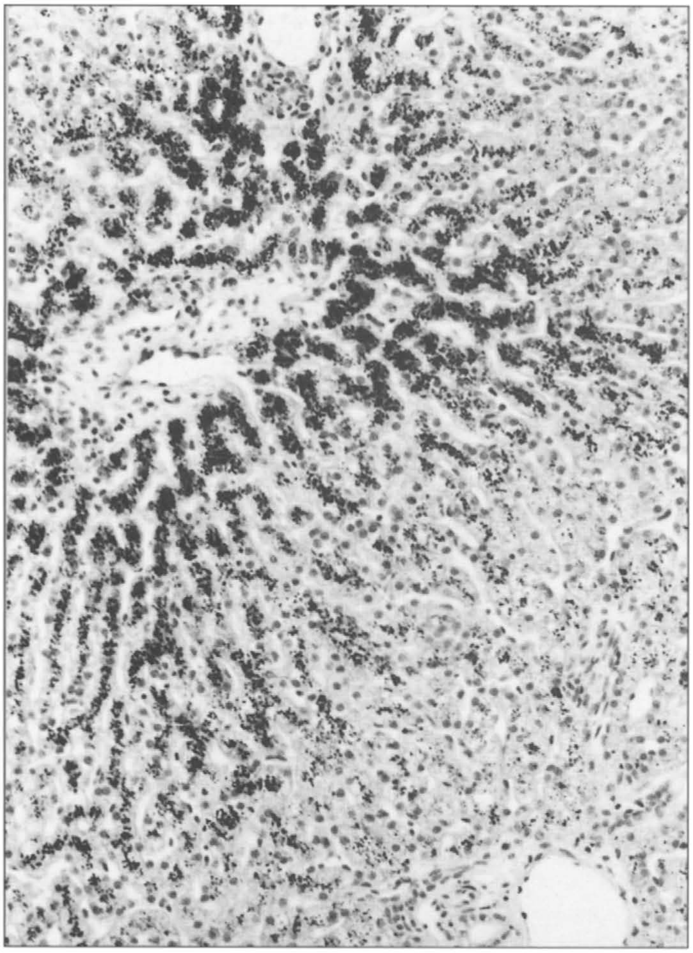

Figure 2.44 Section of liver from Bedlington Terrier, stained with rhodanine for copper to demonstrate the predominantly zone 3 distribution of **lysosomal copper**.

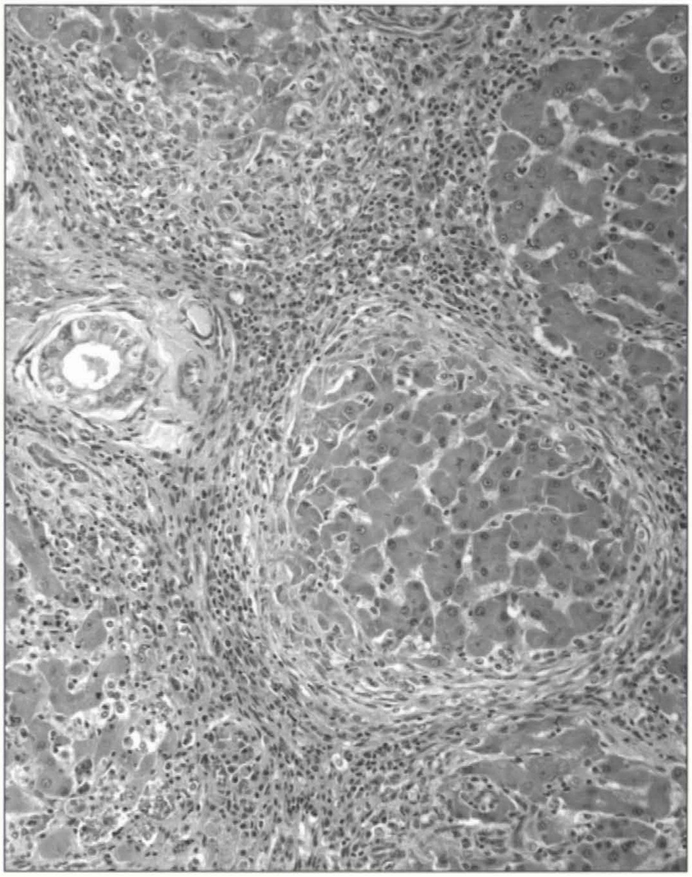

Figure 2.45 Periportal interface hepatitis with mixed inflammatory infiltrates and bridging portal fibrosis in a Doberman Pinscher dog.

accumulate in the cytoplasm of zone 3 hepatocytes. Evidence of hepatitis generally does not develop until levels exceed 2000 μg/g. The initial histologic lesion is multifocal centrilobular hepatitis, with foci of macrophages, lymphocytes, plasma cells, and neutrophils among the copper-laden hepatocytes in zone 3 (Fig. 2.44). Apoptotic hepatocytes, some containing copper granules, appear at the periphery of some foci. Copper levels exceeding 3000 μg/g dry weight result in widespread massive necrosis in some dogs. Survivors may progress to develop postnecrotic cirrhosis. Grossly, the livers in later stages are fibrotic, pale, and finely nodular.

Chronic hepatitis is well documented in **Doberman Pinschers**. The disease is more common in middle-aged female dogs. Histologic changes in the livers of dogs exhibiting clinical signs of advanced hepatic disease include piecemeal necrosis of periportal zone 1 hepatocytes, with a mixed inflammatory cell infiltrate, as well as necrosis of zone 3 hepatocytes with bridging necrosis crossing the lobule. Various degrees of portal fibrosis develop, with bile duct proliferation, bridging fibrosis, and development of cirrhosis in the most severely affected dogs (Fig. 2.45). Accumulation of copper in periportal zone 1 hepatocytes, particularly in areas of degeneration and necrosis, is prominent, although central hepatocytes also have some copper-positive granules (Fig. 2.46). Intrahepatocyte bile pigment accumulation and intracanalicular bile stasis are present in periportal zones, along with iron accumulation in Kupffer cells and macrophages.

Two recent studies, however, document that piecemeal necrosis and marked periportal inflammation are not prominent lesions in early stages of hepatic disease in Dobermans. One retrospective histologic study of the lesions in the livers of 35 Dobermans in the early precirrhotic stages of the disease found a consistently different pattern, with progressive fibrosis, inflammation, and hepatocyte loss beginning in zone 3, affecting hepatocytes around the terminal hepatic vein branches. The earliest changes were inflammation, predominantly small lymphocytes, plasma cells, and individual or clusters of pigmented macrophages often containing iron or copper, collagen deposition around the small hepatic vein branches, and apoptosis of scattered hepatocytes in zone 3. Copper-containing cells were exclusively in zone 3 hepatocytes, contrary to previously published reports. As the disease progressed, collagen deposition increased around the hepatic veins. In some specimens, thin fibrous septa radiated from the hepatic vein branches. In a few dogs, lymphoplasmacytic inflammation was mild and restricted to the connective tissue surrounding smaller branches of the hepatic vein. In the majority of cases, inflammation was distributed equally to the connective tissue around hepatic veins and the connective tissue of the portal tracts. In the most severe cases, infiltrating inflammatory cells were also present in the parenchyma among the hepatocytes. The sinusoids adjacent to the areas of fibrosis were converted to endothelial-lined, thin-walled vessels. Histologic changes were the same regardless of hepatic copper concentration, which appeared to be incidental to the disease progression.

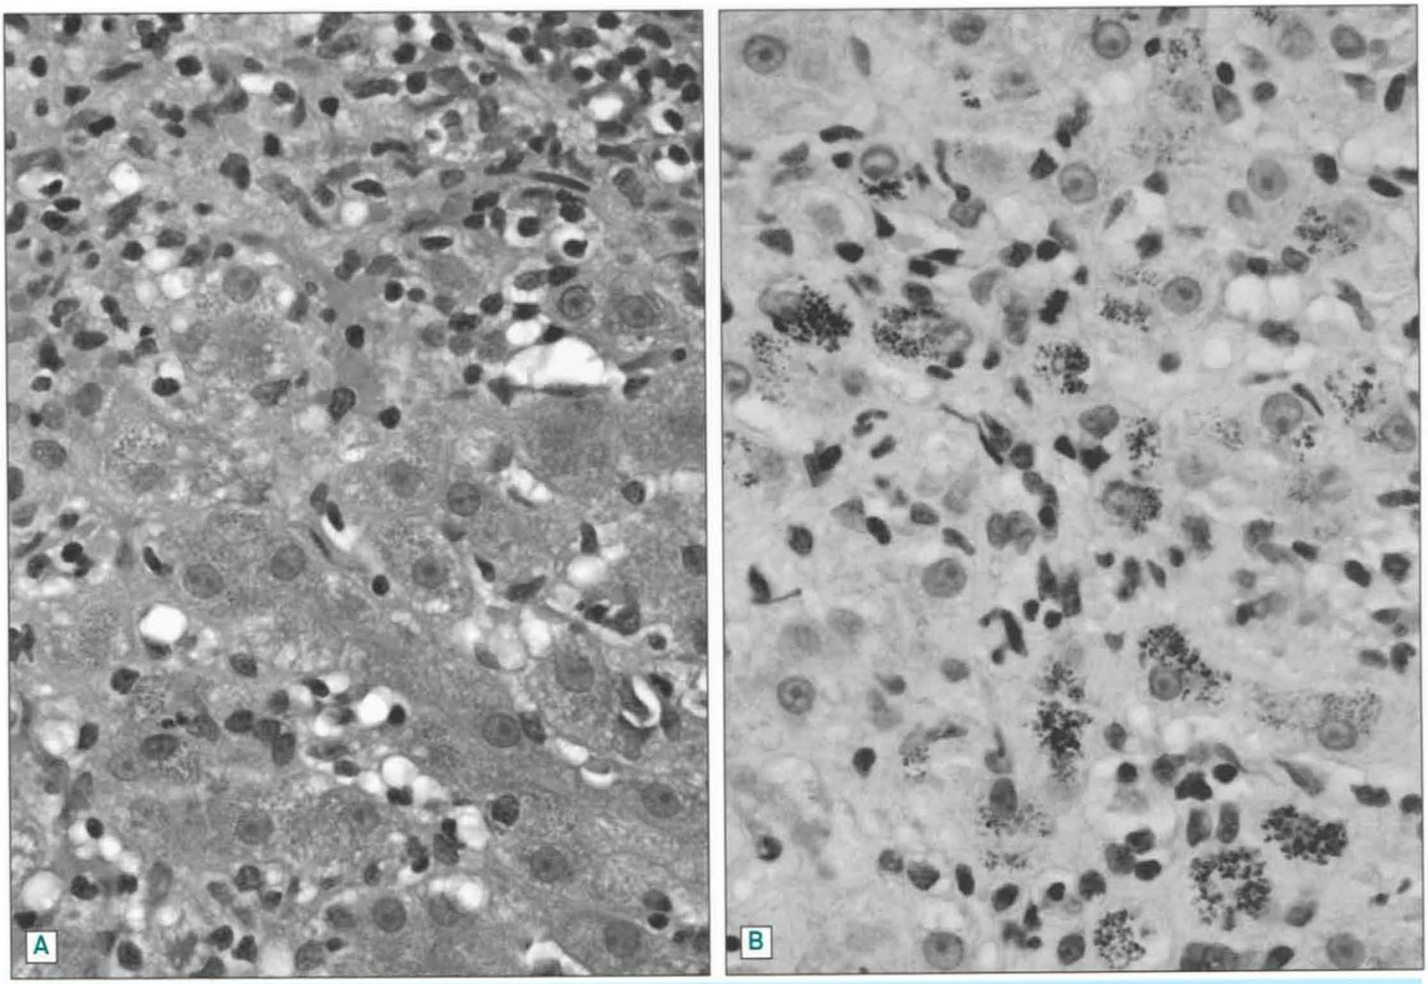

Figure 2.46 **A.** Periportal inflammation and hepatocellular **copper** accumulation in a Doberman Pinscher dog. **B.** Liver in **(A)** stained for **copper** with rhodanine.

The second study of the histologic hepatic lesions in 18 Dobermans suffering from subclinical hepatitis reported that the most significant changes in biopsy samples were multifocal clusters of inflammatory cells in the parenchyma, and portal inflammation. Inflammatory cells were mainly lymphocytes, but neutrophils and macrophages also appeared. Numbers of plasma cells were low. Periportal piecemeal necrosis was usually mild or moderate, and the limiting plate surrounding the portal area was never markedly ruptured. Three dogs had minimal bridging necrosis. Expansion of the portal area, fibrosis, and bile duct proliferation were uncommon, and, if present, mild. Every subclinically affected dog had excessive copper staining in its liver. Five dogs later euthanized for reasons other than liver disease showed progression of hepatic lesions, with at least moderate piecemeal necrosis, and moderate to marked portal expansion. Four dogs were later euthanized because of progressive hepatic disease. All had moderate to marked piecemeal and bridging necrosis, moderate to marked portal expansion, bile duct proliferation, and fibrosis.

Elevated concentrations of hepatic copper have been reported in many, but not all, Doberman Pinschers with chronic hepatitis. *The significance of increased hepatic copper concentration in this breed remains controversial.* It has been reported that clinically normal Doberman Pinschers (with no evidence of liver disease on liver biopsy) are one of several breeds that have higher hepatic copper concentrations than what is considered normal, with a mean hepatic copper concentration of 413 ± 298 μg/g and a range of 140–1500 μg/g. In one report of clinically affected Dobermans, the mean concentration was approximately 2000 μg/g dry weight, sequestered in zone 1 (periportal) hepatocytes. A study of 23 affected Dobermans reported one dog with normal hepatic copper concentration (250 μg/g), 12 dogs with copper levels <2000 μg/g (range from 650 to 1900 μg/g), and 10 dogs with copper levels >2000 μg/g (the highest 4700 μg/g). A study of Dobermans with early precirrhotic hepatitis reported elevated hepatic copper concentrations in 30 of 35 dogs. Of the 22 affected dogs whose liver copper was measured by atomic absorption analysis, 10 dogs had hepatic copper concentrations ≥2000 μg/g dry weight, 3 of which had copper >3000 μg/g, and 12 dogs had copper concentrations ranging from 650 to 1900 μg/g dry weight. In these dogs, the copper-laden hepatocytes were found in zone 3, adjacent to the hepatic vein. The copper accumulation was suggested to be neither the cause nor the effect, but occurred antecedent to the disease, and was incidental to disease progression. However, a recent investigation into the possibility of impaired copper excretion in affected Doberman Pinschers reported that 5 dogs with elevated liver copper and persistent subclinical hepatitis but without demonstrable cholestasis had comparable rates of plasma copper clearance to control dogs, but reduced rates of biliary excretion of ^{64}Cu. This provides additional support for the view that copper accumulation contributes to chronic hepatitis in Dobermans, and is more likely a cause than a consequence of liver damage in this breed.

West Highland White Terriers *are at increased risk of developing chronic hepatitis and cirrhosis.* There is evidence to support *familial* hepatic copper accumulation in some West Highland White Terriers, although the mode of inheritance is not completely understood. Hepatic copper accumulates in zone 3 hepatocytes, up to about 8 months of age, with concentrations rarely exceeding 2000 μg/g dry weight. Clinical illness directly attributable to copper hepatotoxicity (concentrations >2000 μg/g dry weight) in West Highland White Terriers is, however, apparently uncommon. *Idiopathic chronic hepatitis progressing to cirrhosis does also occur in this breed,* and may be distinguished on the basis of a different zonal location and morphology of the inflammatory lesions. In the idiopathic disease, inflammatory foci are smaller, composed of a single apoptotic hepatocyte or fragments of cells accompanied by a few lymphocytes and plasma cells, and are commonly localized to zone 1, or may be random in distribution. In dogs with copper toxicosis, foci of inflammation and necrosis were larger, always found around the central vein among copper-laden hepatocytes, and were composed of debris-filled macrophages, lymphocytes, plasma cells, and scattered neutrophils, with occasional apoptotic hepatocytes around the periphery. *Distinguishing between copper toxicosis and idiopathic chronic hepatic disease may be difficult in cirrhotic livers,* which, irrespective of the underlying cause, may have reduced copper burdens due to connective tissue displacement of hepatic parenchyma, and typically lower concentrations of copper in regenerative nodules.

Chronic hepatitis been reported in genetically related **Skye Terriers**, accompanied by modest and somewhat inconsistent hepatic copper accumulation. Lesions ranged from hepatocellular degeneration and necrosis with mild inflammation in zone 3, to chronic hepatitis and cirrhosis with marked intracanalicular cholestasis. Hepatic copper concentrations ranged from 800 to 2200 μg/g dry weight, and copper-containing hepatocytes were found predominantly in zone 3. The etiology is unknown, although a defect in bile secretion has been suggested.

Chronic liver disease associated with elevated hepatic copper concentrations has been reported in **Dalmatians**. A range of necroinflammatory changes has been reported, including multifocal, piecemeal, centrilobular to massive hepatic necrosis, and cirrhosis, although, in one study of 10 dogs, various degrees of piecemeal necrosis and bridging fibrosis were the most common histologic change, with either primarily lymphocytic or neutrophilic inflammatory infiltrates. Morphologic or biochemical evidence of cholestatic liver disease was not prominent. Hepatic copper concentrations ranged from 745 to 8390 μg/g dry weight (mean 3197 μg/g) in one report of 10 dogs, aged 2–10 years, with a variable zonal distribution. Three previous cases in young Dalmatians reported hepatic copper concentrations of 7940 μg/g dry weight, 1916 μg/g wet weight, and 2356 μg/g wet weight, and two of these reports describe diffuse positive staining for copper in all hepatocytes, with the strongest staining observed in centrilobular hepatocytes.

Chronic hepatitis has been reported in **Cocker Spaniels**, characterized by a brief clinical illness with ascites, weight loss, and other signs typical of hepatic disease. Affected dogs develop chronic hepatitis and cirrhosis, and, at necropsy, livers are typically small and firm, with multiple small regenerative nodules. Histologically, there is moderate to severe portal hepatitis, with inflammatory infiltrates of predominantly lymphocytes, plasma cells, and fewer neutrophils, and variable degrees of portal fibrosis and bridging fibrosis. Piecemeal necrosis and limiting plate destruction have been reported. Biliary hyperplasia is a common feature. Hepatic copper staining is variable, and hepatic copper accumulation does not appear to be a consistent feature. α_1-antitrypsin deficiency *has been suggested to play a role in chronic hepatitis in some dog breeds, including English Cocker Spaniels,* although whether this is an epiphenomenon or cause of chronic liver disease has not yet been proven. α_1-antitrypsin is a member of the serine proteinase inhibitor (serpin) superfamily, and is a potent inhibitor of neutrophil elastase. Hereditary α_1-antitrypsin deficiency in humans is associated with mutations that perturb the protein's tertiary structure and promote polymerization. Accumulation of altered forms of α_1-antitrypsin in the endoplasmic reticulum of hepatocytes, with the formation of inclusion bodies and subsequent cell death has been associated in humans with neonatal hepatitis, juvenile cirrhosis, and adult hepatocellular carcinoma.

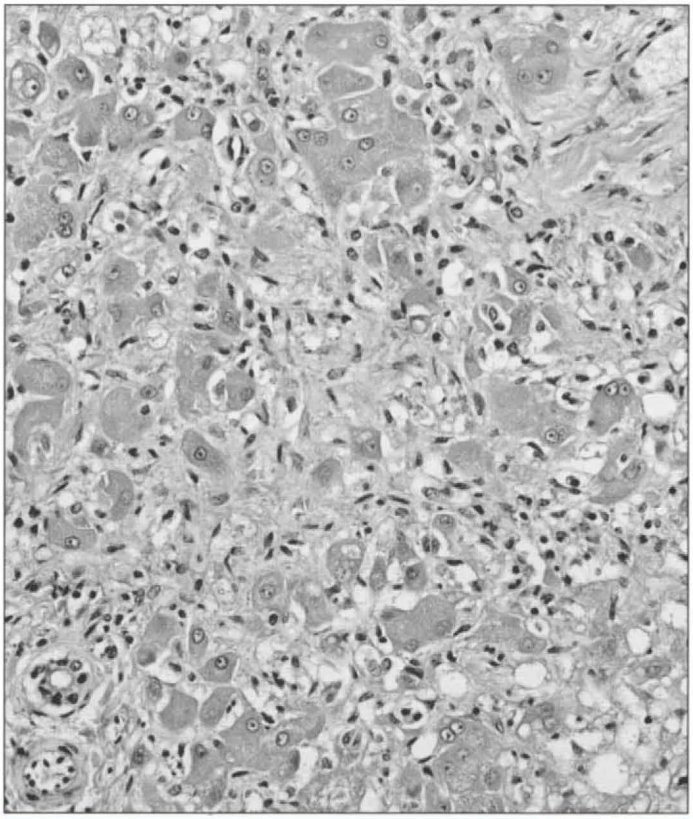

Figure 2.47 Lobular dissecting hepatitis with diffuse fine interstitial fibrosis isolating hepatocytes in a juvenile Golden Retriever dog.

Noninflammatory **idiopathic hepatic fibrosis** *has been reported in young dogs,* typically <2 years of age, and is associated with chronic hepatic failure and portal hypertension. Histologically, there are various patterns of hepatic fibrosis, including diffuse pericellular (reticulofibrosis), periportal, and central perivenous (periacinar) fibrosis. Diffuse pericellular fibrosis is characterized by intralobular reticulin deposition that surrounds individual hepatocytes, and alters normal hepatic architecture (lobular dissecting hepatitis). The periportal pattern (hepatoportal fibrosis) has been discussed previously, and has been associated in some cases with congenital hypoplasia of the portal vein. Central perivenous fibrosis resembles hepatic veno-occlusive disease; however, there is no evidence of intimal damage, and the fibrous tissue is deposited peripheral to the intimal lining of the terminal hepatic veins.

Lobular dissecting hepatitis, *associated with predominantly sinusoidal inflammation and fibrosis, has been described in young dogs with ascites and acquired portosystemic shunts.* The liver is usually small, pale with a predominantly smooth surface, and occasional hyperplastic nodules. The histologic lesion is characterized by dissection of lobular parenchyma by reticulin and fine collagen fibers into individual and small groups of hepatocytes, accompanied by a mixed inflammatory infiltrate of lymphocytes, plasma cells, and lesser numbers of neutrophils and macrophages (Fig. 2.47). Activated fibroblastic cells, likely hepatic stellate cells, may also be prominent along sinusoids. Hepatocytes form rosettes or pseudoductular structures, and regenerative nodules may be present. Portal inflammation and periportal fibrosis are not conspicuous features of this disease. The etiology of this disorder remains unknown.

Granulomatous hepatitis *has been reported in dogs with various systemic parasitic, mycotic, and bacterial infections.* However, granulomatous hepatitis with signs of clinical liver disease, including hepatomegaly, icterus, ascites, and elevated hepatic enzymes, has also been reported in dogs with intestinal lymphangiectasia and inflammatory bowel disease, lymphosarcoma, and histiocytosis. The histologic lesion consists of multifocal infiltrates of histiocytes, often associated with lymphocytes and plasma cells, neutrophils, or eosinophils.

Miscellaneous inflammatory liver disease

Idiopathic acute hepatic disease, *also known as* **equine serum hepatitis** *or* **Theiler's disease**, *is a common cause of acute hepatic failure in horses.* The disease was originally observed in horses passively immunized against African horse sickness and later in horses passively immunized against anthrax, tetanus, and equine encephalomyelitis. Various injectable biologics of equine origin have been associated with the disease, including *Clostridium perfringens* toxoids, tetanus antitoxin, and equine herpesviral vaccines prepared from equine fetal tissue and pregnant mare serum. However, while such an association holds for the majority of cases, there are many, usually sporadic, cases in horses that have not received any injections.

While the disease remains idiopathic, *a viral cause that is serum-transmissible, similar to hepatitis B in humans, is proposed*. The incubation period of 42–60 days, sometimes up to 90 days, is similar to some other viral causes of hepatitis. The occurrence of equine serum hepatitis among inoculated animals is variable and attempts to reproduce the disease by experimental transmission have rarely been successful. It is unknown how many exposed horses get subclinical disease, because the condition is seldom diagnosed before the onset of hepatic failure. However, some horses do recover after transient illness with jaundice, and some can survive with residual neurologic problems.

The onset of the typical clinical syndrome is sudden, with death occurring in 6–24 hours. Clinically, there is jaundice, hyperexcitability, often with mania, continuous walking and pushing, apparent blindness, and ataxia. Death occurs suddenly without a period of prostration.

At autopsy, icterus is present, with moderate ascites; the spleen is normal or congested, and there may be petechial hemorrhages on serous membranes and renal cortices, and some congestion of the intestine with hemorrhage into its lumen. Grossly, the liver usually appears to be of normal size, although it may be slightly enlarged or atrophic and flabby due to the acute loss of many hepatocytes. The liver may be stained by bile pigments, and its surface mottled with a few strands of fresh fibrin. The mottling is more evident on the cut surface, which appears as if severely congested and sometimes fatty (Fig. 2.48A).

Microscopically, the hepatic lesion is considerably older than the clinical course would suggest (Fig. 2.48B). *There may be a few surviving swollen and vacuolated periportal hepatocytes or sometimes complete depletion of parenchymal cells in the section.* In less affected regions in animals with adequate dietary or adipose reserves to mobilize, there is severe macrovesicular fatty change in most remaining hepatocytes. Acute necrosis is typically not seen, and there is no significant hemorrhage. Variable numbers of apoptotic hepatocytes are expected. In the periphery of the acini, severely ballooned cells undergo dissolution to leave scattered fatty cysts, but most of them disappear to leave either sinusoids that are dilated and filled with blood or a condensed and distorted reticulin framework. Extensive deposits of bile pigments are present in Kupffer cells and hepatocytes. Leukocytes, including lymphocytes, plasma cells, histiocytes, and a few neutrophils, may infiltrate diffusely, but not in large numbers. There is diffuse but very slight fibroplasia, especially in the portal units. In some livers, there are small irregular clusters of proliferating ductular cells in the portal areas, resembling the regenerating cholangiolar or oval cells that replicate in atrophic livers.

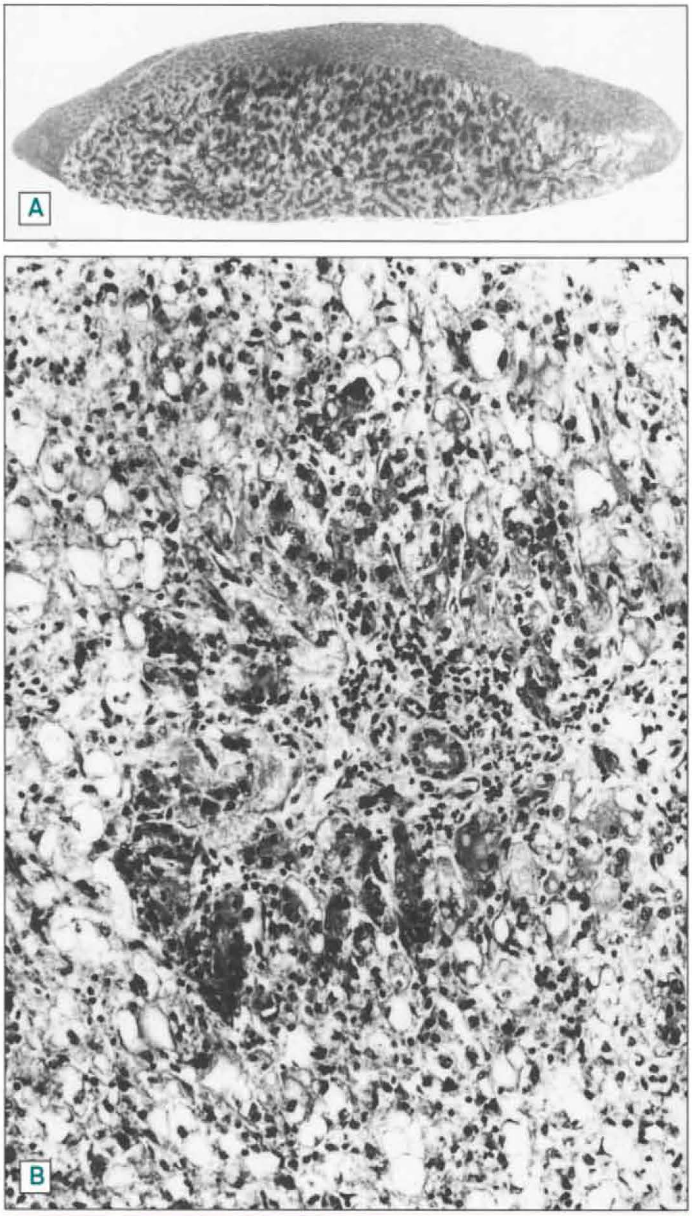

Figure 2.48 Equine serum hepatitis. A. The reticular pattern in this slice of liver suggests **zonal necrosis**. **B.** Section of the liver in **(A)** to show extensive periacinar degenerative changes, cellular infiltration, and periportal survival zone.

Focal or diffuse **fetal hepatitis** *occurs in a number of intrauterine fetal infections.* Whether caused by bacteria or viruses, focal necrosis is often present and bacteria or viral inclusions can often be identified. Frequently, however, the lesions are subtle and diffuse and without necrosis, and the inflammatory process may be difficult to distinguish from hematopoiesis. There is inflammatory edema of the connective tissues of the portal triads with distension of lymphatics there and beneath Glisson's capsule. A preponderance of mature granulocytes in the portal triads and in the adventitia of hepatic veins helps to distinguish inflammatory infiltrates from hematopoietic foci, which are predominantly in sinusoids.

Giant cell hepatitis *is an uncommon lesion in animals, but is recorded in cats, calves, and foals.* There is evidence for maternal leptospirosis in some cases in foals. Two cases are reported in young cats with concurrent thymic lymphomas. The liver is deeply bile-stained. Histologically, the acinar structure is effaced and the blood vessels engorged. Hepatocytes are large and syncytial and may contain 10 or more nuclei. The pale or ballooned cytoplasm contains bile pigments, and cytoplasmic invaginations into hepatocyte nuclei are common. Inflammatory cells are not conspicuous. Liver parenchymal giant cell transformation occurs in humans in a wide variety of congenital and neonatal liver disorders, including bile duct obstruction associated with biliary atresia, viral and bacterial infections, some metabolic disorders such as galactosemia, some cases of Down syndrome and other genetic disorders, as well as in idiopathic neonatal hepatitis, a cholestatic condition of undetermined cause. While giant cells were originally suggested to be a marker of infantile obstructive cholangiopathy, their association with a wide range of disorders supports an *alternative conclusion that giant cell formation represents a nonspecific reaction of the infant's hepatocytes to various types of injury.*

Hypertrophic hepatic cirrhosis in calves is described from Germany and occasionally observed elsewhere. Death may occur in liver failure within a few days to weeks of birth or the disease may be discovered at slaughter for veal. The liver is moderately enlarged with rounded borders, very firm but smooth on the surface, and gray. Histologically, there is some biliary hyperplasia but the lesion is dominated by diffuse fibrosis infiltrated in the early stages by mononuclear inflammatory cells. No cause has been identified. Similar lesions of **congenital hepatic fibrosis** may be found in unborn or aborted calves.

Systemic granulomatous disease has been reported in cattle grazing *hairy vetch (Vicia villosa).* The disease is characterized clinically by dermatitis, pruritus, diarrhea, wasting, and high mortality. Histologic lesions include infiltration of skin and internal organs, including portal areas of the liver, by monocytes, lymphocytes, plasma cells, eosinophils, and multinucleated giant cells. The pathogenesis is unknown, although the inflammatory reaction has characteristics of a type IV hypersensitivity reaction. Alternatively, vetch lectin may act to activate T lymphocytes directly to initiate the cellular response.

Inflammatory diseases of the biliary tract

Inflammation of the gallbladder is termed **cholecystitis**. *Inflammation of the large bile ducts is* **cholangitis**, *whereas inflammation of the smallest intrahepatic bile ductules is termed* **cholangiolitis**. Cholangiolitis is uncommon in animals, and occurs mainly in conjunction with inflammation of larger ducts. Destructive cholangiolitis has been observed in dogs, and is associated with adverse drug reactions in humans.

Cholecystitis

Cholecystitis is uncommon, and may occur alone if the neck of the gallbladder is obstructed. More typically, it is associated with concurrent cholelithiasis. *Cholecystitis is thought to be due to reflux of intestinal bacteria into the gallbladder via the bile ducts, or to hematogenous entry of bacteria from the adjacent hepatic circulation.* Aerobic gram-negative bacteria are the most frequent isolates from canine cases, although occasionally anaerobic bacteria such as clostridia have been cultured. *Campylobacter jejuni* has been isolated from two dogs with bacteremia and cholecystitis. Canine cholecystitis has been associated with various disorders, including diabetes mellitus, severe enteritis, biliary stasis, septicemia, as well as with the use of immunosuppressive drugs, each of which may promote bacterial colonization of the gallbladder. In the acute lesion, histologic changes include neutrophilic inflammatory infiltrates in the wall and lumen of the gallbladder, with focal erosion or ulceration, and edema. More chronic stages develop typical mixed inflammatory infiltrates, with fibrosis. Occasionally, the infiltrate may be predominantly lymphoplasmacytic, with formation of lymphoid follicles within the mucosa.

Gallbladder infarction characterized by transmural coagulative necrosis of the gallbladder wall with intravascular fibrin thrombi has been reported in dogs. Predisposing factors have not been identified; however, the lack of significant concurrent inflammatory response suggests that this is not simply a sequela to underlying cholecystitis.

Cholangitis/cholangiohepatitis

Although pure cholangitis does occur, involvement of the periportal hepatic parenchyma by extension of inflammation from the ducts is almost inevitable, and such lesions can quite accurately be regarded as cholangiohepatitis.

Bile contains various antimicrobial factors, including beta defensins and bile acids that are inhospitable to most bacteria, except for some species with particular capsule adaptations. Bacterial cholangiohepatitis is usually caused by common opportunists of enteric origin, such as coliforms and streptococci. Some bacteremic organisms, including some *Salmonella*, can be cultured from the bile, but the mechanism by which they get there is unknown. Salmonellosis is a distinctive cause of fibrinous cholecystitis in cattle, especially calves.

The *pathogenesis of bacterial cholangiohepatitis* depends on various predisposing conditions, similar to those involved in the pathogenesis of pyelonephritis. These include infection by bacteria that reach the ducts hematogenously, facilitated by localization in the peribiliary plexus or by extension from sinusoidal Kupffer cells or foci of necrosis. Descending cholangitis is occasionally observed in cattle with suppurative hepatitis with extension from abscesses directly into the ducts or via the portal lymphatics. Cholangiohepatitis of this origin may be restricted in its distribution to biliary fields, but in some cases it does become quite diffuse in the biliary system. Alternatively, bacteria can extend up the ducts from the intestine, facilitated by bile stasis due to mechanical or functional obstructions. The inflammatory and proliferative responses in cholangitis further interfere with bile flow and exacerbate the ductular spread of bacterial infections once they are established.

The course and pathologic changes in cholangiohepatitis vary greatly, from fulminating suppurative infection to persistent mild inflammation that over a period of months or years leads to hepatic fibrosis of biliary distribution. *Severe suppurative cholangiohepatitis* may follow a short course to death, the effects being those of the infection itself, which may become septicemic, rather than of hepatic injury. At autopsy, the liver is swollen, soft, and pale, and its architecture is blurred. Few or many suppurative foci may be visible beneath the capsule and on the cut surface (Fig. 2.49). They are small, sometimes miliary in distribution, and not encapsulated. Lesions in other organs may be those of septicemia and jaundice. Microscopically, the larger

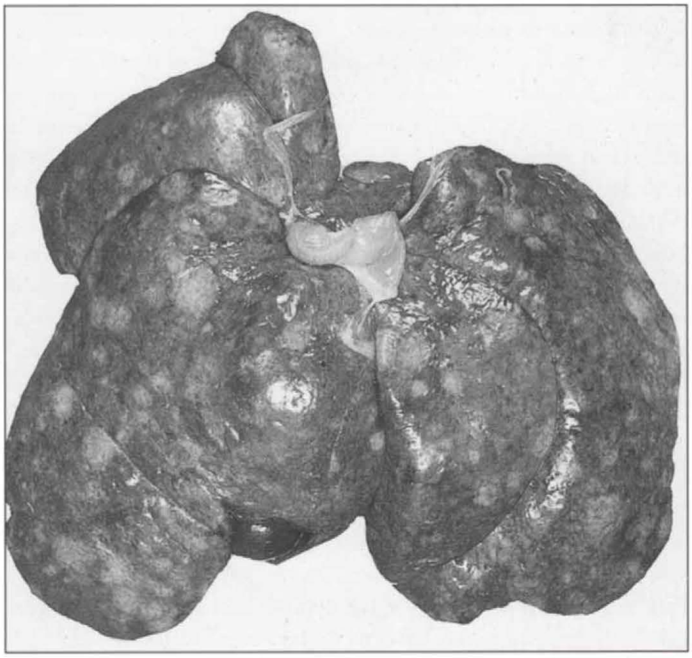

Figure 2.49 Acute **cholangiohepatitis** in a dog.

ducts contain purulent exudate, and the smaller ones are disintegrated. Dense masses of neutrophils, liquefied or not, are present in the portal triads and infiltrate the degenerate parenchyma.

In *subacute and chronic cholangiohepatitis*, the inflammation is more proliferative than exudative. The liver is enlarged and may be of normal shape, or distorted owing to irregular areas of atrophy and regenerative hyperplasia. Its surface may be smooth or finely granular; the capsule is thickened and may bear fibrous villi or be adherent to adjacent viscera. Within areas of duct obstruction, retention of bile pigments can be found in the regions served by the occluded ducts, but systemic icterus (or photosensitization in herbivores) is unlikely unless a very large amount of liver is affected. On the cut surface, the enlarged portal tracts are easily visible and accentuate the architecture of the organ. Eventually, the new fibrous tissue replaces the parenchyma, and in chronic diffuse cases in which the original infection persists, continuous fibroplasia may produce hepatic enlargement, the organ becoming huge, gray, and gristly. This spectrum of liver changes is typical of alsike clover poisoning ("big-liver disease") in horses (discussed in the section on Toxic hepatic disease, below). Alternatively, the chronic fibrosis may occur in wedge-shaped areas oriented to a small bile duct. The enlarged interlobular ducts may be readily visible and frequently contain plugs of inspissated secretion and debris. This lesion may be referred to as *biliary infarction.*

Microscopically, the reaction remains centered on portal tracts. These are expanded in subacute cases by infiltration of leukocytes and macrophages and the proliferation of small ducts and, in chronic cases, chiefly by organizing fibrous tissue and proliferating bile ducts (see Fig. 2.37). Encroachment on the parenchyma is minimal but inevitable. Continued degeneration of the periportal parenchyma is probably an additional stimulus to local fibroplasia, which, as well as thickening the smallest portal triads, extends along their length and links up with neighboring triads, thus subdividing the acini into segments. The hepatic venules and sublobular veins are involved. Regenerative nodules are not a prominent feature of cholangiohepatitis unless large areas of parenchyma have been destroyed, in which case the least damaged lobes are expanded by coarse nodules.

Suppurative or neutrophilic cholangiohepatitis *of ill-defined pathogenesis occurs in mature cats and less commonly in dogs.* The acute stage is characterized by edema and neutrophilic portal infiltrates, inflammation and degeneration of bile ducts with neutrophils in ductular lumens and emigrating through the ductular epithelium, infiltration of inflammatory cells into hepatic lobules and periportal hepatocellular necrosis. Mixed cholangiohepatitis, with neutrophils, lymphocytes, and plasma cells infiltrating portal areas accompanied by bile duct proliferation, biliary epithelial degeneration, and various degrees of periportal to bridging fibrosis, may represent the subacute stage (Fig. 2.50), while concentric periportal fibrosis and pseudolobule formation may represent the most chronic stage of the disease. Suppurative cholangiohepatitis is more prevalent in cats 11–15 years of age, and often occurs in conjunction with other disorders, including acute extrahepatic bile duct obstruction, pancreatitis, or inflammatory bowel disease. *This condition has been suggested to be the result of acute inflammation in the biliary tree associated with ascending bacterial infection.* In the cat, the biliary and pancreatic ducts have a common entry to the duodenum, and simultaneous infectious inflammation of these systems is common. *Escherichia coli* is the most common bacterial isolate; however, *Bacteroides*, hemolytic *Streptococcus*, and clostridia have also been reported.

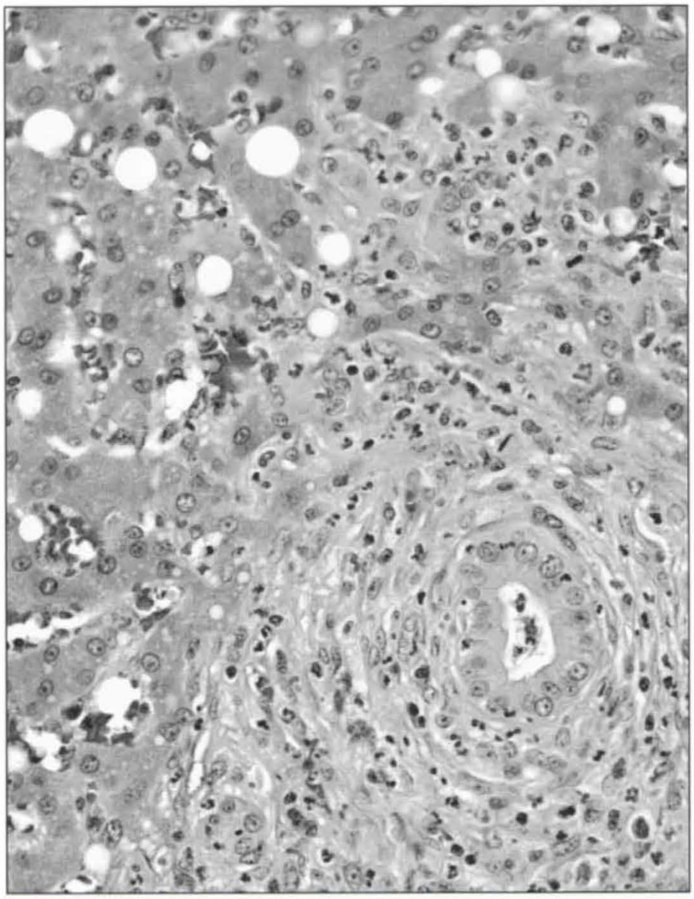

Figure 2.50 Bile duct inflammation with portal edema, mixed inflammation, and early fibrosis in a case of **suppurative cholangiohepatitis** in a dog.

An apparently distinct condition of cats, **lymphocytic portal hepatitis** *is characterized by lymphocytic or lymphoplasmacytic infiltrates confined to the portal area, with no evidence of periportal necrosis or invasion of adjacent hepatic lobules* (Fig. 2.51A). Bile duct proliferation is present, but there is no evidence of bile duct epithelial degeneration or cholangitis. Periportal fibrosis is typically present, but there is no bridging between portal areas and central veins. The condition is seen most often in cats over 15 years of age, and is slowly progressive, but does not result in pseudolobule formation. Lymphocytic portal hepatitis differs from descriptions of **feline progressive lymphocytic cholangitis/cholangiohepatitis**, which has been suggested by some authors to be part of the chronic phase of neutrophilic cholangiohepatitis, as described above (Fig. 2.51B). However, progressive lymphocytic cholangitis/cholangiohepatitis has been reported predominantly in younger cats, is not apparently associated with concurrent intestinal or pancreatic disease, and is postulated to have an immune-mediated pathogenesis. This condition is typified by lymphocytic inflammation of portal tracts, with infiltration of bile ducts, extension into periportal hepatic parenchyma, bile duct proliferation accompanied by small foci of neutrophil and macrophage infiltration, and fibrosis.

Biliary tract obstruction

Cholelithiasis *(gallstone formation) is seldom observed in animals.* The choleliths usually form in the gallbladder and are composed of a

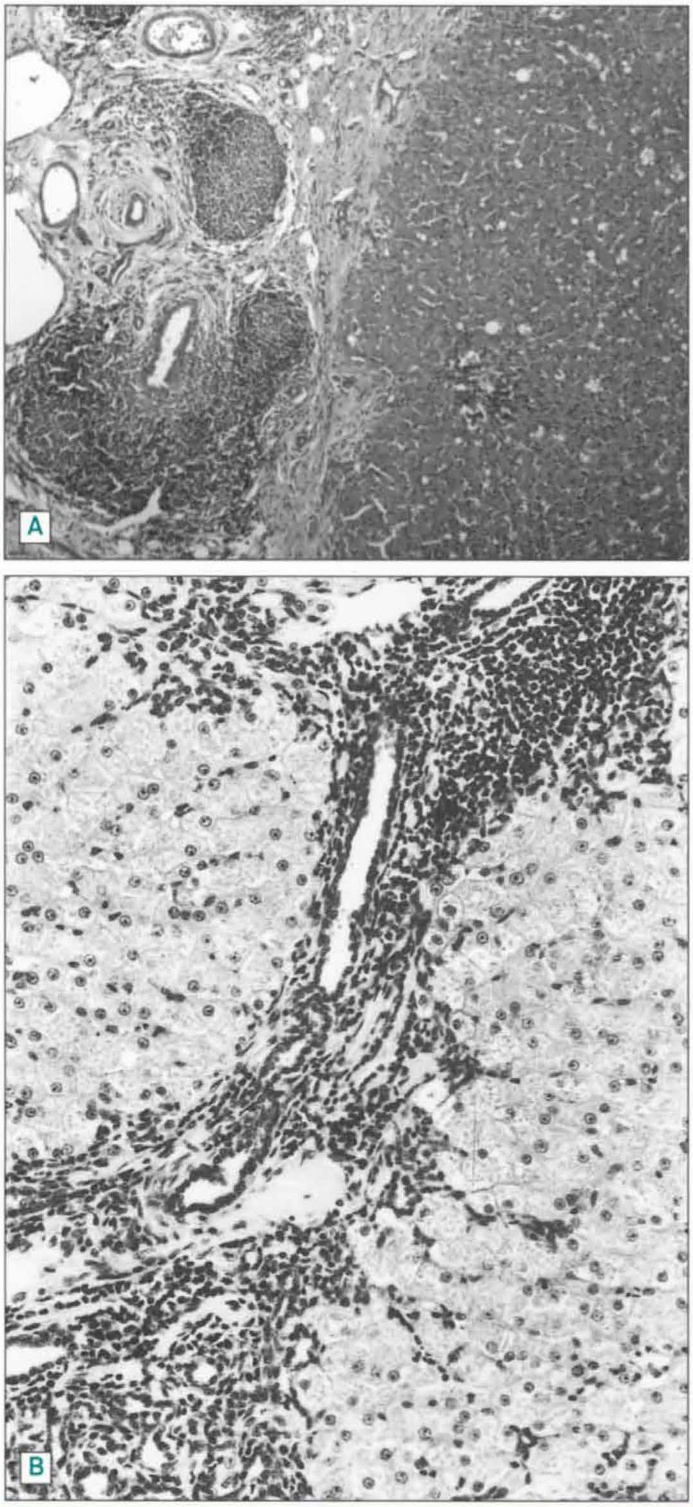

Figure 2.51 A. Lymphocytic portal hepatitis in a cat. **B. Lymphocytic cholangiohepatitis** in a cat.

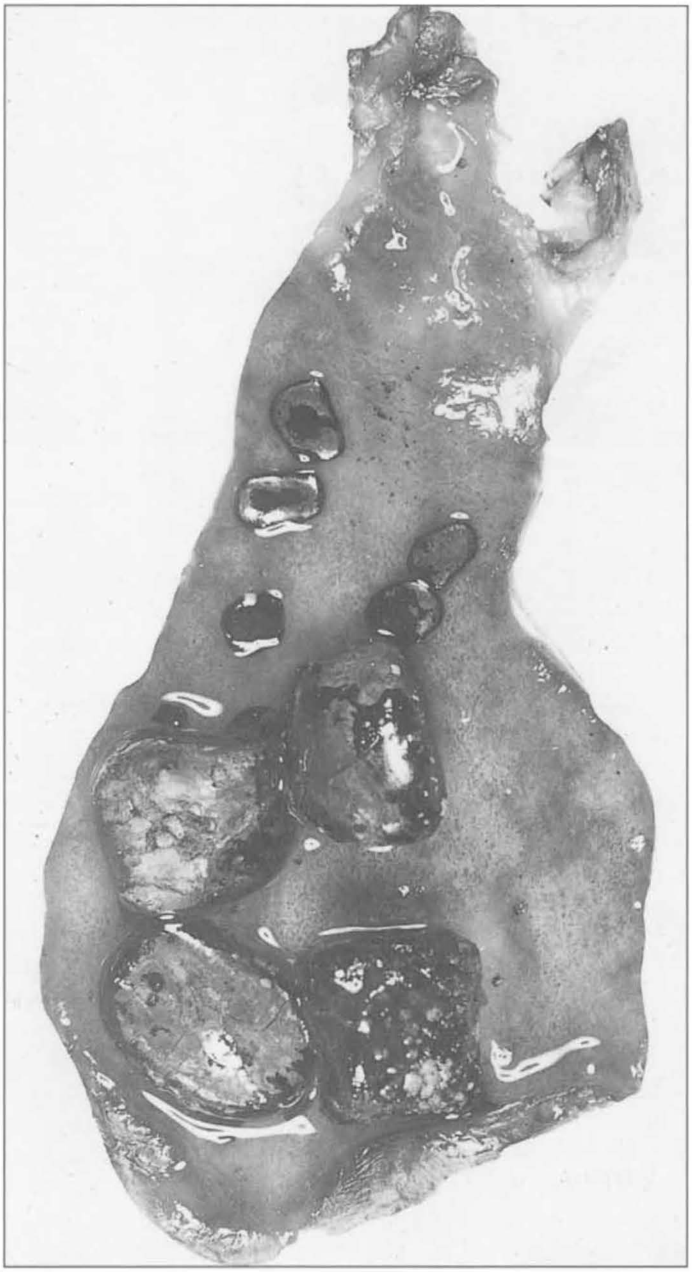

Figure 2.52 Gallstones in the opened gallbladder of a dog.

mixture of cholesterols, bile pigments, salts of bile acids, calcium salts, and a proteinaceous matrix. Choleliths of mixed composition are yellow-black or green-black and are friable. *Pigment stones*, composed of calcium bilirubinate, and *cholesterol stones* have also been reported in dogs. There may be hundreds of small stones or a few large ones (Fig. 2.52). The large stones are usually faceted. The origin of these mixed gallstones is uncertain, but their development is probably secondary to chronic mild cholecystitis and related to disturbances of the resorptive activities of the gallbladder, whereby the bile salts are removed faster than the stone-forming compounds. Gallstones are usually asymptomatic. Occasionally, they lodge in and obstruct bile ducts and cause jaundice. The larger stones may cause pressure necrosis and ulceration of the mucosa, local dilations of the bile ducts, and saccular diverticula of the gallbladder. Calculi seldom form in the ducts, although calcareous deposits often do so in fascioliasis of cattle. Calcium bilirubinate calculi have been reported in the bile ducts of horses (Fig. 2.53), associated with intermittent jaundice.

Occasionally, particles of solid ingesta may find their way into the gallbladder; sand has been seen in sheep, and seeds in pigs.

Biliary obstruction is rarely due to impacted gallstones. Usually it is *due to cholangitis or cholecystitis*, the obstruction being produced

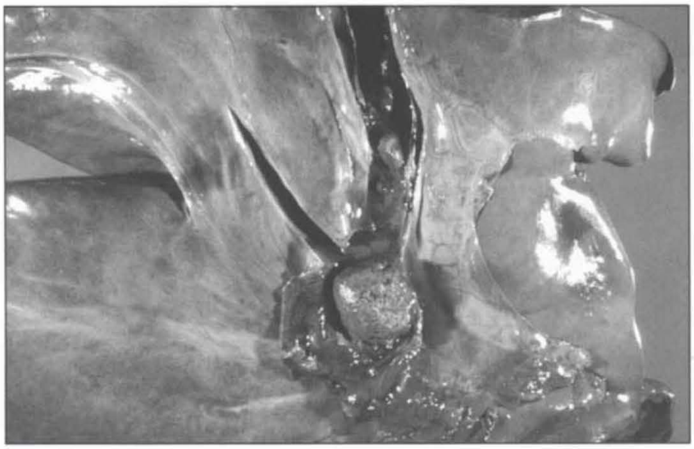

Figure 2.53 Cholelith obstructing the bile duct in a horse.

by masses of detritus and biliary constituents, parasites, or cicatricial stenosis of the ducts. Adult ascarids may cause mechanical obstruction. Inspissated bile-stained friable plugs are occasionally responsible for obstructions in segments of the liver in horses. Tumors of the pancreas and duodenum, and tumors and abscesses of the hilus of the liver and portal nodes, may cause compression stenosis of the ducts. Edematous swelling of the papilla in enteritis may also be of significance. Biliary obstruction by abnormal intraluminal mucoid secretion (*gallbladder mucocele*) has been reported in dogs (see section on Ectopic, metaplastic, and hyperplastic lesions, below).

The consequences of biliary obstruction depend on the site and duration of the obstruction. When the main duct is involved, there is jaundice. When one of the hepatic ducts is involved, there is no jaundice, and depending on the efficiency of biliary collaterals, there may be no pigmentation of the obstructed segments of liver. Increases in serum γ-glutamyltranspeptidase and alkaline phosphatase usually occur when a sufficiently large amount of the duct system is affected. The ducts undergo progressive cylindric dilation, which may be extreme. The smallest interlobular ducts and the cholangioles proliferate. There is inflammation in the walls of the ducts and the portal triads, and this is probably due in part to chemical irritation by bile acids but is largely due to secondary bacterial infections. These infections may be acute and purulent, or low-grade; in these cases, bacteria may not be easily cultured. The cholangiohepatitis that almost inevitably follows has been described earlier.

Inflammatory stenoses of larger ducts may recanalize via mucosal glands, which can proliferate and link to form a tortuous detour around the obstruction.

Rupture of the biliary tract or the gallbladder causes steady leakage of bile into the peritoneal cavity, the omentum being unable to seal even small defects. The bile salts are very irritating and may cause *acute chemical peritonitis*. The peritoneal effusion that follows may remain sterile; more often it is infected by enteric bacteria, and severe diffuse peritonitis ensues. This may be rapidly fatal, particularly if clostridia are involved. Most perforations of the biliary tract are traumatic in origin.

INFECTIOUS DISORDERS OF THE LIVER

Viral infections

Various systemic viral diseases may affect the liver. Adenoviral infections of lambs, calves, and goat kids can cause multifocal hepatic necrosis and cholangitis, in addition to pneumonia. Lymphohistiocytic hepatitis with single-cell necrosis of hepatocytes and perilobular fibrosis is a frequent histologic lesion in cases of postweaning multisystemic wasting syndrome in pigs, associated with *Porcine circovirus* type 2 infection. Neonatal *Canid herpesvirus 1* infection in puppies causes disseminated focal necrosis and hemorrhages in parenchymal organs, including the liver, with formation of amphophilic intranuclear inclusion bodies in epithelial cells of kidney, lung, and liver. Similar microfoci of hepatic necrosis sometimes occur in aborted or newborn foals with congenital *Equid herpesvirus 1* infections (see Fig. 2.26). *Feline coronavirus* infection can cause granulomatous hepatitis in some infected cats, as part of feline infectious peritonitis.

The viral diseases included below are those in which the liver is the major target organ for viruses that cause substantial hepatic disease that sometimes culminates in hepatic failure. Unlike humans, in which several pathogenic hepatitis viruses from various families are well described, the major domestic mammals are vulnerable to few viruses that target hepatocytes. Some hepadnaviruses have been found in ducks, woodchucks, and herons. Closely related human and swine genotypes of *Hepatitis E virus* (HEV – Caliciviridae) can replicate in porcine hepatocytes wherein antigens and viral nucleic acids can be detected. There is evidence for fecal–oral transmission of HEV in pigs, and zoonotic transmission, but experimental HEV infection has not been reported as a primary cause of hepatitis in pigs.

Infectious canine hepatitis

Canine adenovirus 1 (CAdV-1) infection can cause infectious canine hepatitis, a severe liver disease in dogs and other canids. Vaccination has made the disease rare in many countries in which it was endemic.

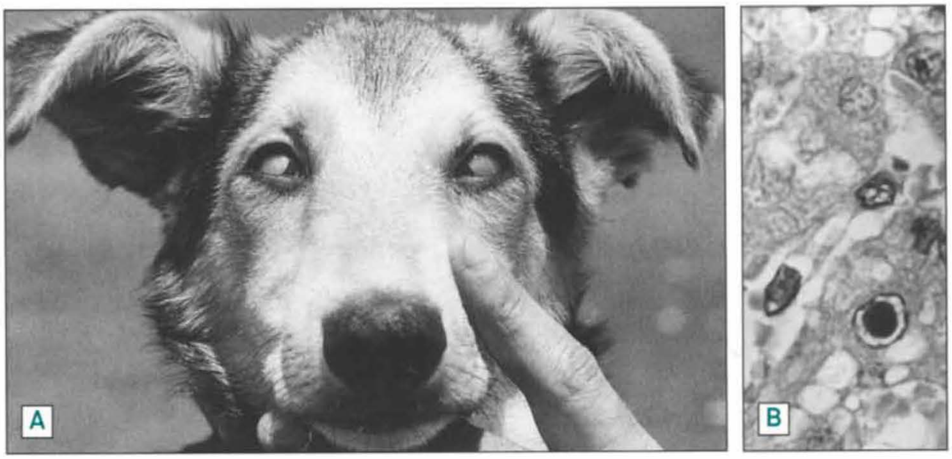

Figure 2.54 Infectious canine hepatitis (*Canine adenovirus 1* infection). **A. Corneal edema** in convalescent stage. **B. Intranuclear inclusion body** in hepatocyte.

Deaths from infectious canine hepatitis are usually sporadic, although small outbreaks can occur among young dogs in kennels. Fatalities seldom occur among dogs more than 2 years of age. In areas where the disease is not controlled by vaccination, it is probable that most dogs in the general population contact CAdV-1 in the first 2 years of life and suffer either inapparent infection or mild febrile illness with pharyngitis and tonsillitis.

In more severe cases, there is vomiting, melena, high fever, and abdominal pain. There may be petechiae on the gums; the mucous membranes are blanched, and only occasionally are they slightly jaundiced. Nervous signs of nonspecific character occur in a few cases. There is also a peracute form of the disease in which the animal is found dead without signs of illness, or after an illness of only a few hours. In convalescence, there may be a unilateral or bilateral opacity of the cornea caused by edema, which disappears spontaneously (Fig. 2.54A).

Canine adenovirus 1 has special tropism for endothelium, mesothelium, and hepatic parenchyma, and it is injury to these that is responsible for the pathologic features of edema, hemorrhage (which is predominantly serosal), and hepatic necrosis. The histologic specificity of the lesions depends on the demonstration of *large, solid intranuclear inclusion bodies in endothelium or hepatic parenchyma* (Fig. 2.54B). Inclusions are occasionally observed in other differentiated cells but always have the same morphologic and tinctorial features, being deeply acidophilic with a blue tint.

The morbid picture of spontaneously fatal cases is usually distinct enough to allow a diagnosis to be made grossly at necropsy. Superficial lymph nodes are edematous, slightly congested, and often hemorrhagic. Blotchy hemorrhages may be present on the serous membranes (Fig. 2.55A), and there is usually a small quantity of fluid, clear or blood-stained, in the abdomen. Hemorrhages on the serosa of the cranial surface of the stomach are usually linear, the so-called *paintbrush* type. Jaundice, if present, is slight. The mesenteries are slightly moist, and the serosa of the small intestine has a ground-glass appearance. The liver is slightly enlarged, with sharp edges, and is turgid and friable, sometimes congested, with a fine, uniform, yellow mottling. Red strands of fibrin can be found on its capsule, especially between the lobes. In the majority of cases, the wall of the gallbladder is edematous (Fig. 2.55B); when edema is mild, it may be detected only in the attachments of the gallbladder. In cases in which the gallbladder is edematous, it may also be darkened by intramural hemorrhages.

Gross lesions in other organs are inconstant. Small hemorrhagic infarcts may be found in the renal cortices of young puppies. Hemorrhages may occur in the lungs, and occasionally there are irregular areas of hemorrhagic consolidation in the caudal lobes. Hemorrhages in the brain occur in a small percentage of cases. These are capillary and venular hemorrhages best appreciated when darkened by formalin, and then, depending on their concentration, the affected portions of brain appear gray or dark brown. Microscopic hemorrhages occur in any part of the brain, but when numerous enough to be grossly visible, they are confined to the midbrain and brainstem, avoiding the cerebral cortex and cerebellum. Hemorrhagic necrosis of medullary and endosteal elements occurs in the metaphyses of long bones in young dogs, and the hemorrhages are readily visible through the thin cortex of the distal ends of the ribs.

At low magnification, the histologic changes in the liver are quite reminiscent of the zonal necrosis of acute hepatotoxicities. *There is an as yet unexplained susceptibility of the periacinar parenchyma to necrosis in this disease.* Close to the portal triads, the hepatocytes may be near normal in appearance, except for loss of basophilia and the presence of a scattering of inclusion bodies. In spontaneously fatal cases, most of the parenchyma of the peripheral and central portions of the acini is dead, the hepatocytes having undergone granular acidophilic coagulative necrosis, and in some of these, ghosts of inclusion bodies may be detectable. The margin between necrotic parenchyma and viable tissue is usually quite sharp, although in the viable tissue there are many individual hepatocytes undergoing apoptosis, most of them without inclusion bodies. Fatty changes are common but not constant. The dead cells do not remain long, so the sinusoids become dilated and filled with blood. The reticulin framework remains intact, an observation in keeping with the fact that, *in recovered cases, restitution of the liver is complete.* Massive necrosis with collapse does not occur. As is typical of severe periacinar necrosis, the necrotic zones, initially eccentric areas about hepatic venules, extend and link up to isolate portal units. Intranuclear inclusions can be found in Kupffer cells in variable numbers. Many of the Kupffer cells are dead, others are proliferating, and others are actively phagocytic in the removal of debris. Leukocytic reactions in the liver are mild and are directed against the necrotic tissue; mononuclear cells are present, but neutrophils, many degenerating, predominate. There is some collection of bile pigment, but it is moderate, in keeping with the short course of the disease.

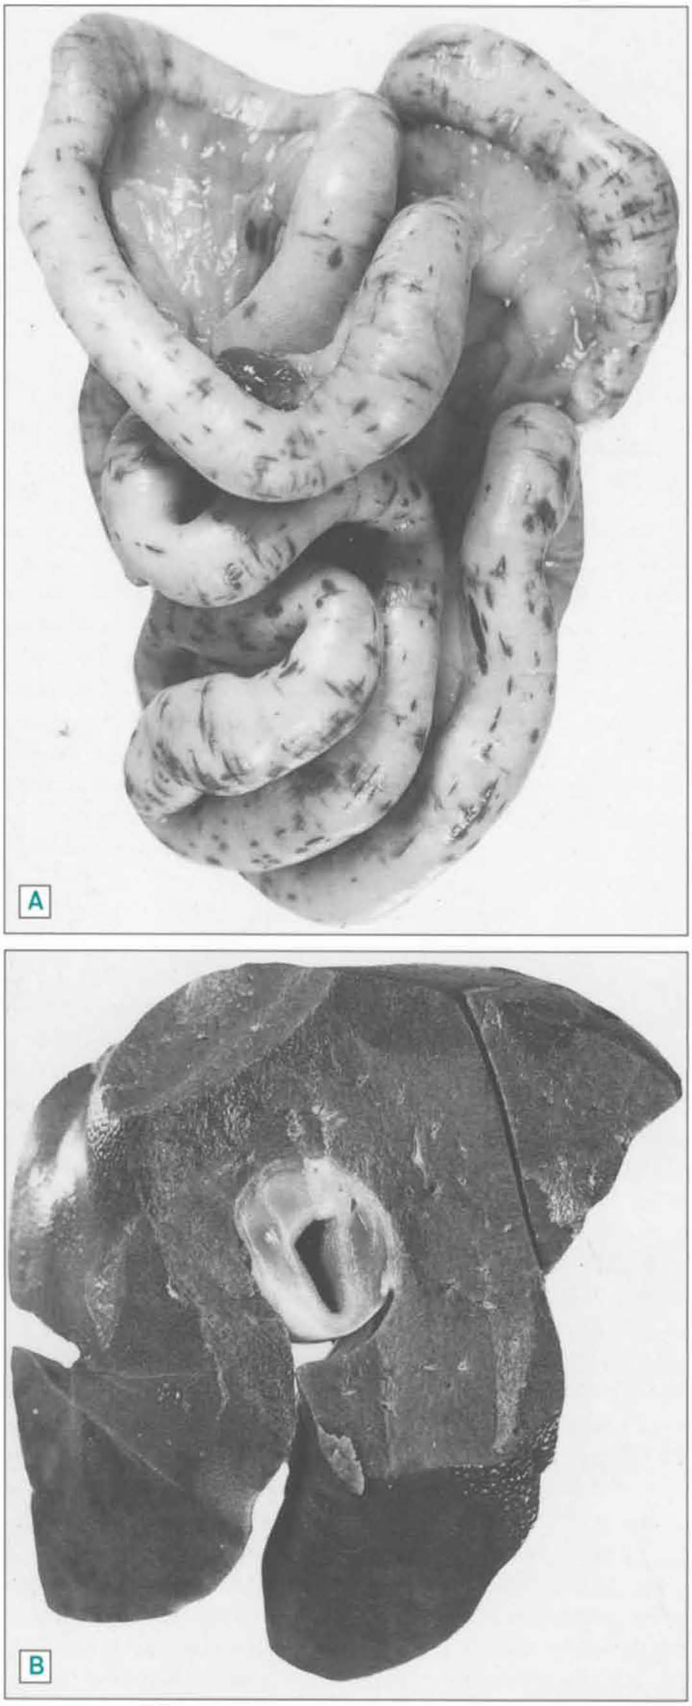

Figure 2.55 Infectious canine hepatitis. **A. Serosal hemorrhages** over the intestines. **B.** Severe **edema of the gallbladder wall**.

Microscopic lesions in other organs are largely due to injury to endothelium. Inclusion bodies in endothelial cells can be difficult to find and are looked for with most profit in renal glomeruli, where endothelium is concentrated. Occasionally, they are found in the epithelium of collecting tubules. When areas of hemorrhagic consolidation of the lungs are present, there is hemorrhage, edema, and fibrin formation in the alveoli, and in these consolidated areas, inclusions are often common in alveolar capillaries and even in dying cells of the bronchial epithelium. Changes in the brain are essentially secondary to vascular injury and may be absent. Hemorrhages, if present, are from capillaries and small venules, and inclusions in endothelial nuclei can usually be found in vessels that have bled. Other endothelial and adventitial cells are hyperplastic and mixed with a few lymphocytes. Small foci of softening or demyelination may be present in relation to the hemorrhages.

Lymphoreticular tissues are congested, and inclusions may be found in the primitive reticulum cells of follicles, in the red pulp of the spleen, and in macrophages anywhere.

The detailed pathogenesis of infectious canine hepatitis has yet to be worked out. Many infections appear to be clinically silent, and other dogs recover after mild febrile disease with tonsillitis. The fulminating pattern of clinical disease and convalescent phenomena needs further examination. Some sudden deaths in this disease are associated with midbrain hemorrhage, and others occur with, at most, slight structural evidence of liver injury. Following oral exposure, which is probably the natural route of infection, viral multiplication occurs in the tonsils and leads to tonsillitis. The tonsillitis is sometimes quite severe and may be fatal with extensive clear edema of the throat and larynx. Fever accompanies the tonsillitis and apparently precedes the viremic phase, which is of short duration and accompanied by severe leukopenia. Hepatic necrosis develops at about day 7 of experimental infection. The sequence of developments in the liver is not clear, but it is possible that viral proliferation occurs first in Kupffer cells. In surviving animals, hepatic regeneration occurs rapidly, and there do not appear to be any significant residual lesions. Small foci of hepatocellular necrosis involving one to several liver cells may still be present at 2 weeks, and foci of proliferated Kupffer cells may be detectable for another week or two, but progressive hepatic injury does not occur in the natural disease. Progressive hepatic injury does not seem to follow the acute phase of the natural disease, despite the fact that adenoviral antigen may be demonstrated immunohistochemically in Kupffer cells in dogs with various forms of chronic hepatitis, and chronic hepatitis has been produced by experimental adenoviral infection in dogs after certain immunological manipulations. This is consistent with failure to demonstrate virus in the liver after about day 10 of experimental infection. A review of 45 dogs with chronic hepatitis or cirrhosis failed to reveal CAdV-1 by either polymerase chain reaction or immunohistochemistry, although the possibility that the virus initiates hepatic damage by provoking self-perpetuating hepatitis could not be excluded. Focal interstitial nephritis occurs commonly, and the cellular infiltrates are persistent but not functionally significant. They consist of interstitial lymphocytic accumulations, especially about the corticomedullary junction and in the loose stroma of the pelvis.

Corneal edema is a late development (see Fig. 2.54A). It may occur by day 7 of infection, but is usually delayed to between 14 and 21 days. Viral antigen can be detected in these eyes by fluorescent techniques, but not in the corneal structures. Inflammatory edema is present in iris, ciliary apparatus, and corneal propria, and inflammatory cells are abundant in the filtration angle and iris. The infiltrates are principally plasma cells, and there is evidence that the ocular lesion is a hypersensitivity reaction to viral antigen.

Originally it was assumed that the widespread tendency to hemorrhage in this disease was due to leakage from damaged vascular endothelium, coupled with an inability on the part of the damaged liver to replace clotting factors. While these effects play a role, it is now known that *the exhaustion of clotting factors is in large part due to their accelerated consumption, as the widespread endothelial damage is a potent initiator of the clotting cascade.*

Wesselsbron disease

This disease is caused by *Wesselsbron virus*, an arthropod-borne flavivirus that, according to serological surveys, is widespread in Africa in various species of animals and birds. Various *Aedes* mosquitoes are the vectors. Humans are also susceptible to clinical and inapparent infection. *The virus produces outbreaks of abortion and perinatal death in sheep.* Susceptible adults rarely show clinical signs but may have a biphasic febrile response to infection; other clinical signs, when present, are of hepatitis and jaundice.

The lesions in lambs dying within 12 hours of birth consist mainly of widespread petechiae and gastrointestinal hemorrhage; longer survival allows jaundice to develop, and the liver becomes orange-yellow, enlarged, friable, and patchily congested. The bile in the gallbladder becomes thick and dark in some cases, but this may be due more to hemorrhage into the gallbladder than to hemolysis. Lymph nodes are rather constantly enlarged, congested, and edematous.

The most characteristic histologic changes are seen in the liver. There are randomly scattered foci of necrosis, with apoptosis and proliferation of sinusoidal lining cells (Fig. 2.56). Mononuclear cells and pigment-filled macrophages accumulate in the portal stroma as well as in the sinusoids. In a variable proportion of cases, *hepatocyte nuclei may contain eosinophilic, irregular inclusions.* These are not accompanied by as much margination of nuclear chromatin as that associated with conventional viral inclusions, and their significance is obscure. Wesselsbron viral antigen can be demonstrated in necrotic acidophilic and degenerating hepatocytes and rarely in the inclusions. In jaundiced animals there may be considerable canalicular cholestasis; whether or not this is the result of hemolysis does not appear to have been determined. Hepatocellular proliferation is apparent in the less acute cases. Lymphoid follicles in lymph nodes and spleen show pronounced lymphocyte necrosis and stimulation of lymphoblasts.

Rift Valley fever

This is an *arthropod-borne viral infection of ruminants and humans*, in many respects similar to Wesselsbron disease. *Rift Valley fever virus* (RVFV) is, however, responsible for greater losses than the former infection. Morbidity and mortality may occur in adult sheep; death sometimes occurs in adult cattle, but it is chiefly a disease of the young, causing *heavy mortality among lambs, kids, and calves and abortion in ewes, does, and cows.* The infection in enzootic form is widespread in eastern and southern Africa but it has, in plague-like proportions, extended to West Africa, Egypt, and the Arabian peninsula. RVFV is a member of the *Phlebovirus* genus, one of the five genera in the family Bunyaviridae. It is transmitted by many species of mosquito of the genera *Culex* and *Aedes,* in which transovarial passage can occur. Mosquitoes, once infected, remain so and in them the virus is not pathogenic. High levels of viremia occur in sheep and cattle and are maintained for up to 5 days. During epizootics, the virus may be spread by fomites, aerosols, and mechanically by other biting insects.

In endemic situations, the disease in adults is usually mild, but in epidemics in sheep and goats, severe illness occurs with fever, vomiting, mucopurulent nasal discharge, and dysentery. The mortality rate is then very high in lambs and up to 50% in adults. The disease in cattle is less severe but pregnant animals abort and the mortality rate in calves may reach 30%.

As in Wesselsbron disease, *the gross postmortem picture is dominated by widespread hemorrhage, ranging from serosal petechiae to severe gastrointestinal bleeding.* The liver in the acute cases in neonatal lambs is similar to that in cases of Wesselsbron disease, being yellow, swollen, soft, and patchily congested or hemorrhagic. In older animals and in less acute cases, however, the liver tends to be darker and show scattered pale foci of necrosis 1–2 mm in diameter. There may be fibrinous perihepatitis, edema of the gallbladder wall, and moderate, blood-tinged ascites. Experimental infection of calves produced encephalomyelitis in an animal that survived the initial viremic stage.

Within 12 hours of experimental infection of lambs, there are *randomly distributed foci of hepatocellular necrosis in the liver.* These foci include knots of inflammatory cells and prominent apoptotic bodies and initially involve about half a dozen hepatocytes (Fig. 2.57). Within a few hours, however, these primary foci enlarge and may become almost confluent. In the meantime, the remaining parenchyma may rapidly undergo necrosis that spares only a small rim of periportal hepatocytes. In naturally infected calves, the primary foci of necrosis undergo lysis more rapidly than the surrounding parenchyma; these foci thus have a striking "washed-out" appearance. Where the expanding foci of necrosis include portal triads, there may follow fibrinous vasculitis and thrombosis. Fibrin deposition in sinusoids is common, and so is mineralization of necrotic hepatocytes. Cholestasis is apparent in sections but is not a prominent feature.

Eosinophilic intranuclear inclusion bodies, often elongated, are sometimes seen in degenerate hepatocytes; there is associated nuclear vesiculation and chromatin margination. There is necrosis in germinal centers of lymphoid follicles in lymph nodes and spleen similar to that seen in Wesselsbron disease. Renal glomerular hypercellularity and necrosis have been described in the experimental disease. By immunohistochemistry, RVFV antigen can be detected in focal areas in cytoplasm of degenerating and necrotic hepatocytes but not in nonparenchymal cells.

Ultrastructural studies have shown condensation of degenerate hepatocytes, abundant apoptosis, and the presence of mummified, membrane-bound fragments of hepatocellular cytoplasm, but sinusoidal lining cells are not notably damaged; the Kupffer cells instead participate in the uptake of the dying hepatocytes. There is abundant fibrin in sinusoids in the vicinity of the primary foci of necrosis and also within hepatocytes and macrophages. *The intranuclear inclusions are composed not of recognizable viral particles but of filaments.* Virus is occasionally discernible in the cytoplasm, associated with tubular membranes.

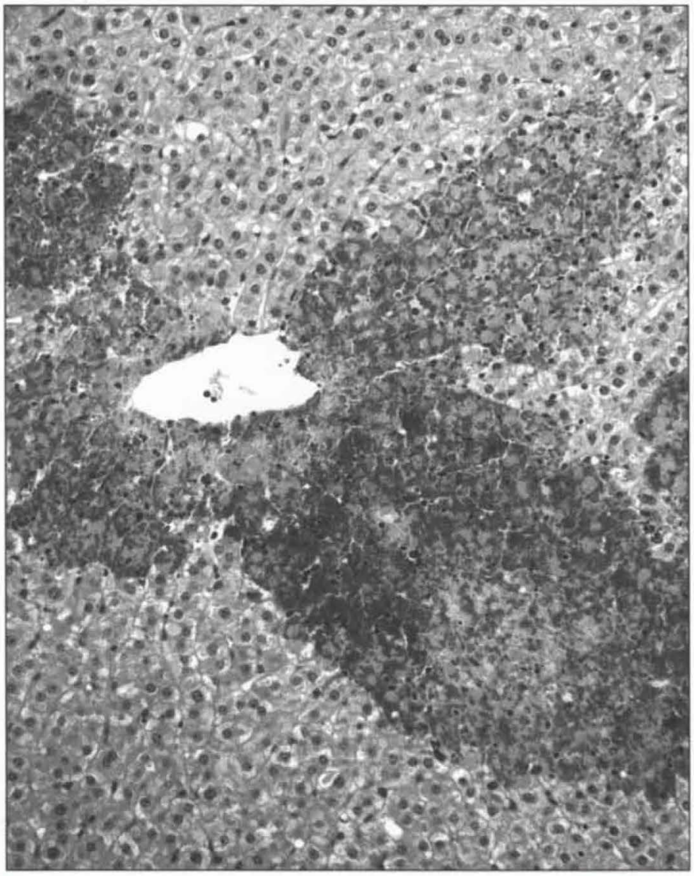

Figure 2.57 Focal necrosis with hemorrhage in Rift Valley fever in a lamb. (Courtesy of S Youssef.)

It seems that the primary infection of the liver produces the primary necrotic foci, from which more virus spreads to damage neighboring parenchyma; the virus clearly has a marked preference for hepatocytes over other tissues. The hemorrhagic component of the syndrome is probably related to consumption of clotting factors; there is no direct evidence for the endothelial damage seen in infectious canine hepatitis.

There has been some confusion in early reports from Africa of liver diseases of ruminants. Some cases of phyto- and mycotoxicosis and of chronic copper poisoning have probably been ascribed to viral infection, and vice versa. It is also understandable that Rift Valley fever and Wesselsbron disease may have been mistaken for one another, but these two diseases may be distinguished by careful pathologic examination as well as by immunodetection or isolation of the viruses. *In summary, Rift Valley fever is characterized by obvious focal hepatic necrosis, on which is superimposed an almost massive periacinar and midzonal necrosis; cholestasis is not as prominent as it is in Wesselsbron disease. The liver lesions in the latter disease consist of smaller, randomly distributed foci of hepatocellular necrosis, more active reaction by the sinusoidal lining cells, and more obvious cholestasis.*

Canine acidophil-cell hepatitis

This is a transmissible hepatitis of dogs described only in the UK and Ireland. It has been transmitted experimentally to normal dogs and rats by parenteral injections of liver and serum from affected animals. The naturally occurring disease takes the form of *chronic progressive liver damage with eventual liver failure,* attended clinically by ascites, signs of hepatic encephalopathy, and causing shrinkage and nodular distortion of the liver. *The most characteristic histologic feature of affected livers is the presence of shrunken, acidophilic hepatocytes that are concentrated initially in the limiting plates adjacent to the portal triads.* There is little or no inflammation associated with affected cells, but portal triads eventually become linked by fibrous trabeculae. Experimentally infected dogs usually remain clinically normal, but regular serum sampling reveals intermittent elevations in alanine aminotransferase levels. The characteristic acidophilic hepatocytes tend not to be so obvious in some experimentally transmitted cases, which raises the possibility that this virus may be involved in otherwise unexplained cases of chronic canine liver disease.

No infectious agent has been isolated from the original cases of canine acidophil cell hepatitis. Recent efforts to reproduce the condition by transmission of material from various spontaneous cases of canine hepatitis have had limited success. Transient hepatitis has been observed in one recipient. However, no agent has been found and polymerase chain reaction screening of livers has been negative for hepadnaviruses, *Canine adenovirus 1, Hepatitis E virus, Hepatitis C virus,* and *Canine parvovirus.*

Bacterial infections

Bacterial hepatitis is common, but, with a few important exceptions, is usually focally distributed and of little clinical significance. Bacteria may gain entrance to the liver in various ways: by direct implantation, for example by foreign-body penetration from the reticulum; by invasion of the capsule from an adjacent focus of suppurative peritonitis; hematogenously via the hepatic artery or portal and umbilical veins; or via the bile ducts.

Excepting peracute septicemias, *there are few specific bacterial infections that have a sustained or repeated bacteremic phase without producing hepatic lesions.* There are, in addition, many cases of nonspecific bacteremia, especially portal in origin, in which focal hepatitis occurs. Because their differential diagnosis is of some importance, it is probably useful to list here those specific bacterial diseases in which focal hepatitis is expected or characteristic, but not constant. The specific infections may occur as fetal or perinatal infections. The list includes *Listeria monocytogenes* in fetal and neonatal lambs, calves, foals, and piglets; *Campylobacter fetus* in fetal and neonatal lambs; *Actinobacillus equuli* in foals; *A. suis* in pigs; *Yersinia pseudotuberculosis* in lambs and occasionally in dogs and cats; *Francisella* (*Yersinia*) *tularensis* in lambs and cats; *Mannheimia haemolytica* and *Histophilus somni* (*Haemophilus agni*) in lambs; *Salmonella* spp. in all hosts (see Fig. 2.25), *Clostridium piliforme* (Tyzzer's disease) in foals and dogs; *Nocardia asteroides* in dogs; and the mycobacteria in all hosts.

Hepatic abscess

Hepatic abscesses, quite apart from the lesions of the specific infections just given, *are common*, especially in cattle. They may arise by direct implantation of a foreign body from the reticulum or by direct invasion of the capsule from a suppurative lesion of traumatic reticulitis and may be single or multiple, but in either case they are often preferentially distributed to the left lobe. They may be hematogenous from portal emboli, or by direct extension of omphalophlebitis. Arteriogenic abscesses via the hepatic artery may occur in pyemias but are quite uncommon.

Omphalogenic abscesses are more common in calves than in other species but occur in all. The bacterial flora is frequently mixed, but *Arcanobacterium* (formerly *Actinomyces* or *Corynebacterium*) *pyogenes*, *Fusobacterium necrophorum*, streptococci, and staphylococci usually predominate. Hepatic abscesses are not inevitable sequelae to omphalitis or even to omphalophlebitis, but they do not develop from navel infections in the absence of omphalophlebitis. As there is no flow of blood in these vessels after birth, involvement of the liver is by direct growth along the physiologic thrombus. Omphalophlebitis can be quite severe without extension to the liver. Hepatic abscesses of omphalogenic origin are often restricted to the left lobe (Fig. 2.58), but they may be restricted to the right or be diffuse in their distribution.

Hepatic abscesses are also common and of much economic importance in feedlot cattle. They are usually found at slaughter but, when numerous, may be fatal after a few days of vague digestive illness. Their pathogenesis and character are discussed with rumenitis, to which they are a sequel (see Vol. 2, Alimentary system). Liver abscesses in feedlot sheep likely have a similar pathogenesis, with *F. necrophorum* as the primary isolate. A second category includes parasitic granulomas populated by various opportunistic bacteria.

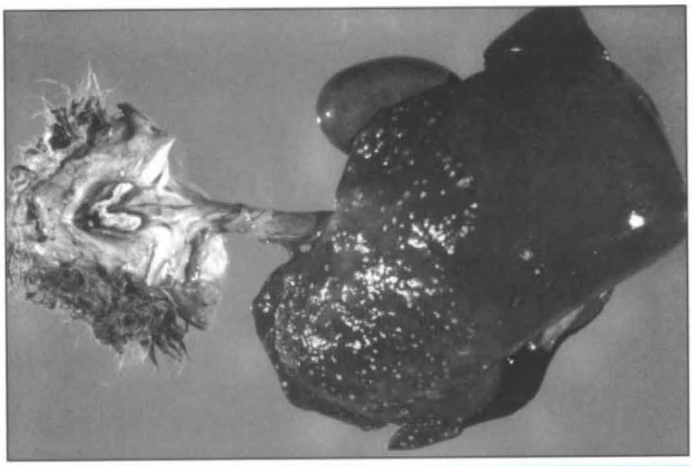

Figure 2.58 Omphalophlebitis with **miliary metastatic abscesses** in the left lobe of the liver in a calf.

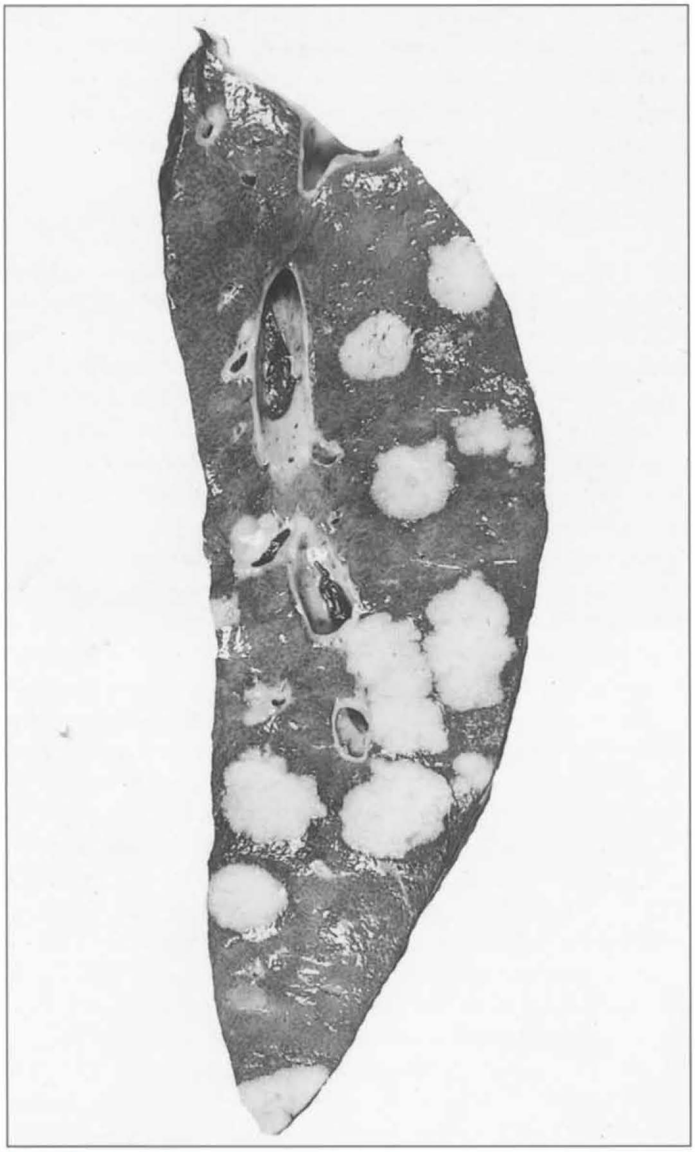

Figure 2.59 Early **hepatic necrobacillosis** in an ox (*Fusobacterium necrophorum* infection). Pale areas of coagulative necrosis are bordered by acute inflammation.

Hepatic abscesses of biliary origin occur in all animals. They are perhaps most frequent in pigs in which ascarids have migrated into the bile ducts. Cholangitic abscesses in horses, dogs, and cats are usually caused by enterobacteria as part of a fulminating ascending cholangiohepatitis that is fatal after a short course.

The *sequelae* of hepatic abscessation are variable. Usually, they are insignificant and asymptomatic. Sterilization of the focus with either resorption and complete healing or encapsulation is common. Those near the surface of the liver regularly produce fibrinous and then fibrous inflammation of the capsule and adhesion to adjacent viscera. They seldom perforate the capsule but do commonly break into hepatic veins to produce any one or a combination of thrombophlebitis of the vena cava, endocarditis, or pulmonary abscesses or embolism. Acute extension of a hepatic abscess into the major hepatic vein can lead to pulmonary embolism that can be acutely fatal. In adults, death may occur if the hepatic abscesses are multiple and fresh, and especially if they are necrobacillary in origin; death is probably the result of toxemia. Generalization is common, especially from omphalogenic abscesses of young animals.

Hepatic necrobacillosis

Occasionally, *F. necrophorum* infection of the liver is observed following *omphalophlebitis in lambs and calves*, or as a complication of *rumenitis in adult cattle.* In feedlot cattle, both *F. necrophorum* subsp. *necrophorum* (biotype A) and subsp. *funduliforme* (biotype B) have been isolated. The hepatic lesions are multiple and typical of necrobacillary infection, being slightly elevated, rounded, dry areas of coagulative necrosis, sometimes a few centimeters in diameter (Fig. 2.59) and surrounded by a zone of intense hyperemia. Affected neonates seldom live long enough for the necrotic foci to liquefy and assume the appearance of ordinary abscesses, but this may be seen in adult cattle. *The histologic appearance of the foci in the stage of coagulative necrosis is quite characteristic.* The necrotic amorphous central area is bordered by a zone of wholesale destruction of leukocytes, whose nuclear chromatin is dissipated in a finely divided form, and among which the filamentous fusobacteria are mostly concentrated. Outside this zone there is severe hyperemia and hemorrhage, and thrombosis of local vessels is common. The lesion in neonatal lambs is to be distinguished from that caused by *Campylobacter fetus*.

The pathogenic mechanisms of *F. necrophorum* involve various toxins, especially a high-molecular-weight leukotoxin specifically toxic to ruminant neutrophils. This unique toxin activates neutrophils and induces their apoptosis, consistent with the remarkable abscess-inducing propensity of *F. necrophorum* in ruminants. However, other toxins, including collagenolytic activity, are also implicated as virulence factors. Mixed infections are frequent, and synergism between *F. necrophorum* and other pathogens may also play a role in the pathogenesis of liver necrosis and abscessation.

Necrotic hepatitis (black disease)

Organisms of the genus *Clostridium* are notably circuitous in their means of producing disease. This is true of *C. novyi*; *type B strains produce potent exotoxins and are the cause of black disease* (*infectious necrotic hepatitis*). The alpha toxin of *C. novyi* belongs with the large clostridial cytotoxins produced by *C. difficile* and *C. sordelli.* These toxins enter cells by receptor-mediated endocytosis and inhibit ras and rho guanosine triphosphatases by glycosylation. The beta toxin is a necrotizing and hemolytic phospholipase C (lecithinase). Black disease occurs in nonimmune animals when these exotoxins are released by *C. novyi* within an anaerobic focus in the liver. These anaerobic sites, which provide a suitable environment for germination of *C. novyi* spores, are most commonly a result of migrating helminths.

C. novyi is widely distributed in soil, and the spores are continually ingested by grazing animals in areas where black disease occurs. Some spores cross the mucous membranes, probably in phagocytes, and remain as latent infections in histiocytic cells, mainly in the liver, spleen, and bone marrow. The duration of latency in tissue is not known, but it can be many months. In endemic areas, many healthy sheep, cattle, and dogs harbor latent infections in their livers. *Black disease is principally an acutely fatal disease of sheep in regions where the inciting helminths are endemic.* The disease is most commonly initiated by migrating larvae of the common liver fluke *Fasciola hepatica.*

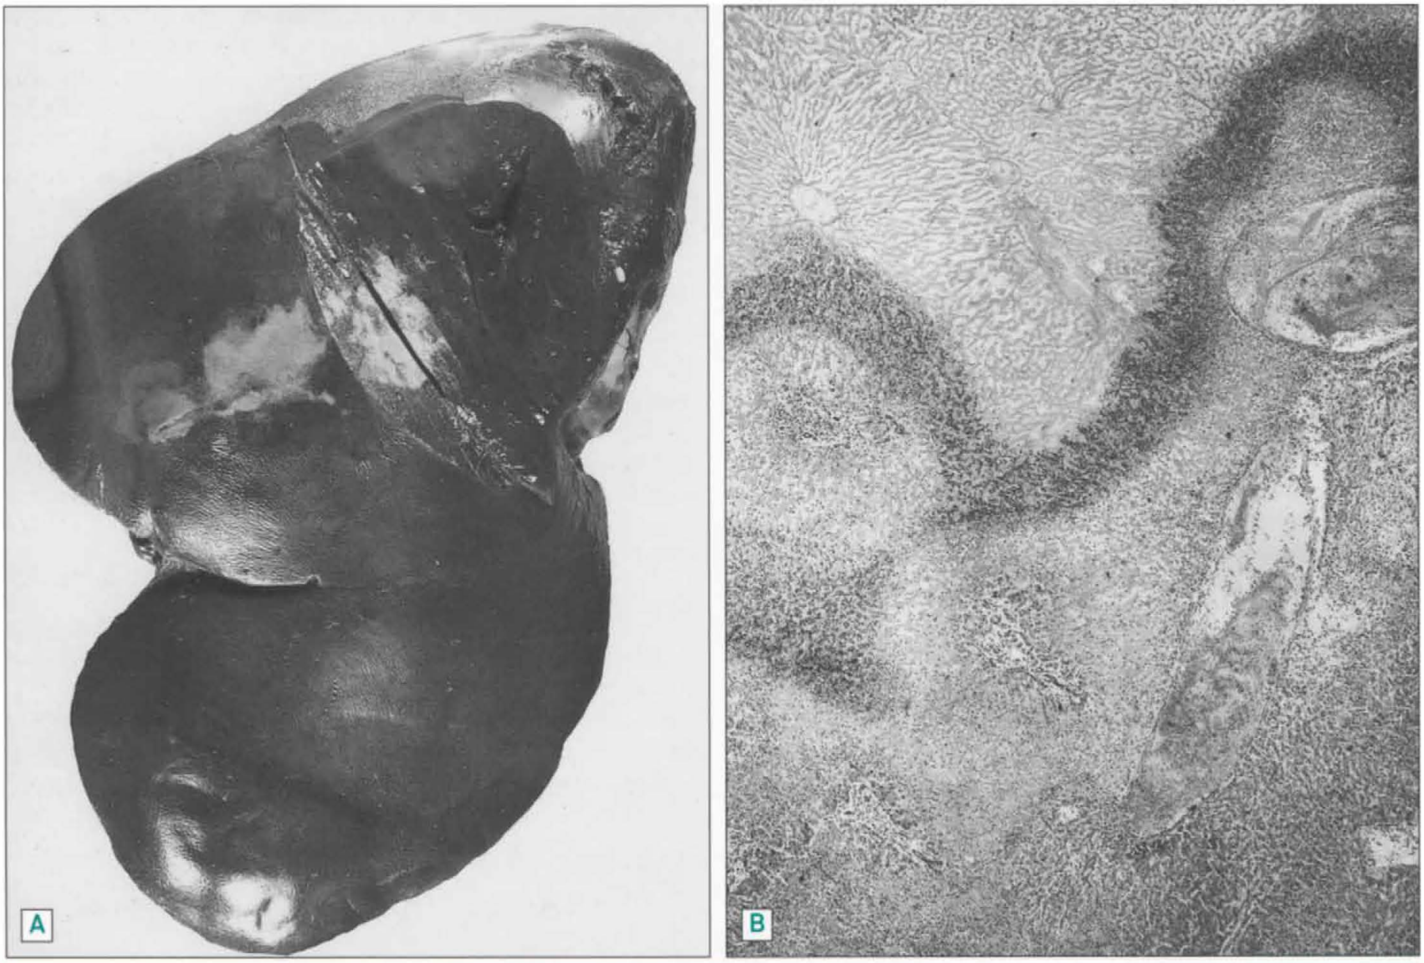

Figure 2.60 A. Infectious necrotic hepatitis ("black disease") in a sheep. Note irregular pale area of necrosis in right lobe. **B.** Section of (**A**). Vascular thrombosis and an area of **coagulative necrosis** isolated by a zone of acute inflammatory infiltrate.

In Bessarabia and France, it is endemically related to the distribution of *Dicrocoelium dendriticum*, the lancet liver fluke. Sporadic cases may be related to *Cysticercus tenuicollis* infection or may be idiopathic.

Deaths in sheep from black disease occur rapidly and usually without warning signs. Illness, if observed, is brief and characterized by reluctance to move, drowsiness, rapid respiration, and quiet subsidence. Affected animals are usually in good nutritional condition. Postmortem decomposition occurs rapidly. *The name of the disease is derived from the appearance of flayed skins, the dark coloration being caused by an unusual degree of subcutaneous venous congestion.* Frequently there is edema of the sternal subcutis, and airways contain stable foam. Serous cavities contain an abundance of fluid that clots on exposure to air. The fluid is usually straw-colored, but that in the abdomen may be tinged with blood. The volume of fluid in the abdomen and thorax may vary from about 50 mL to 1.5 L. The pericardial sac is distended with similar fluid in amounts up to ~300 mL. Subendocardial hemorrhages in the left ventricle are almost constant. Patchy areas of congestion and hemorrhage may be present in the pyloric part of the abomasum and in the small intestine.

The typical and diagnostic lesions occur in the liver and are always present. They are usually clearly evident on the capsular surface, the diaphragmatic surface especially, but the organ may have to be sliced carefully to find them. The liver will be the seat of either the acute traumatic hemorrhagic lesions of acute fascioliasis, or the cholangiohepatitis of the chronic disease, or both. *The lesion of black disease, and occasionally there are several, is a yellow-white area of necrosis 2–3 cm in diameter, surrounded by a broad zone of intense hyperemia, roughly circular in outline, and extending hemispherically into the substance of the organ* (Fig. 2.60). There may be a coagulum of fibrin on the capsular surface overlying the necrotic area. Occasionally, the essential lesions are rectilinear in shape or very irregular. The lesions appear homogeneous on the cut surface, but some contain poorly defined centers of soft or cheesy material.

The histologic evolution of the hepatic lesions begins with the necrotic and hemorrhagic tracts caused by wandering immature flukes. These are sinuous tunnels ~0.5 cm in diameter that contain blood, necrotic hepatic cells, and the leukocytes, chiefly eosinophils, attracted by the flukes. About the tunnels is a narrow zone of coagulative necrosis, also produced by the flukes. As usual, the necrotic tissue is demarcated by a thin zone of scavenger cells, chiefly neutrophils. If latent spores are present in the necrotic areas, they quickly vegetate and are visible in sections as large, gram-positive bacilli. In nonimmune animals, the vegetative organisms elaborate exotoxins that cause necrosis of the surrounding tissue, including the eosinophils of the fluke tunnel. As the area of necrosis expands, the bacterial proliferation keeps pace so that bacilli can be found in all parts of the necrotic focus but not in the surrounding viable tissue. *Usually bacteria are concentrated at the advancing margin of the lesion*, just inside a zone of infiltrated neutrophils. At about the time of death and immediately afterward, the bacilli scatter in the liver and to other organs.

Bacillary hemoglobinuria

Bacillary hemoglobinuria is a counterpart of black disease. The cause is *Clostridium haemolyticum*, which is closely related to *C. novyi*. Both species produce the beta toxin, a necrotizing and hemolytic lecithinase (phospholipase C). The pathogenesis of the two diseases is comparable, as both depend on a focus of hepatic injury within which latent spores can germinate. *Bacillary hemoglobinuria as an endemic disease exists only in areas where Fasciola hepatica abounds, and it is probable that flukes are the primary cause of the initiating lesion.* The disease does occur sporadically where there are no flukes and may be prompted by other parasites or other diverse focal lesions, which are smudged out in the expanding areas of necrosis. There is scant information on the ecology of the organism, but it is clear that it has its own environmental requirements, and the disease will not persist in areas where these requirements are not met. The spores will remain in the livers of cattle for several months after removal from pastures where the disease is endemic. Spores may persist in the bones of cadavers for 2 years. Spores of this and other sporulating anaerobes can frequently be demonstrated in the liver, where they are probably retained in Kupffer cells.

Bacillary hemoglobinuria occurs in *cattle and sheep*. It is characterized clinically by *intravascular hemolysis with anemia and hemoglobinuria*, but, perhaps reflecting variety in exotoxins between strains of the organism, hemolysis may not be a feature. The essential lesion is hepatic and similar to that of black disease but is much larger and usually single. It has been described as an infarct secondary to portal thrombosis, and although this may occur in isolated cases, it is scarcely a creditable pathogenesis for a disease of endemic occurrence. Thrombosis does occur in the affected areas but can be a result rather than a cause of the initial lesion and is found more frequently in the hepatic venules than in branches of the portal vein. There is severe anemia, the kidneys are speckled red or brown by hemoglobin, and the urine is of port-wine color. Peritoneal vessels are injected, and in some cases there is severe, dry, fibrinohemorrhagic peritonitis.

Clostridium piliforme infection

Clostridium piliforme (formerly *Bacillus piliformis*) infection has been known for a long time as *Tyzzer's disease*, a cause of severe losses in laboratory rodents; however, it has also been reported in *foals, calves, dogs, and cats*. Although the disease is probably initiated by an intestinal infection, lesions in the gut are less specific and constant than those in the liver, which consist of *focal hepatitis and necrosis*.

Affected foals usually die between the ages of 1 and 4 weeks; often they are found dead after a short illness. The liver shows pale foci up to a few millimeters across; these are represented microscopically by randomly distributed foci of coagulative necrosis with moderate neutrophilic infiltrate. This lesion is not diagnostic in itself; its specificity depends on the presence of the causal organism in hepatocytes in the periphery of the necrotic zones. At present, *C. piliforme* can only be isolated with difficulty on artificial media, so diagnosis is usually based on demonstration of the large, long bacilli in the cytoplasm of degenerate and also otherwise apparently normal hepatocytes at the periphery of the necrotic zones. The organisms are gram-negative and are best delineated with silver impregnation techniques such as that of Warthin–Starry, but they may be seen with routine stains such as Giemsa, particularly when the material is fresh. Differentiation from other organisms including postmortem saprophytes can be achieved by immunohistochemistry or immunofluorescence. *The bacilli tend to lie in sheaves or bundles* (Fig. 2.61). There may also be colitis sufficiently severe to cause diarrhea, but not as severe as that seen in rabbits with this disease.

Only a few cases of Tyzzer's disease have been reported in dogs and cats. The liver lesions are essentially the same as those in foals and rodents, and there is also enteritis or enterocolitis. Immunodeficiency predisposes to the disease because it occurs sporadically in dogs that have undergone immunosuppressive or anticancer therapy. Such cases may be complicated by concurrent viral, mycotic, or protozoal infections.

Leptospirosis

Leptospirosis is associated with acute jaundice and cholestatic hepatic disease and renal failure in dogs, and is discussed in more detail in Vol. 2, Urinary system. The hepatic lesions described following acute experimental infection of dogs with *Leptospira kirschneri* serovar *grippotyphosa* include mixed perivascular periportal infiltrates of neutrophils,

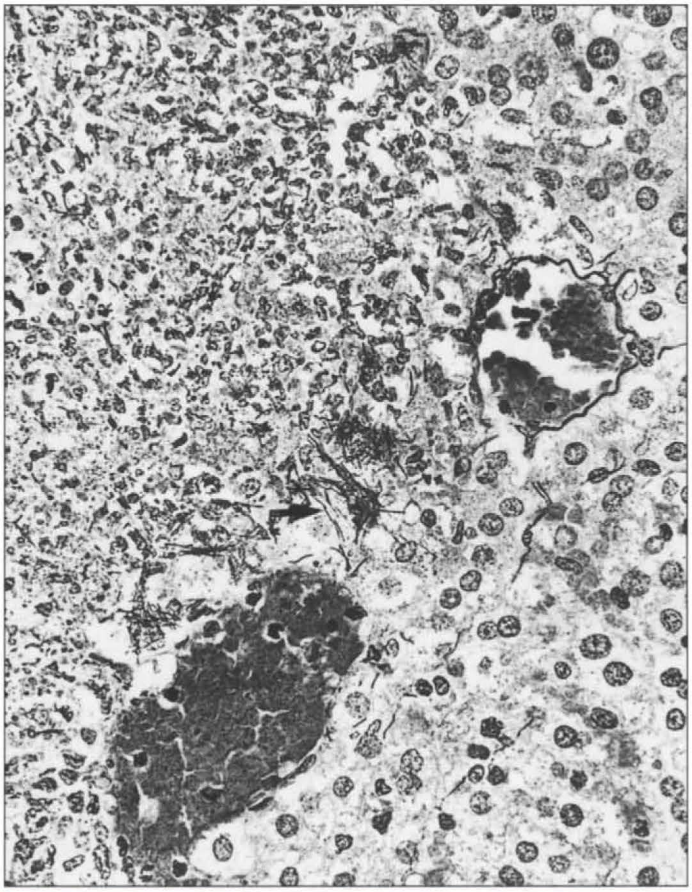

Figure 2.61 Focal hepatitis in *Clostridium piliforme* (*Bacillus piliformis*) infection (**Tyzzer's disease**). Bacilli in bundles in hepatocytes at margin of lesion (arrow), with Warthin–Starry stain.

lymphocytes, and plasma cells, with mild hepatic lipidosis, dissociation of hepatocytes and intracanalicular bile plugs evident by day 12 postinfection, along with increased hepatocellular mitotic activity. *Clinical icterus has been attributed to cholestasis due to dissociation of hepatocytes*. In a retrospective study of dogs with supportive clinical signs and microscopic agglutination test titers of ≥320 for one or more serovars tested including *autumnalis*, *bratislava*, *canicola*, *grippotyphosa*, *icterohaemorrhagiae*, and *pomona*, histologic lesions in the liver were subtle, with sinusoidal neutrophil margination, Kupffer cell hypertrophy, and low levels of hepatocellular single-cell necrosis and mitoses. Some livers had diffuse interstitial lymphocytic hepatitis, with mitotic figures, anisokaryosis, binucleation, and some degree of lobular collapse. Chronic hepatitis has also been experimentally produced by leptospiral infection in dogs; however, clinical cases are rarely documented. Sixteen juvenile Beagle dogs from a single breeding colony vaccinated for *L. interrogans* serogroups *canicola* and *icterohaemorrhagiae* developed chronic hepatitis. Leptospires were identified within bile canaliculi by special stains, electron microscopy, and immunohistochemical techniques. Significant antibody titers were not identified in 6 dogs from which leptospires were isolated. However, serological survey of kennelmates demonstrated high titers to serogroup *australis*.

Other bacteria

A single case of clinical disease associated with ***Helicobacter canis*** has been reported in a 2-month-old puppy with peracute disease causing weakness and vomiting prior to death. Multiple coalescing yellow foci in the liver up to 1.5 cm in diameter consisted of hepatocellular coagulative necrosis with infiltrating mononuclear cells and neutrophils. Spiral bacteria were visualized by Warthin–Starry silver stains in area of necrosis, within bile canaliculi and occasionally in bile duct lumens. This organism has previously been identified in the blood of diarrheic children, and in the feces of 4% of dogs in an epidemiologic study examining the incidence of *Campylobacter*-like organisms in 1000 dogs.

Bartonella spp. infection has been associated with a wide variety of granulomatous syndromes and peliosis hepatis in humans, often in association with immunosuppression; however, the extent to which infection induces disease in dogs is currently unknown. *Bartonella henselae* has been identified in liver tissue by polymerase chain reaction from a single case of peliosis hepatis in a Golden Retriever and granulomatous hepatitis in a Basset Hound, while *B. clarridgeiae* DNA was identified in liver tissue from a Doberman Pinscher with histologic lesions of Doberman hepatopathy.

Helminthic infections

Various helminths, cestodes, nematodes, trematodes, and even the degenerate arachnid *Linguatula serrata* produce inflammation of liver and bile ducts. Those parasites that have the biliary system as their final habitat will be discussed in detail below. The others produce hepatic lesions in the course of their natural or accidental migrations, and are discussed under the organ (for most of them, the gut) that is their final habitat. It is useful however to describe briefly here the lesions produced by larvae in transit.

The initial lesion produced by wandering larvae is traumatic. Sinuous tunnels permeate the parenchyma and often breach the capsule. In the tunnels there are free red cells, degenerating hepatocytes, and leukocytes, chiefly eosinophils, which react to the parasites. Bordering the tunnel is a narrow zone of coagulative necrosis of parenchyma with infiltrated neutrophils at its margin. Eosinophils also infiltrate the portal triads. The necrotic parasitic tracts heal by scarification, and the fibroblastic tissue, infiltrated with eosinophils, is eventually incorporated into the portal units (interstitial hepatitis). Most larvae escape from the liver but some eventually become encapsulated in the liver in abscesses containing numerous eosinophils. The abscesses may caseate and come to resemble tubercles, and eventually many are heavily mineralized to form permanent pearly nodules. In sheep, the most common cause of this type of hepatitis (aside from liver fluke) is ***Cysticercus tenuicollis*** in its wandering phase. Lambs may die of severe hemorrhagic hepatitis (Fig. 2.62) caused by very heavy infections of this parasite, and in pigs, an aberrant host, *C. tenuicollis*, can produce a very intense inflammatory reaction.

In pigs, larvae of ***Ascaris suum*** and ***Stephanurus dentatus*** produce similar but distinct patterns of focal interstitial hepatitis. The ascarids produce their distinctive accentuation of the stroma ("*milk spots*") (Fig. 2.63) when quite small larvae are immobilized by the host's inflammatory reaction; thus the foci are relatively small. The fibrotic lesion produced by *S. dentatus* larvae, on the other hand, is less focal and more in the nature of a track, and there are usually small, inflamed, capsular craters where the larvae have emerged from the liver to migrate to their preferred perirenal site. There will be obvious portal phlebitis at the hepatic hilus when infection by *S. dentatus*

has been by the oral route, and in these livers the parenchymal lesion is more severe in this vicinity.

Migration tracks left by *larval strongyles* are common under the liver capsule in young horses and are probably related to the dense, discrete fibrous tags that are almost universally found on the diaphragmatic surface of the liver of mature horses. The range of strongyle species capable of causing these lesions has not been defined. There are other and more devious means by which parasites produce hepatic

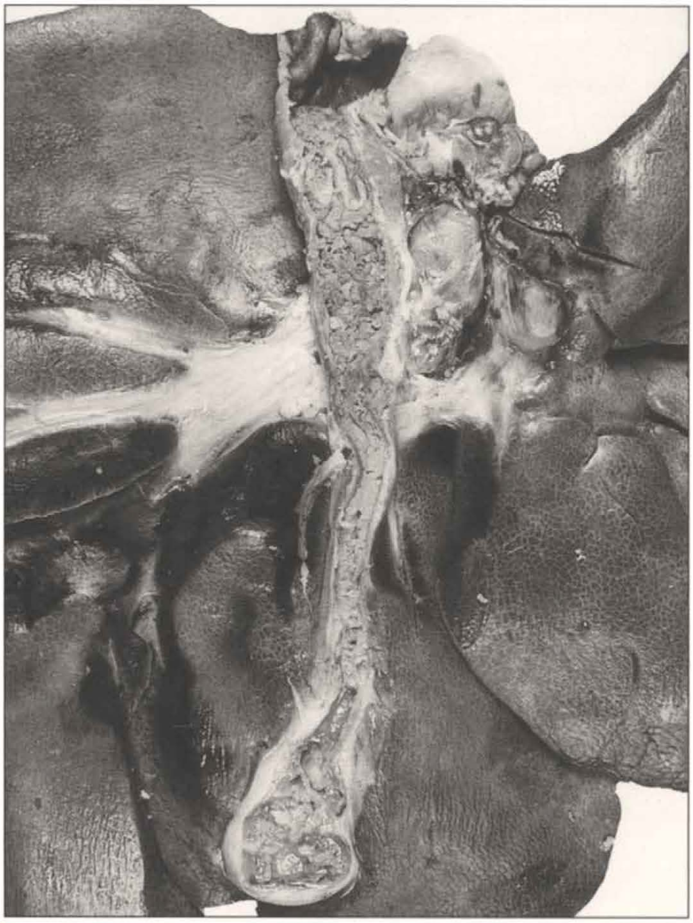

Figure 2.65 Cholangitis and cholecystitis secondary to *Ascaris suum* invasion in a pig.

lesions; the hydatid intermediate stages of *Echinococcus* encyst in the liver and may destroy much of it (Fig. 2.64); the larvae of *Ascaris suum* in cattle add to the usual insult by causing portal phlebitis and small areas of infarction; the adults of *Ascaris* in all species, but especially in pigs, may migrate into the bile ducts (Fig. 2.65); and the eggs of schistosomes enter in the portal blood to lodge in the intrahepatic portal vessels and provoke granulomatous inflammation.

Cestodes

Stilesia hepatica and ***Thysanosoma actinioides***, the "fringed tapeworm," are the only cestodes that inhabit the bile ducts. They are parasites of ruminants, *Stilesia* occurring in Africa, *Thysanosoma* in North and South America. The life cycles of the parasites are not completely known but probably involve oribatid mites as intermediate hosts. *T. actinioides* may also be found in the pancreatic ducts and small intestine. Usually, the infestations are light but, even when heavy, are not of much significance. Very heavy infestations by *S. hepatica* occur without signs of illness, though the bile ducts may be nearly occluded, slightly thickened, and dilated. Saccular dilations of the ducts may occur and be filled with worms. The fringed tapeworm is perhaps more pathogenic, and unthriftiness may accompany heavy infestations.

Echinococcus granulosus hydatid cysts occur most commonly in the liver of ruminants in endemic areas but have been reported as incidental necropsy findings in the liver of horses. The cysticerci and hydatids, which in the intermediate stages invade the liver, are discussed further in Vol. 2, Alimentary system.

Nematodes

Calodium hepaticum (Capillaria hepatica) is the one nematode that in the adult phase inhabits the liver. It is a slender worm, morphologically resembling the whipworms, and it lives in the parenchyma rather than in the bile ducts. The usual hosts of the adult stage are rodents, but sporadic infestations are observed in dogs. These worms are *not highly pathogenic.* The adults provoke some traumatic hepatitis, and the eggs, which are deposited in clusters, provoke the development of localized granulomas. The eggs are readily recognized by their ovoid shape and polar caps. The granulomas can be seen through the capsule or in the substance of the liver as yellow streaks or patches. The eggs cannot escape from the liver unless a predator eats them. Predators, however, act only as transport hosts, and the ingested eggs are passed in the feces. Larvae develop in the eggs only in the external environment, and the cycle is completed when a suitable host eats the mature larvae in the eggs.

Trematodes

Various trematodes (flukes) are parasitic in the livers of animals. They belong to the families Fasciolidae (*Fasciola hepatica*, *F. gigantica*, *Fascioloides magna)*, Dicrocoeliidae (*Dicrocoelium dendriticum*, *D. hospes*, *Platynosomum concinnum)*, and Opisthorchiidae (*Opisthorchis tenuicollis*, *O. sinensis*, *Pseudamphistomum truncatum*). The diseases produced are known collectively as **distomiasis**.

Fasciola hepatica*, the common liver fluke of sheep and cattle, is the most widespread and important of the group.* Patent infestations can develop in other wild and domestic animals and in humans. These flukes are leaf-shaped and ~2.5 cm long in sheep and slightly larger in cattle. *They are found in the bile ducts.* Being hermaphroditic, only one fluke is necessary to establish a patent infestation, and each adult may produce 20 000 eggs per day. The longevity of the adult flukes is amazing and is potentially as great as or greater than that of the host; they have been known to survive for 11 years, and it seems that they can produce eggs all this time. The eggs are eliminated in bile, and on pasture, in conditions of suitable warmth and moistness, hatch a larva (miracidium) in ~9 days. If the environmental temperature is low, the incubation period may be delayed for some months. The miracidium can survive only in moisture. It is actively motile and penetrates the tissues of the intermediate host, which is an aquatic snail. Different snails serve this purpose in different countries, but all of them belong to the genus *Lymnaea.*

Each *miracidium*, on penetrating a snail, develops into a mother *sporocyst* that reproduces, probably parthenogenetically, giving rise to a small number of the second generation, the *redia.* Each redia gives birth to either redia or *cercariae*, or to the two successively. Cercariae, the larval stage of the third (sexual) generation, first appear 1–2 months after the miracidium penetrates. Cercariae continue to escape daily for the life of the snail, but even so, total cercarial production is only 500–1000. They actively escape from the snail and are attracted to green plants, where they encyst and become infective metacercariae in 1 day. These can remain infective for 1 month in summer

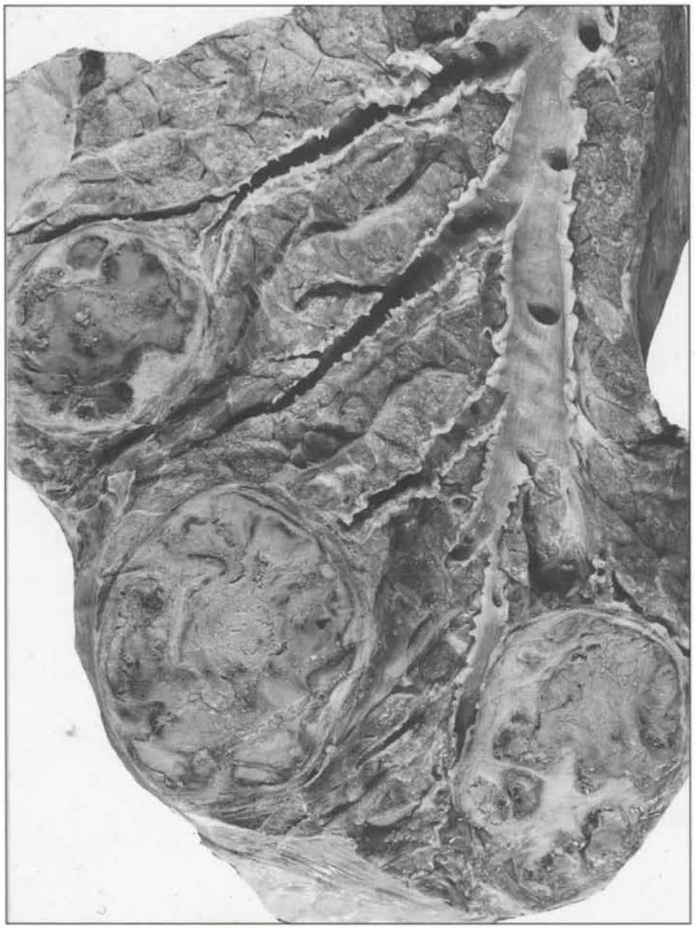

Figure 2.66 Three **caseous abscesses** at the ends of bronchi due to aberrant migration of flukes in an ox.

and up to 3 months in winter. The developmental events from egg to this stage take 1–2 months under favorable conditions.

Infestation occurs by ingestion. Excystment occurs in the duodenum. The young flukes penetrate the intestinal wall and cross the peritoneal cavity, attaching here and there to suck blood and penetrate the liver through its capsule; a few no doubt pass in the portal vessels or migrate up the bile duct. They wander in the liver for a month or more before settling down in the bile ducts to mature, which they do in 2–3 months. Some may, by accident, enter the hepatic veins and systemic circulation to lodge in unusual sites; intrauterine infestations are on record. *Lesions caused by aberrant flukes are quite common in bovine lung.* They consist of resilient nodules just under the pleura of the peripheral parts of the lung. They range in diameter from ~1 to many centimeters and consist of thinly encapsulated abscesses situated at the ends of bronchi (Fig. 2.66). The content is slightly mucoid, unevenly coagulated brown fluid; in some lesions the reaction is predominantly caseous. The location of the lesion suggests that it begins as a peripheral bronchiectasis that later becomes sealed off. The fluke persists in the debris, but is small and hard to find.

The essential lesions produced by *F. hepatica* occur in the liver and may be described, first, as those produced by the migratory larvae, and second as those produced by the mature flukes in the bile ducts; the two often intermingle. There is the further incidence of peritonitis, which is produced by the young flukes on their way to the liver and, perhaps also, by some that break out through the capsule.

Usually there is no obvious reaction to the passage of young flukes through the intestinal wall and across the peritoneal cavity, except for small hemorrhagic foci on the peritoneum, where the flukes have been temporarily attached. Few or many parasites may be found in any ascitic fluid and attached to the peritoneum of the diaphragm and the mesenteries. When the infestations are heavy and repeated, such as may be observed in sheep, cattle, and swine, *peritonitis* occurs. The young flukes at this stage are <1.0 mm long. The peritonitis may be acute and exudative or chronic and proliferative. It is usually concentrated on the hepatic capsule (Fig. 2.67), especially its visceral surface, but may be restricted to the parietal peritoneum or to the visceral peritoneum, including the mesenteries of the gut. In acute cases, there are fibrinohemorrhagic deposits on the serous surfaces, and in chronic cases there may be fibrous tags, with adhesions or a more or less diffuse thickening by connective tissue. Many young flukes can be found microscopically in the fibrinous deposits, and in the diffuse peritoneal thickenings there are tortuous migration tunnels containing blood, debris, and the young parasites (Fig. 2.68). In cases with involvement of the visceral peritoneum, young flukes can be found in enlarged mesenteric lymph nodes.

The acute lesions in the liver caused by the wandering flukes are basically traumatic, but there is an element of coagulative necrosis, which is possibly related to toxic excretions of the flukes. The migratory pathways are tortuous tunnels that appear on cross-section as hemorrhagic foci 2–3 mm in diameter. If a tunnel is followed, a young fluke less than 1.0 mm long can be found at the end. When the infestation is heavy, the liver may appear to be permeated by dark hemorrhagic streaks and foci. Older tunnels from which the debris has been cleared may appear as light yellow streaks due to infiltration of eosinophils (Fig. 2.67). Microscopically, fresh tunnels are filled with blood and degenerate hepatocytes and are soon infiltrated by eosinophils. Later, histiocytes and giant cells arrange themselves about the debris and remove it, and healing occurs by granulation tissue, which is rich in lymphocytes and eosinophils. In light infestations the scars may disappear, but in heavy infestations they may fuse with each other and with portal areas to produce moderate irregular fibrosis. There may, as yet, be no change in the bile ducts. Probably, *most of the young flukes reach the bile ducts, but some do not and become encysted in the parenchyma.* One or more flukes may be present in each cyst, which consists of a connective-tissue capsule and a dirty brown content of blood, detritus, and excrement from flukes. The cysts ultimately caseate and may mineralize or are obliterated by fibrous tissue. These cysts are most frequent on the visceral surface, where they cause bulging of the capsule.

Heavy infestations by immature flukes may cause death in the stage of acute hepatitis. Such an outcome is not common, but occurs in sheep. It is estimated that 10 000 metacercariae ingested over a short period are necessary to produce acute death in sheep. Death may occur suddenly or after a few days of fever, lassitude, inappetance, and abdominal tenderness. This is also the stage of the parasitism in which *black disease* occurs (see above).

Mature flukes are present in the larger bile ducts and cause cholangiohepatitis. The relative importance of different factors in their pathogenicity is not known, but they cause mechanical irritation by the action of their suckers and scales, cause obstruction of the ducts with some degree of biliary retention, predispose to bacterial infections,

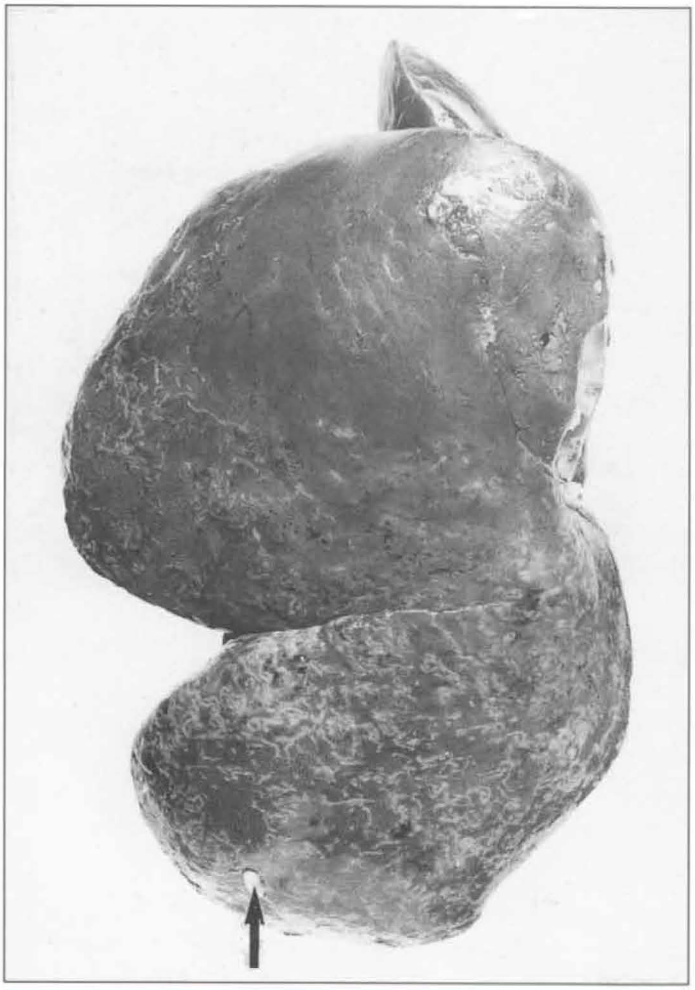

Figure 2.67 Tracks of immature ***Fasciola hepatica* flukes** in acute infestation, concentrated in left lobe of a sheep. Degenerate cysticercus (arrow).

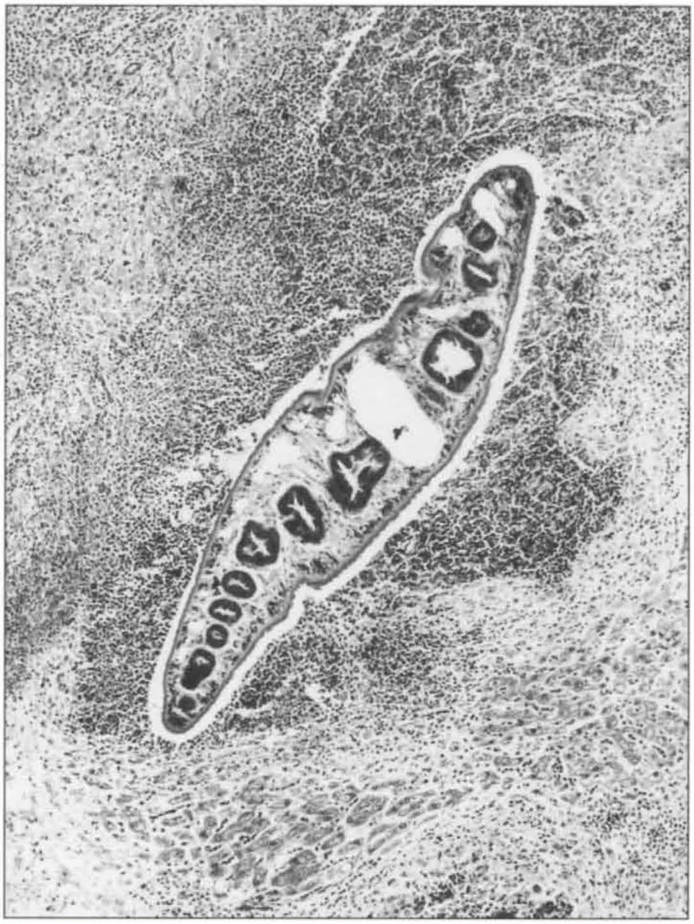

Figure 2.68 Immature fluke, accompanied by acute inflammation in a sheep.

suck blood, and probably produce toxic and irritative metabolic excretions.

The *biliary changes* occur in all lobes but are usually most severe in the left, and the right may be moderately hypertrophied (Fig. 2.69A). From the hilus, *the bile ducts on the visceral surface stand out as white, firm, branching cords* that in extreme instances may be 2 cm in diameter and allow detectable fluctuation over extended segments or in localized areas of ectasia. This dilation of the ducts in sheep, swine, and horses is largely mechanical and is due to *distension by masses of flukes and bile*. It is permitted by the relative paucity of new connective-tissue formation in the walls of the ducts in these species; this in turn is probably related to the rather mild catarrhal type of inflammation in the lumina of the ducts. In *cattle*, desquamative and ulcerative lesions in the large bile ducts are more severe than in other species, and there is a correspondingly greater proliferation of granulation tissue in and about the walls of the ducts. The walls of the ducts in cattle are, in consequence, much thickened, and the lumen is irregularly stenotic and dilated and lined largely by granulation tissue. This contributes the typical "*pipe stem*" appearance to the ducts in cattle; the connective tissue may be, in addition, mineralized, sometimes so heavily that it cannot be cut with a knife. The bile ducts contain dirty dark-brown fluid of a mucinous or tough consistency, formed from degenerate floccular bile, pus, desquamated cells and detritus, clumps of flukes, and small masses of eggs in dark-brown granular aggregates.

Although the lesions are most obvious in ducts large enough to contain the flukes, there is, with time and severe or repeated infestations, *progressive inflammation in the smaller portal units* due to direct irritation by the flukes, superimposed infections, and biliary stasis. The course of events is as described earlier for subacute and chronic cholangiohepatitis. The proliferating connective tissue and bile ductules in individual portal areas extend to join each other and the scars left over from the migratory phase, so that inflammatory fibrosis may obliterate parenchyma in many foci. In such livers, the left lobe, which is the one most severely affected, may be atrophied, indurated, and irregular (Fig. 2.69B).

The development of cholangiohepatitis of the degree described depends on long-standing or heavy infestations. Lesions of lesser severity, or those less fully developed, are associated with light infestations of short duration. They may then be recognized only by local dilations of the ducts, or even these may not be readily apparent. In such mild infestations, the fact of past or present parasitism may only be suggested by the detection of characteristic black iron-porphyrin pigments, grossly visible in the hilar nodes. It also contributes to the character of the biliary contents.

Chronic debility with vague digestive disturbances is common in chronic fascioliasis, and deaths are common among sheep. Clinically and at postmortem there are, in addition to the essential lesions,

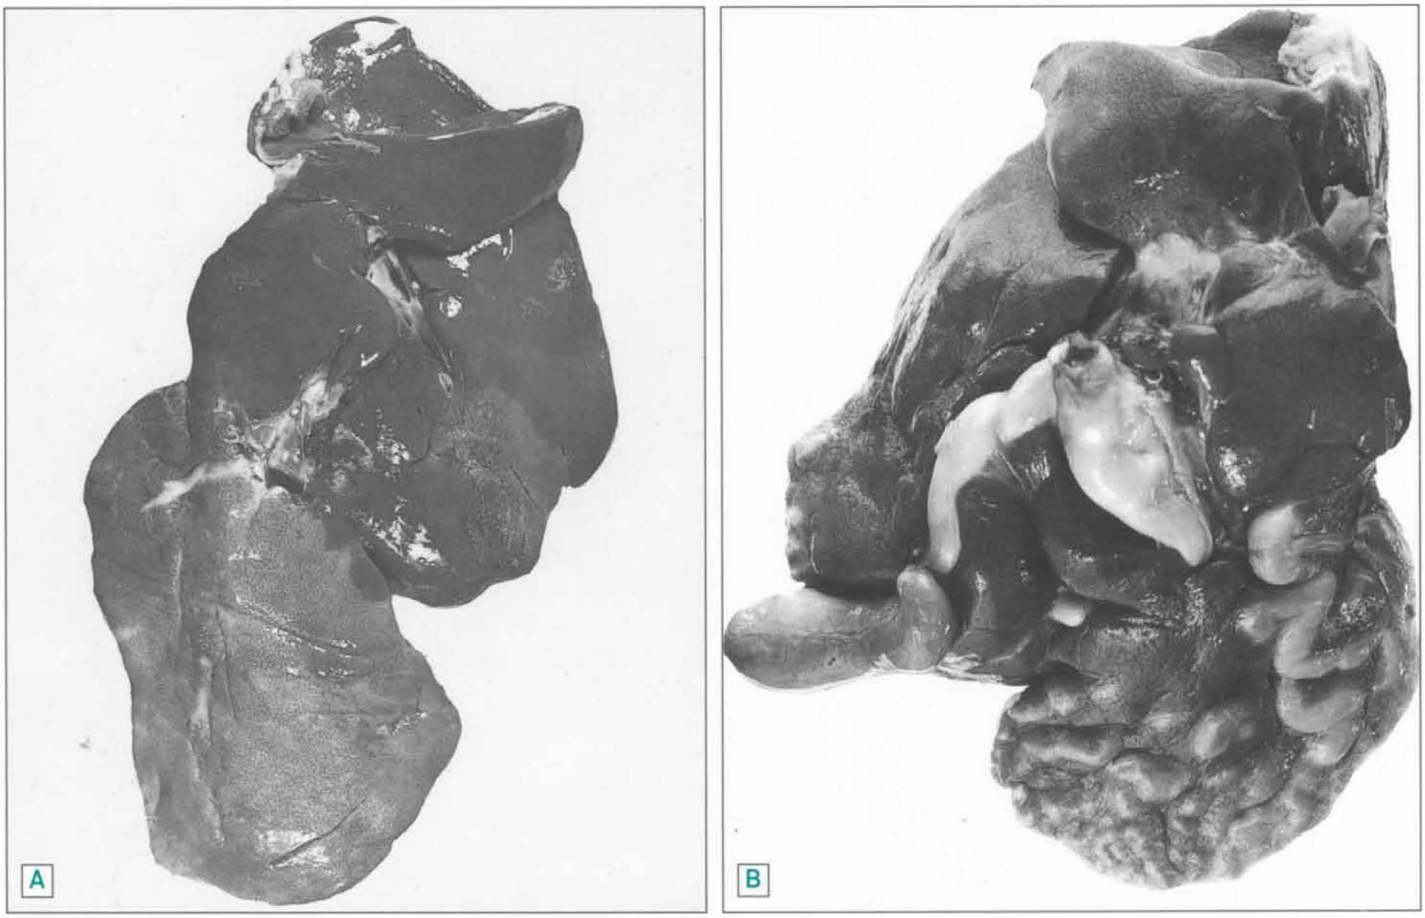

Figure 2.69 Fascioliasis in sheep. **A.** Subacute *Fasciola hepatica* infestation, causing early **cholangiohepatitis and cholestasis** in left lobe. **B.** Bile duct ectasia, atrophy of left lobe, hypertrophy of right lobe resulting from **chronic fascioliasis**.

more or less severe anemia, moderate anasarca, and cachexia. Jaundice is seldom seen.

Fasciola gigantica displaces *F. hepatica* as the common liver fluke in many parts of Africa and in nearby countries, southeast Asia, and the Hawaiian islands. It is two or three times as large as *F. hepatica*, but its life cycle and pathogenicity are comparable.

Fascioloides magna *is the large liver fluke of North America.* It is a parasite of ruminants and lives in the hepatic parenchyma, not in the bile ducts, although in tolerant hosts, Cervidae, the cysts in which it localizes communicate with the bile ducts to provide an exit for ova and excrement. The life cycle of this parasite generally parallels that of *Fasciola hepatica*. The young flukes are very destructive as they wander in the liver. In cattle, they wander briefly, producing large necrotic tunnels before becoming encysted. The cysts, enclosed by connective tissue, do not communicate with bile ducts but form permanent enclosures for the flukes, their excreta, and ova. *The cysts, which may be 2–5 cm in diameter, are remarkable for the large deposits of jet black, sooty iron-porphyrin pigment they contain* (Fig. 2.70), and except for the flukes and soft contents, they superficially resemble heavily pigmented melanotic tumors. Commonly, these flukes pass from the liver to the lungs of cattle, to produce lesions of similar character. In sheep, this parasite wanders continuously in the liver, producing black, tortuous tracts, which may be 2 cm in diameter, and extensive parenchymal destruction. Even a few flukes may kill a sheep.

The **dicrocoelid flukes** inhabit both biliary and pancreatic ducts. *Eurytrema pancreaticum* prefers the pancreas (and is described with that organ) but in heavy infestations can be found in the bile ducts. *Dicrocoelium* and *Platynosomum* prefer the bile ducts. These are small, narrow flukes 0.5–1.0 cm long and may easily be mistaken for small masses of inspissated bile pigment. They are not highly pathogenic, and even in heavy infestations there may be no signs of the toxemia observed in infestations by *F. hepatica*. These flukes may occur as mixed infestations.

Platynosomum fastosum is a parasite of cats in North America and the Amazonian regions of South America. The life cycle involves snails and lizards and presumably an arthropod. The infested livers are enlarged, friable, and may be bile-stained. There is catarrhal inflammation of biliary passages, but it is not severe, and the walls may not be much thickened. The ducts are dilated and easily visible. There are vague digestive disturbances, and heavy infestations may cause complete anorexia and death.

Dicrocoelium hospes is found in cattle in countries south of the Sahara. Little is known of it, but it is presumed to be comparable in all respects to the better-known *D. dendriticum* (the lancet fluke or small liver fluke), which is common in Europe and Asia and sparsely distributed in the Americas and North Africa. *Dicrocoelium* spp. are found in dry lowland or mountain pastures, whereas *Fasciola* spp. occur in wetter habitats, so the prevalence of *Dicrocoelium* is increasing

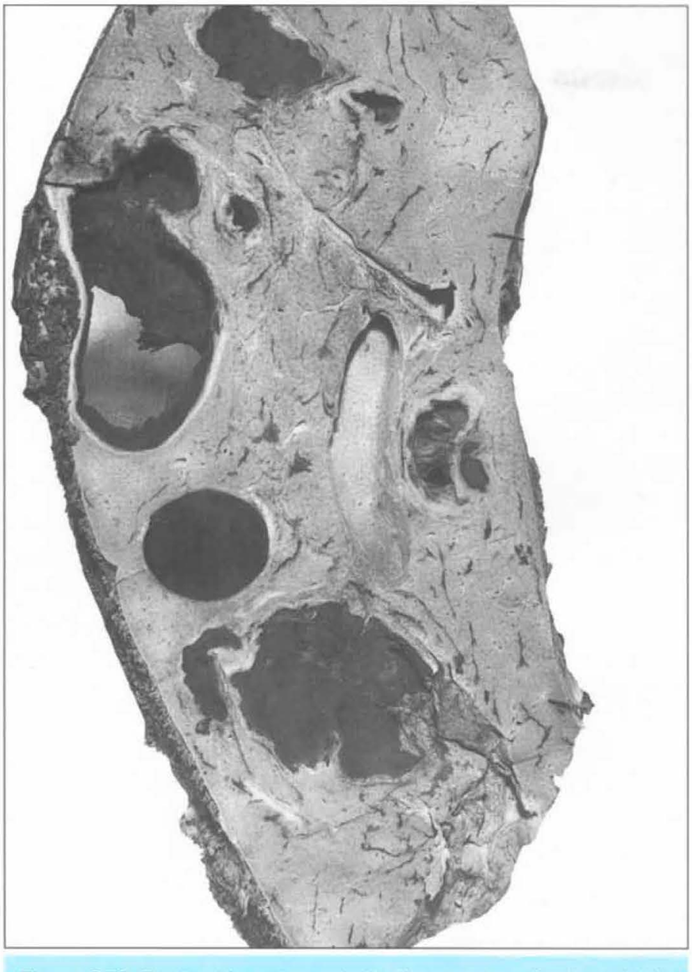

Figure 2.70 Destructive pigmented lesions produced by *Fascioloides magna* in an ox.

with desertification. This fluke is no more fastidious in its choice of final hosts than many other species of fluke, and, depending on opportunity, it can infest all domestic species, with the possible exception of cats. It is, however, of most importance as a parasite of sheep and cattle, in which it inhabits the bile ducts. Other domestic species and rodents are important as reservoirs.

The life cycle of ***Dicrocoelium dendriticum*** differs in some details from that of *F. hepatica*. The eggs are embryonated when laid and do not hatch until swallowed by one of the many genera of land snails that are the first intermediate hosts. In the snails, the mother sporocyst produces a second generation of daughter sporocysts, which in turn produce cercariae. The cercariae leave the snail in damp weather and are expelled from the snail's lung, clumped together in slime balls. The slime balls are not infective until the cercariae are swallowed by, and encyst in, the ant *Formica fusca*; other ants may be involved in different countries. The cycle is completed when the definitive hosts swallow the ants. The route of migration of the larvae from the gut to the liver is probably via the bile ducts from the duodenum.

The pathologic changes in the liver produced by *D. dendriticum* are those of cholangiohepatitis that is less severe than that produced by *Fasciola hepatica*. The severity and diffuseness of the hepatic lesion are determined by the number of lancet flukes present, and they may be in the thousands. The flukes and their eggs darken the dilated ducts. Even in early infestations, there may be some scarring of the organ at its periphery. In heavy infestations of long standing, there is extensive biliary fibrosis, producing an organ that is indurated, scarred, and lumpy and that at the margins may bear areas that are shrunken and completely sclerotic. The histologic changes are the same as those in fascioliasis, with perhaps more remarkable hyperplasia of the mucous glands of the large ducts.

The **opisthorchid flukes** are parasites in the bile ducts of carnivores. They may also occur in swine and humans, and one species, *Opisthorchis sinensis* (*Clonorchis sinensis*), is an important human parasite. There is some uncertainty regarding the proper classification of these flukes, and some of those given below may not be valid species. The life cycles, where known, include mollusks as the first intermediate hosts and freshwater fish as the second.

***Metorchis conjunctus** is the common liver fluke of cats and dogs in North America* and is important as a parasite of sled dogs in the Canadian Northwest Territories. The first intermediate host is the snail *Amnicola limosa porosa*, and the second is the common suckerfish *Catostomus commersonii*. The cercariae actively burrow into the musculature of the fish to encyst and become infective. The immature flukes crawl into the bile ducts from the duodenum and mature in ~28 days. Infestations may persist for more than 5 years. *Metorchis albidis* has been described in a dog from Alaska, *Parametorchis complexus* in cats in the USA, and *Amphimerus pseudofelineus* in cats and coyotes in the USA and Panama; the life cycles are not known but are presumed to include fish. *Metorchis bilis* has been reported in red foxes and occasionally in cats from Germany.

***Opisthorchis felineus** is the lanceolate fluke of the bile ducts of cats, dogs, and foxes in Europe and Russia.* It is particularly common in eastern Europe and Siberia and is more sparse in other areas. *Metorchis bilis* infects red foxes. *Opisthorchis sinensis* is well documented as the Oriental or Chinese liver fluke; it is endemic in Japan, Korea, southern China, and southeast Asia. There are additional species of *Opisthorchis* in humans and animals, but they are less well known than the species cited. The first intermediate hosts for the miracidia of *O. tenuicollis* and *O. sinensis* are snails of the genus *Bithynia*, and several genera of cyprinid fishes can act as second intermediate hosts.

Pseudamphistomum truncatum occurs in carnivores and humans sporadically in Europe and Asia. Its life cycle is as for *Opisthorchis*.

The opisthorchid flukes, so far as known, resemble *Dicrocoelium* in migrating up the bile ducts to their habitat. This may be the reason that they are more numerous in the left than in the right lobes of the liver. They can probably live in the liver for as long as the host lives. The pathologic effects are comparable to those of *D. dendriticum*. Light infestations may be asymptomatic, and heavy infestations may cause jaundice, chronic cholangiohepatitis, and severe biliary fibrosis. Both in humans and animals, adenomatous and carcinomatous changes of the biliary glands have occurred in association with these parasites; the association is probably more than coincidental.

Protozoal infections

Protozoal hepatitis is due mainly to infection with *Toxoplasma*, *Neospora*, and *Leishmania*, described elsewhere. Granulomatous hepatitis has been described in dogs associated with systemic infections by *Hepatozoon canis*.

Hepatic coccidiosis, expressed as acute cholangiohepatitis similar to that in mink and rabbits, has been observed in isolated cases in the goat, calf, and dog. These infections are usually considered aberrant, and often coincide with intestinal coccidiosis. Coccidial meronts and in some cases gamonts are present within the cytoplasm of biliary epithelium. The organisms are presently unclassified.

Fungal infections

Fungal infections of the forestomachs with hematogenous dissemination to the liver occur occasionally in cattle and sheep, usually as a complication of rumenitis. Lesions in the liver are typically hemorrhagic infarcts initially or granulomatous with chronicity, and are associated with infection by *Aspergillus fumigatus* and various members of the class Zygomycetes.

Granulomatous hepatitis associated with disseminated fungal or algal infections has also been reported in dogs. The species involved include *Histoplasma capsulatum*, *Cryptococcus neoformans*, *Coccidioides immitis*, *Sporothrix schenckii*, *Aspergillus* sp., and *Prototheca* sp.

TOXIC HEPATIC DISEASE

Role of hepatic biotransformation

An understanding of hepatic biotransformation is essential for an appreciation of the hepatotoxic potential of foreign compounds. Lipid-soluble compounds, including endogenous metabolites as well as nonpolar foreign compounds (known as **xenobiotics**, and *including plant or fungal-derived secondary metabolites consumed in food, environmental chemicals, and drugs*) must be converted to water-soluble products to permit elimination from the body in urine and bile. The enzymatic machinery responsible for this biotransformation is most active in the liver. The liver is strategically located to intercept ingested foreign compounds, and it is likely that *hepatic biotransformation enzymes* co-evolved in part to deal with naturally occurring toxic and lipid-soluble metabolites produced by plants that formed part of the diet. While these enzyme systems were formerly referred to as drug-metabolizing enzymes, or liver detoxification systems, recent research has underscored the importance of these systems in metabolism of endogenous compounds, including arachidonic acid, eicosanoids, cholesterol, biosynthesis of bile acids, and synthesis and metabolism of steroids and vitamin D.

Enzymatic biotransformation in the liver consists of two phases. *Phase I reactions* typically involve the addition of reactive polar groups through *oxidation* and, less frequently, reduction and hydrolysis reactions. In *phase II*, the metabolic product of phase I (or the original compound if it possesses a polar group that permits metabolism) undergoes *conjugation*, typically with water, glutathione, sulfate, glucuronate, or other groups. The conjugate is typically less toxic, and more water-soluble than the parent compound.

Phase I reactions are mainly performed by members of the *cytochrome P450 superfamily*, the so-called *mixed-function oxidase system*, which are integral parts of the smooth endoplasmic reticulum. The oxidative reactions of phase I are a double-edged sword, and while they are important in providing reactive sites for further conjugative detoxification reactions, in the process they can yield transient reactive intermediates, including epoxides and free radicals, which can potentially bind to and damage adjacent macromolecules, resulting in hepatotoxicity. *Toxic hepatic injury depends on the balance between production of reactive metabolites and their detoxification by conjugation and other protective reactions.* The cytochrome P450s can be found in all parts of the hepatic acinus, but the hepatocytes of zone 3 have a higher content than those of zone 1, which apparently accounts for the *zone 3 predominance of injury produced by compounds metabolized by this system*, including carbon tetrachloride and acetaminophen. In contrast, *hepatocytes in zone 1 are more susceptible to direct-acting toxicants such as metal salts*, due to their proximity to incoming portal and arterial vascular flow.

Phase II reactions are generally *detoxification reactions*, although there are exceptions. The enzymes of phase II are predominantly located in the cytosol, and include various transferases capable of conjugating molecules containing suitable polar groups with endogenous substances. One important conjugation pathway is with reduced glutathione, mediated by the glutathione *S*-transferases. Active metabolites of acetaminophen and various other agents are detoxified by conjugation with glutathione, and depletion of glutathione reserves plays a critical role in the development of toxicity. Hepatic glutathione is also important in the removal of free radicals and reactive oxygen species through the action of glutathione peroxidase.

Efforts to elucidate mechanisms for hepatic injury are complicated by the presence of multiple alternative pathways for metabolism of compounds, the presence of many different isoforms of various enzyme families, particularly the cytochromes P450, and the increasing numbers of genetic polymorphisms identified within individual alleles coding for these isoforms. Many genes for cytochromes P450 and various phase II conjugation enzymes have regulatory sequences that include various transcriptional response elements that respond to nuclear receptors. These receptors resemble steroid receptors and include the arylhydrocarbon hydroxylase receptor, peroxisome proliferator-activated receptors, the constitutive androstane receptor, and the pregnane X receptor. These receptors are activated by various xenobiotics and endogenous ligands so the overall biotransformation phenotype depends on both genetic background, and the environmental, dietary, and medical experiences that can influence expression of these genes. The nuclear receptor genes themselves also vary among species, and there are species differences and gene polymorphisms that affect the receptors or the expressed genes. Many factors can therefore modify metabolism, including sex, age, diet, previous or concurrent exposure to environmental compounds, or the effects of intercurrent disease, particularly those that alter hepatic functional mass. These complexities explain some of the differential susceptibility among species and individuals to drug-induced and other toxic hepatic injury.

Classification of hepatotoxins and mechanisms of toxicity

Hepatotoxic agents have typically been classified according to their mechanism of injury, and by the morphologic type of injury they cause. Hepatotoxins have either *intrinsic toxicity*, or they may injure only particularly susceptible hosts as an *idiosyncratic reaction* (discussed further in the section on Adverse drug reactions, below). Intrinsic toxins may be *direct-acting*, or *indirect-acting*, if they are metabolized to reactive metabolites.

Acute hepatotoxic injury may be **cytotoxic**, resulting from damage to the structural or functional components of hepatocytes that maintain cellular integrity, or **cholestatic**, resulting from interference with the various components essential for bile flow. *Acute cytotoxic injury is often manifest as steatosis (lipidosis)*, a result of impairment of movement of triglycerides through the liver, interference with VLDL synthesis or transport, or impaired hepatic consumption of fatty acids by mitochondrial oxidation. *It may also be manifest as necrosis or apoptosis.* Acute hepatic injury can injure elements of the structure or function of the biliary tree, resulting in defects in bile transport.

The histologic changes in acute toxic hepatic injury are rather stereotyped. They range from apoptosis, through confluent coagulative and zonal necrosis, to massive hemorrhagic destruction that includes sinusoidal lining cells. The histology of these acute intoxications is usually characterized by *severe periacinar necrosis*. Rarely, the pattern of necrosis may be periportal or midzonal (the characteristics of these injuries are described above in the section on Patterns of cell death in the liver). Depending on the nutritional status of the animal, there may be variably severe fatty or hydropic change in hepatocytes adjacent to the necrotic zones. The necrotic cells may accumulate calcium. Variations on the general process of hepatocellular necrosis have little diagnostic or pathogenetic specificity. In sublethally injured cells there may be spectacular but nonspecific clumping of smooth endoplasmic reticulum, particularly in the periacinar zones.

The *clinical and gross characteristics of fatal acute intoxications* that destroy liver parenchyma are rather consistent, regardless of the origin of the toxin. The animal dies after a brief period of dullness, anorexia, colic, and various neurologic disturbances, including convulsions; these are attributed to hepatic encephalopathy. Postmortem examination reveals a slight excess of clear, yellow abdominal fluid, which contains sufficient fibrinogen to form a loose, nonadherent clot. The appearance of the liver depends on the severity and stage of the injury. Severe acute toxicity that destroys endothelium typically results in a hemorrhagic zonal pattern, in which case the liver may be deep red-purple and obviously swollen and turgid. In less severe injury without hemorrhage, the liver tends to be lighter brown due to a combination of edema (exclusion of sinusoidal blood), destruction of cytochrome pigments, and accumulation of bile pigments and/or fat. If the animal survives for several days, the liver develops a typical zonal yellow fatty change as triglyceride accumulates in sublethally injured hepatocytes.

In acute fatal hepatotoxicities there is almost always widespread hemorrhage resulting from lack of coagulation factors. Petechiae and ecchymoses are seen most consistently on serous membranes, especially on the epi- and endocardium and abdominal viscera. Diffuse hemorrhage into the gut, particularly the duodenum in ruminants, is also common, as are hemorrhages into the wall of the gallbladder. Hemorrhages are largely due to excessive consumption of clotting factors and platelets within the areas of necrosis in the liver, although the concurrent failure of the damaged liver to replace those coagulation factors undoubtedly becomes important when these factors are consumed. Gross lesions such as icterus and photosensitization that reflect failure of biotransformation or excretion of endogenous materials develop too slowly to be a feature of acutely fatal hepatotoxicities. However, the rate of accumulation of bilirubin increases when hemorrhage occurs in the necrotic liver or as a consequence of coagulopathy.

Chronic hepatotoxic injury *may manifest in many patterns*, as previously described. These include chronic necroinflammatory hepatitis, steatosis, cirrhosis, atrophy with nodules, hepatic vein thrombosis, veno-occlusive disease, peliosis hepatis, cholangitis, cholangiofibrosis, and carcinogenesis. In contrast to the acute intoxications, chronic hepatotoxicities are more likely to present a mix of these responses and this can provide more diagnostic specificity. For example, agents that impair hepatocellular regeneration might not be potent necrogens but tend to produce hepatic apoptosis and atrophy, fibrosis of various patterns, compensatory bile duct hyperplasia, nodular regeneration, some degree of cholestasis, and frequently megalocytosis (polyploidy). Such hepatotoxins are potential carcinogens because they favor the selective growth of hepatocellular nodules that are resistant to mitoinhibitory effects.

Clinical signs of chronic hepatotoxicity are usually problems resulting from inadequate detoxification and excretion; these include jaundice, photosensitization, and hepatic encephalopathy. Most of the toxins responsible for chronic hepatotoxicity may produce acute nonspecific zonal or massive necrosis if experimentally administered at dose rates higher than those to which animals are likely to be exposed in the field, although such acute toxicity is occasionally observed in field cases of the diseases.

The range of substances that can cause hepatotoxicity is so broad that it encompasses virtually all categories of natural and synthetic chemicals. These include metals (iron, copper), drugs (e.g., acetaminophen), plant components (phytotoxins), fungal metabolites (mycotoxins), bacterial products (e.g., cyanobacterial microcystin-LR) and various industrial products (especially aromatic solvents). Many drugs are also hepatotoxic in idiosyncratically sensitive, overdosed, or accidentally poisoned animals, as in humans. Differences in individual susceptibility to hepatotoxic responses likely occur for all classes of chemicals that are metabolized in the liver.

Hepatotoxic plants occur in botanical families as diverse as the relatively primitive Cycadaceae through the Compositae and Solanaceae. The evolutionary relationships between herbivores and toxic plants are complex; in some situations, consumption of plants by herbivores has competitive or neutral advantage for the plant, especially those that are lush and prolific, so toxicity is counterproductive or unnecessary. However, in arid or semiarid habitats, plants must put up more resistance to herbivores that could obliterate them. Indigenous herbivores are typically reluctant to do this, and are either resistant or reluctant to graze some plants. Plants sometimes protect critical parts at particular stages of growth. For example, *Xanthium pungens* (Noogoora burr) concentrates its toxin in the cotyledons. The seeds are rarely eaten, even by cattle, but intoxications can occur when this plant is eaten shortly after germination. Phytotoxic liver disease is therefore more frequently encountered in animals grazing pastures at particular times of the year, with limited choice or supply, or when hungry animals are introduced to plants for which their natural or induced resistance is low. The patterns of liver disease resulting from consumption of toxic plants is for the most part regular in comparison with what is seen with exposure to other classes of hepatotoxins. An exhaustive review of the toxicity of all such plants would be repetitive. However, some plants that do produce more distinctive patterns of liver lesions will be discussed in more detail.

In the following sections, toxic hepatic disease will be separated into drug- or pharmaceutical-induced hepatotoxicity (so-called adverse drug reactions), and hepatotoxicity associated with exposure to plant or environmental toxins, including metals. The latter have been somewhat arbitrarily divided into acute and chronic, and while it is recognized that the difference between acute and chronic hepatotoxicity is often simply a matter of dose rate, it is convenient to categorize the sources according to the syndrome of liver damage which they most commonly produce. Various plants and moldy feeds are hepatotoxic and some phytotoxins (e.g., pyrrolizidine alkaloids) and mycotoxins (e.g., aflatoxins) are notorious hepatotoxins and hepatocarcinogens. Many phytotoxins and mycotoxins target other organ systems or have physiological rather than pathological effects. Some of those that cause diagnostic lesions are discussed under the respective target tissues elsewhere. Generally, these areas of toxicology are better accessed in comprehensive references on phytotoxins or mycotoxins.

Adverse drug reactions: drug-induced hepatic disease

Hepatotoxicity is an important adverse drug reaction in humans, and while hepatotoxic drug reactions have been recognized in dogs and cats, the true prevalence of adverse hepatic drug reactions in domestic animals is unknown. The vulnerability of the liver to drug-induced injury relates to several factors. The liver is exposed to high concentrations of orally administered drugs due to its location as the recipient of portal venous blood flow. The uptake of exogenous and endogenous compounds from the portal circulation is facilitated by a number of basolaterally located, sodium-independent solute transporters known as *organic anion transporting polypeptides*. Foreign compounds may be concentrated in the liver to various degrees by mechanisms that remain obscure, but which are related to special binding proteins of hepatocytes, and attachment to enzymatic sites where metabolic conversions occur. The most important factor, however, is the liver's role as the primary site of biotransformation for many therapeutic agents, resulting in exposure to high concentrations of metabolites. These water-soluble metabolites are excreted in the bile via members of the ATP-binding cassette superfamily of transport proteins located on the apical canalicular membrane; some may be reabsorbed in the enterohepatic circulation. In addition, many drug administration regimens may achieve relatively high millimolar concentrations, resulting in depletion of conjugating cofactors such as glutathione, which can reach the lower limits required for other cytoprotective roles.

Adverse drug reactions in general can be classified as intrinsic or idiosyncratic, and these categories apply well to the types of drug-induced hepatotoxicity that are observed in humans and animals. **Intrinsic adverse drug reactions** *are considered to be dose-related, predictable, reproducible in experimental animals, and the underlying mechanisms are typically known*. Intrinsic hepatotoxic drugs can cause liver injury in overdose situations in most normal recipients but are also capable of inducing similar liver damage at lower doses in individuals with genetic or acquired abnormalities in drug metabolism. The majority of intrinsic hepatotoxicants are converted to *reactive metabolites*, or co-generate lipoperoxidative free radicals. By comparison, **idiosyncratic adverse drug reactions** *are typically less dose-related and more unpredictable and occur in only a small proportion of exposed individuals.* The mechanism of idiosyncratic hepatotoxicity is often not known, but it reflects an unusual susceptibility of individual recipients to effects that are unrelated to the drug's therapeutic action or overdose toxicity. The basis for the idiosyncracy may be acquired, for example, a result of previous or concurrent exposure to other agents that induce drug-metabolizing pathways, or genetic, a result of enzyme polymorphisms. There is accumulating evidence of considerable genetic diversity (polymorphisms) in hepatic drug metabolism and immune responsiveness among individual humans and domestic animals, and these may explain many unusual responses to drugs. *Idiosyncratic adverse drug reactions can be further classified as metabolic or immunologic.* **Metabolic idiosyncracies** involve excessive generation of a regular toxic metabolite, or altered metabolism to unusual hepatotoxic metabolites. This variation could be qualitative, with the production of a toxic metabolite not normally produced, or quantitative, with overproduction of a normally minor hepatotoxic metabolite. **Immunologic idiosyncracies** involve immune-mediated hypersensitivity responses to the drug metabolites that covalently bind to liver proteins and initiate a hapten allergy, with further liver injury resulting from the ensuing specific immune response or upregulation of components of the innate immune system.

The morphological forms of hepatic injury produced by chemical agents are varied. Acute toxic injury to the liver can be cytotoxic (hepatocellular), cholestatic, or mixed. *Cytotoxic hepatocellular injury* results in hepatic degeneration, zonal necrosis, focal and nonzonal necrosis (apoptosis), or lipidosis, accompanied by the clinicopathological features of acute hepatic injury. In general, necrosis produced by intrinsic hepatotoxins is zonal, whereas that produced as an idiosyncratic reaction to a drug is usually nonzonal, and can be diffuse, focal, or massive. *Cholestatic injury* is a reflection of failure of bile excretion associated with canalicular injury or other alteration of bile secretion, and presents with the features of obstructive jaundice. The histologic manifestation consists of bile casts in canalicular spaces, with variable parenchymal injury. *Mixed toxic insults* display the features of both hepatocellular and obstructive injury. Chronic toxic injury to the liver may be manifest as chronic hepatitis, with fibrosis progressing to cirrhosis, vascular injury such as veno-occlusive disease, and neoplasia.

The analgesic **acetaminophen** represents a well-characterized example of an intrinsic hepatotoxin with species differences in metabolism and associated susceptibility to oxidative and hepatic injury. Dogs and cats can tolerate doses within therapeutic levels; however, higher doses may saturate the glucuronidation and sulfation detoxification pathways, resulting in increased formation of the reactive benzoquinone-imine metabolites via a third cytochrome P450-mediated pathway. These can be scavenged by glutathione conjugation; however, massive doses can cause lethal acute hepatic failure, associated with overproduction of reactive metabolites, and depletion of hepatic and erythrocyte glutathione. Clinical toxicity occurs at lower doses and is more severe in cats because they express fewer hepatic isoforms of glucuronyltransferase and are unable to accelerate excretion of excess metabolites through glucuronide conjugation. This is compounded by a propensity to hemoglobin oxidation, resulting in methemoglobinemia. Toxicity results when reduced glutathione levels drop below a threshold level, resulting in marked oxidative stress, and allowing reactive metabolites to bind covalently to cellular macromolecules.

Acute hepatic disease has been attributable to adverse reactions to administration of a wide variety of therapeutic drugs, particularly in companion animals. Submassive to massive hepatic necrosis and cholestatic hepatitis have been reported in dogs as an idiosyncratic reaction to **trimethoprim-sulfonamide** combination therapy. Severe lobular to massive hepatic necrosis may occur in cats associated with repeated oral administration of **diazepam** at recommended doses. Severe periacinar hepatic necrosis has been associated with use of the anthelmintic **mebendazole** in dogs. Hepatotoxicity has been reported in 4 dogs treated with **amiodarone**, a class III antiarrhythmic agent. This is one of the more commonly reported adverse effects of amiodarone in humans, related to the drug's effect on lipid metabolism. Diffuse and massive hepatocellular injury characterized by hepatocellular vacuolar change, lytic necrosis, apoptosis and bridging necrosis, with mild secondary inflammation and cholestasis, has been reported in dogs administered therapeutic dosages of **carprofen**, a nonsteroidal anti-inflammatory drug used in the treatment of degenerative joint disease and management of acute pain. Administration of the anabolic steroid, **stanozolol**, has also been associated with elevated alanine aminotransferase, coagulopathy, and development of hepatic lipidosis with cholestasis in cats. Interestingly, adult beef cattle testing positive for stanozolol in urine also had hepatic changes, including cholestasis, periportal fibrosis and inflammation, and focal necrosis, although the changes could not conclusively be attributed to anabolic steroid administration.

Other pharmacologic agents associated with acute hepatic injury include **thiacetarsemide**, **methoxyflurane**, **halothane**, **oil of pennyroyal**, and inadvertent subcutaneous injection of intranasal *Bordetella bronchiseptica* – canine parainfluenza vaccine in dogs, **methimazole**, **glipizide**, and the photodynamic therapy agent **aluminum phthalocyanine tetrasulphonate** in cats.

The anticonvulsant drugs **primidone**, **phenytoin**, and **phenobarbital** have been associated with the development of *chronic hepatic disease and cirrhosis in dogs*. These drugs, used either alone or in combination, can cause biochemical and clinical signs of hepatic dysfunction in up to 14% of dogs treated for more than 6 months, but only a small percentage of cases progress to cirrhosis and hepatic failure. The most consistent histologic finding in the majority of dogs treated with phenobarbital is *proliferation of the hepatocellular smooth endoplasmic reticulum due to induction of microsomal enzymes*, including various subfamilies of cytochrome P450. This results in hepatocellular swelling with fine diffuse granularity, a so-called "ground-glass" appearance to hepatocyte cytoplasm. This histologic change is an adaptive response, reflected clinically by increases in serum concentrations of alkaline phosphatase, alanine aminotransferase, and γ-glutamyltranspeptidase, but is not indicative of hepatocellular injury. Actual hepatotoxicity may represent an idiosyncratic reaction in a small percentage of treated dogs, although the possibility of dose-dependent intrinsic hepatotoxicity with long-term treatment has not been ruled out. It is also possible that the enzyme induction associated with anticonvulsant therapy may alter the ability of the liver to detoxify other nonspecified compounds that could be the effectors of liver damage. Certainly, enzyme induction may alter the pharmacokinetics of other co-administered drugs. *Chronic hepatitis associated with anticonvulsant therapy is characterized by bridging portal fibrosis, biliary hyperplasia, nodular regeneration, and mild inflammatory cell infiltrates.* A separate syndrome of *cholestatic hepatotoxic injury with jaundice* has also been described in dogs receiving high doses of phenytoin in combination with primidone or phenobarbital. This is characterized by intrahepatic cholestasis, with hepatocellular swelling, vacuolation, and small multifocal areas of hepatocellular necrosis, and has been suggested to represent a metabolic disturbance rather than direct cytotoxic hepatocellular injury. *Superficial necrolytic dermatitis* associated with typical hepatic pathology of parenchymal collapse, vacuolation, and nodular regeneration has also been reported as a separate syndrome in dogs with a history of chronic phenobarbital therapy.

Acute and chronic hepatic disease, characterized by periportal hepatitis, periportal fibrosis, and biliary hyperplasia have been reported in dogs treated with **oxibendazole-diethylcarbamazine** combination therapy for prevention of hookworm and heartworm. Chronic hepatic disease has also been reported following administration of **mibolerone**, **methotrexate** and **CCNU** (1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea) in dogs, **ketaconazole** in dogs and cats, and **megestrol acetate** and **griseofulvin** in cats.

Acute hepatotoxicity: plant-derived and environmental toxins

Cyanobacteria (blue-green algae)

These primitive highly toxic microorganisms can flourish as a seasonal bloom on lakes and ponds that have accumulated phosphates and nitrates as runoff from fertilized soils. Outbreaks of poisoning are not common, but they occur in many countries and may be responsible for heavy mortality among mammals or birds that drink from affected bodies of water. Most well-documented cases have involved ***Microcystis aeruginosa***, which may poison stock after the bloom has been piled by wind against the shores of expanses of water. Other toxic species are included in the genera *Anabaena* and *Aphanizomenon*. Some deaths are too sudden to be due to liver damage and are probably the result of the "*fast-death factor*" that has been found in some blooms. The syndrome is one of collapse and prostration, with hyperesthesia that may be manifest as convulsions and death within a few minutes; there are no specific lesions in this form of the toxicosis.

The most well-understood cyanobacterial hepatotoxin is *microcystin-LR, a highly potent cyclic heptapeptide protein phosphatase inhibitor*. Ruminants are most commonly poisoned but poisoning has been reported in horses, sheep, dogs, and domestic poultry. The toxin is released when the microorganisms disintegrate, which may occur spontaneously in bodies of water or after the application of copper sulfate for algae control, or in the rumen or stomach after ingestion. The toxin is taken into hepatocytes by membrane carriers and causes cell damage by inhibiting cytoplasmic protein phosphatase 1 and 2A. This leads to disorganization of hepatocyte and endothelial cytoskeletal actin filaments, and disruption of their shape and integrity, leading to necrosis, apoptosis, and perisinusoidal hemorrhage. The distribution of the necrosis is usually periacinar to massive (see Fig. 2.33). The pattern may vary within the individual liver and from case to case. In subacute intoxications, the liver is severely fatty and necrosis is limited to individual hepatocytes or small groups, rather than being zonal. Phagolysosomes and bile pigments accumulate in the cytoplasm and there is slight biliary proliferation and fibrosis.

Amatoxins

Amatoxins are potent hepatotoxins found in several mushroom genera, including *Amanita, Galerina*, and *Lepiota*. The genus ***Amanita*** contains several species, including *A. phalloides, A. verna, A. virosa*, and *A. ocreata*, which are considered extremely toxic. These mushrooms are mycorrhizal with various species of deciduous and coniferous trees, and may be found in urban, suburban, and rural areas. The amatoxins are *bicyclic octapeptides*, ingestion of which is responsible for gastroenteritis, hypoglycemia, and fulminant liver failure in humans, dogs, and other animals. Amatoxins inhibit nuclear RNA polymerase II, thus interfering with transcription and inhibiting protein synthesis, resulting in cell death. Dogs dying after ingestion of *Amanita* spp. have massive hepatocellular necrosis with focal areas of hemorrhage. Surviving periportal hepatocytes had vesicular nuclei with loss or fragmentation of nucleoli, consistent with ultrastructural reports of chromatin condensation, dissolution of the nucleolus, and decline in nucleolar RNA content.

Cycadales

Members of this order have been responsible for chronic hepatotoxicity and neurotoxicity in cattle, but acute hepatotoxicity has been reported in sheep that have eaten the seeds or young leaves of species of Zamiaceae. The toxin responsible is *methylazoxymethanol, which is the aglycone of various nontoxic glycosides, including cycasin and macrozamin*, in these plants. The toxin is split from the glycoside in the gut, and its hepatotoxicity is the result of further metabolism in hepatic microsomes; the pattern of necrosis is thus periacinar. The metabolites of the aglycone are apparently *potent alkylating agents*, and the chronic liver lesions reflect this; there is megalocytosis (which is not as persistent as that of pyrrolizidine alkaloid poisoning), nuclear hyperchromasia, cholestasis, fatty change, and various degrees of diffuse fibrosis. Cytosegresome formation and cytoplasmic invaginations into nuclei are apparently not a prominent feature. There is fairly consistent nephrosis.

Cycads also produce a *neurotoxic amino acid, beta-N-methylamino-L-alanine* (BMAA), reportedly of cyanobacterial origin. BMAA is excitotoxic, activating neurotransmission mediated by glutamate receptors, which in excess can lead to cytotoxic influx of calcium ions. Chronic cycad poisoning of cattle causes a chronic nervous disorder characterized by a progressive proprioceptive deficit. This is due to axonopathy in upper spinocerebellar and lower corticospinal tracts. The axonopathy, morphologically subtle at first, may eventually progress to frank Wallerian degeneration.

Solanaceae

Toxic species of the genus ***Cestrum*** (jessamine) include *Cestrum diurnum*, a cause of enzootic calcinosis in cattle attributed to active vitamin D analogs; the other known toxic species all produce similar hepatic disease. Speciation within the genus is uncertain, partly due to hybridization; however, the species named as hepatotoxic are *C. parqui, C. laevigatum*, and *C. aurantiacum*.

Cestrum spp. cause acute hepatotoxicity in the field in South America, southern and central Africa, and Australia. Cattle are more frequently poisoned than other species, but sheep and goats are susceptible, and fowl may be if they eat the fruit. The young leaves and unripened berries are the most toxic parts of the plant. In acute hepatotoxicity, there is marked periacinar and midzonal coagulative necrosis and hemorrhage (see Figs 2.29 and 2.30). There are no records of chronic liver disease caused by this plant, and photosensitization is rarely seen. The toxin is water-soluble and has been identified as an *atractyloside* (see below).

Compositae/Asteraceae

Xanthium pungens (Noogoora burr) in Australia *and X. cavanillesii*, (the cocklebur) in Brazil, the USA, and South Africa, have been reported to be hepatotoxic while in the seedling stage because the toxins are concentrated in the cotyledons. The burrs are also toxic, and although usually too coarse to be grazed, they can be consumed if ground into feeds. Cattle, swine, and sheep are susceptible, and toxicosis typically occurs following a period of feed scarcity, after flooding or rain has allowed germination. The clinical signs and lesions are not specific, being those described for acute hepatotoxins in general. The toxic principle is a *diterpenoid glycoside, carboxyatractyloside. Wedelia glauca* also contains atractyloside and causes acute hepatotoxicity in cattle and sheep in Uruguay and Argentina. The condition has been reproduced experimentally in sheep and cattle and rats.

Atractyloside was first identified as the hepatotoxic principle in the Mediterranean thistle, *Atractylis gummifera*, a woody plant that grows in southern Europe and North Africa. These toxins inhibit exchange of ATP from the mitochondria with adenosine diphosphate (ADP) in the cytosol, a process essential for oxidative phosphorylation. Atractylosides inhibit the ADP/ATP carriers (AACs), including the form expressed in the liver. Carboxyatractyloside blocks exchange by binding to a cationic functional domain of bovine AAC1. Lack of ATP and mitochondrial pore leakage lead to apoptosis and necrosis, with ion pump failure, lipid peroxidation, and glutathione depletion. The extent of necrosis depends on dosage, but in lethal poisoning with hepatic failure there is typically midzonal vacuolation and periacinar necrosis, but it can be panlobular.

Other plants produce similar lesions but the toxins have not been identified. *Helichrysum blandowskianum* is hepatotoxic to cattle and sheep and has caused sudden deaths with periacinar necrosis in southern Australia. The condition has been reproduced experimentally. High mortality with acute periacinar liver necrosis has been reported in cattle grazing sprouting plants of *Vernonia rubricaulis* in Brazil. Similar lesions were reproduced with 3 g/kg of sprouting plants. Various species of Asteraceae in South Africa, including *Asaemia axillaris, Athanasia trifurcata, Lasiospermum bipinnatum, Hertia pallens*, and *Pteronia pallens*, have been associated with field outbreaks of acute hepatotoxicity in grazing sheep or cattle. Similar liver lesions have been reproduced experimentally. Experimental intoxications by all of these species have in some animals produced midzonal as well as periacinar necrosis. *Asaemia axillaris, Athanasia trifurcata*, and *Lasiospermum bipinnatum* are also associated with more chronic liver toxicity with photosensitivity.

Ulmaceae

Trema tomentosa (*T. aspera*), the poison peach, has caused severe losses in cattle in Australia. Similar disease has been reported in goats ingesting *Trema micrantha* in Brazil, and hepatotoxicity has been reproduced in rabbits. The syndrome is acute, there is no photosensitization, and mildly intoxicated animals may recover completely. The toxic principle is a glycoside, designated *trematoxin*. The pattern of necrosis is consistently periacinar and is identical in appearance to that of *Cestrum* and *Xanthium* poisoning.

The gross and microscopic pathology of experimental poisoning by *Trema, Xanthium pungens*, and *Cestrum parqui* has been shown to be identical in all morphologic respects in the same group of sheep.

Myoporaceae

Hepatotoxic species so far incriminated are *Myoporum deserti, M. acuminatum, M. insulare*, and *M. tetrandum* of Australia, and *M. laetum* in New Zealand, southern Brazil, and Uruguay. The toxic oils are contained in the leaves and branchlets, but within the species there is variation in the chemical characters and toxicity of the oils; not all strains of toxic species are toxic. There is some delay between ingestion and absorption of the *furanosesquiterpenoid oils*, the best known of which is *ngaione*, which are responsible for intoxication, so 24–48 hours may elapse before signs of toxicity appear. Some animals live long enough to become photosensitized; others may die much more rapidly, with pulmonary edema. The edema appears to be a direct effect of the toxin after metabolism by alveolar lining cells.

Livers from intoxicated sheep may show a striking, broad pattern of variable congestion and even infarction, which is superimposed on the more regular acinar pattern of periportal necrosis. Sections of these livers reveal acute fibrinoid necrosis of portal vessels, which suggests that the coarser lesions may have a vascular basis.

Halogenated hydrocarbons

Various halogenated hydrocarbons, such as *carbon tetrachloride* (used for many years as a fasciolicide), *bromobenzene, hexachloroethane, tetrachloroethylene*, and *chloroform*, are activated by cytochromes P450 to hepatotoxic or nephrotoxic metabolites. They have similar hepatotoxic properties but these agents are little used now, so few animals encounter them in toxic doses. However, some of these chemicals have been used experimentally to investigate the mechanisms of hepatotoxicity so they warrant some consideration here. Carbon tetrachloride is metabolized to trihalomethane, a necrogenic free radical metabolite, and reactive oxygen radicals are concurrently generated. Periacinar hepatic necrosis with midzonal hydropic change due to membrane peroxidation occurs within 30 hours of experimental exposures but lethal toxicity occurs later, when steatosis and the early stages of tissue repair responses are manifest.

Phosphorus

White phosphorus has historically been used for vermin control, and may be present in some incendiary devices such as fireworks. As a rodenticide, it is mixed with fat in order to promote absorption, and much of the dose is transported to the liver shortly after ingestion. A small amount may be lost by vomition, for elemental phosphorus is directly irritant to the gastrointestinal tract. The mechanism of phosphorus hepatotoxicity is uncertain; it is apparent that metabolism to a toxic intermediate is not necessary, but there is some dispute on the involvement of lipoperoxidation in the hepatocellular injury. There is evidence that protein synthesis is impaired early and that this is responsible for the lipid accumulation that is so prominent a feature. A few hours after ingestion of phosphorus there is severe colic and vomition. If the animal survives this acute phase there may be apparent recovery for a few days, followed by jaundice and other signs of liver failure, and death by about the fifth day. At necropsy there is severe icterus and fatty liver, the latter sometimes being predominantly periportal in distribution. Hepatocellular necrosis is not often a prominent feature histologically, notwithstanding the evidence of liver failure. Fatty change is also seen in the myocardium and distal nephrons.

Iron

Iron–dextran complexes have been widely used in the prevention and treatment of anemia in suckling swine. Very occasionally, *severe losses may occur in animals with marginal vitamin E-selenium deficiency*; in these cases there is, apparently, iron-catalyzed lipoperoxidation in hepatocytes and muscle. The result of this is sudden massive hepatic necrosis similar in many respects to that of hepatosis dietetica. Large amounts of potassium escape into the circulation from the liver and muscle, and sudden death may result from the cardiotoxicity of this ion. At necropsy, there is staining of subcutaneous tissues and lymph nodes near the site of injection, and there are lesions in the liver or skeletal muscles. The liver is of normal size and of normal color or pale, depending on whether or not the animal is anemic. The presence of underlying necrosis may be indicated only by the numerous small or large hemorrhages present on the capsular and cut surface (Fig. 2.71). Insoluble iron compounds with the staining reactions of hemosiderin are found in mesenchymal cells in many tissues, the largest amounts being in macrophages of the local lymph nodes and in Kupffer cells.

Death in piglets from hepatic necrosis occurs about 10 hours after administration but saccharated iron may, in the same circumstances as above, produce acute widespread muscle necrosis at about 24 hours rather than hepatic necrosis. The myocardium is not affected.

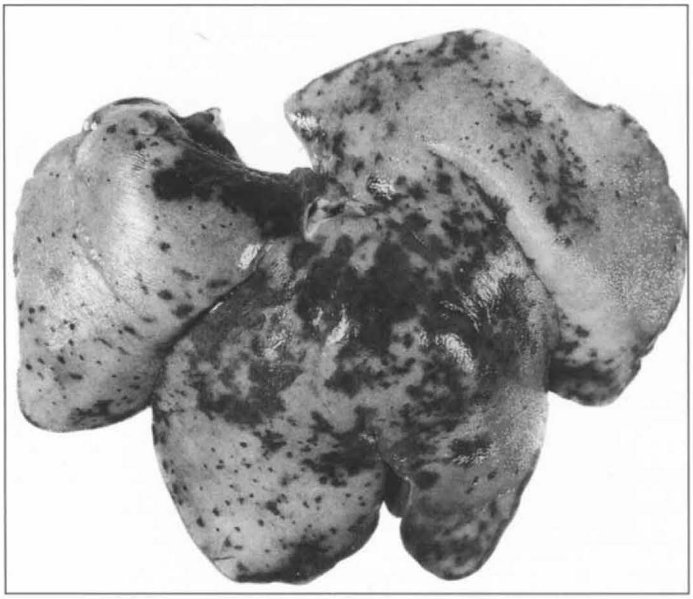

Figure 2.71 Early massive necrosis with random hemorrhage and pallor due to **iron dextran poisoning** in a pig.

Acute hepatotoxicity is reported in young *foals* due to administration of a proprietary paste of iron and yeast products, given as a dietary supplement within a few hours of birth. Not all foals so treated became sick, but those that were developed severe acute periacinar hepatocellular necrosis, resembling the disease in piglets.

Acute iron intoxication has also been reported in young *cattle* administered injectable hematinics containing elemental iron, and rarely in adult *horses* administered oral vitamin supplements containing ferrous fumarate or ferrous sulfate. Oversupplementation, low vitamin E or selenium concentrations, or concurrent disease may have contributed to these cases. Consumption of *elemental iron* produces a periportal or panlobular pattern of necrosis.

Sawfly larvae

This acute hepatotoxicity of cattle and, to a lesser extent, sheep, is of particular interest in that the toxin is present in an insect, the larva of the sawfly *Lophyrotoma interruptus* or *L. zonalis* (Pergidae). This larva is parasitic on the leaves of the tree *Eucalyptus melanophloia*, and heavy infestations may occur in parts of northeastern Australia. *L. zonalis* has been introduced to Florida to control the spread of *Melaleuca quinquenervi*. A similar intoxication by the blue-black birch sawfly, *Arge pullata*, from birch trees has been recognized in sheep and goats in Denmark. In Uruguay, a similar problem has been reported in cattle and sheep that consume the South American sawfly *Perreyia flavipes*. The production of such similar intoxications from unrelated substrates suggests that this class of insect manufactures the hepatotoxin de novo. On completion of feeding, masses of larvae sometimes accumulate at the base of the tree where they may die and decompose. Cattle in particular find these masses attractive, perhaps as a result of nutritional stress. The hepatotoxins produced by *Lophyrotoma* include *lophyrotomin*, a free acid form that causes periportal hemorrhagic necrosis, and *pergidin*, which causes periacinar coagulative necrosis. Pergidin, the major toxic constituent of the South American sawfly, is a heptapeptide containing several D amino acids.

Chronic hepatotoxicity: plant-derived and environmental toxins

Aflatoxin

The **aflatoxins** are a group of *bisfuranocoumarin compounds* produced as metabolites mainly by *Aspergillus flavus*, *A. parasiticus*, and *Penicillium puberulum*. The metabolites are designated by spectral qualities, and the major ones are B_1, B_2, G_1, and G_2. Many others may be produced in minor amounts in fungal colonies or as metabolic products of the major toxins in animals. *The most significant and best studied of the aflatoxins is B_1* because of its relative abundance and its potency as a hepatotoxin.

Strains of ***Aspergillus*** differ in the varieties and amounts of individual toxins produced, indicating that the biosynthesis of the toxins is genetically determined. The production of toxins also varies under different conditions of fungal growth, being influenced by the quality of the substrate, temperature, relative humidity, and moisture content of the substrate, and microbial competition. Thus the toxicity of moldy feedstuffs is impossible to assess without measurement of toxin production. Aflatoxins can be produced on growing crops in the field, but much greater levels are likely to accumulate in *stored or unharvested mature grains*, particularly if they are damaged by moisture. Various feeds other than grains, ranging from legume stubbles to bread, may be the substrate in outbreaks of aflatoxicosis.

Aflatoxins are metabolized by the hepatic mixed-function oxidase system to various toxic and nontoxic metabolites, the proportions of which vary with the species and age of animal involved. The most potent of these is the 8,9-epoxide metabolite of aflatoxin B_1; this binds to adenine in nucleic acids in sensitive species that lack adequate glutathione *S*-transferase-mediated resistance. Sheep, adult cattle, and rats are quite resistant to the toxin, whereas dogs, pigs, calves, mice, and ducklings are sensitive and may be fatally intoxicated by a dose rate of less than 1.0 mg/kg body weight.

Prolonged exposure to low concentrations of the toxin may merely produce reduced growth rates and moderate enlargement of the liver without any significant hepatic signs. The enlargement may be partly due to hypertrophy of hepatocellular smooth endoplasmic reticulum and some degree of fatty change. As the level of aflatoxin in the ration increases (in young pigs, e.g., to 1.0 mg/kg ration), the liver may show all or none of the following changes: pallor, enlargement, bile staining, increased firmness due to fibrogenesis, and fine nodular regenerative hyperplasia. There may also be edema of the gallbladder and bile-tinged ascites in more severe cases. Even under experimental conditions, some individuals may show minimal liver lesions, while their fellows, under the same levels of exposure, die of liver failure. Histologically, affected livers show obvious increase in size of some hepatocytes and their nuclei (megalocytosis) with focal necrosis or apoptosis. Bile ductules proliferate early, and reticulin and collagen deposition occurs throughout the acinus according to no distinct pattern. Fatty change in affected livers is variable in extent and occurrence, and bile pigments accumulate in canaliculi and hepatocytes in more severely affected livers. Minor degrees of megalocytosis may be seen in proximal tubular epithelium in the kidney. *The changes produced resemble those of pyrrolizidine alkaloid toxicosis.* This can be attributed to the fact that aflatoxin and pyrrolizidine alkaloids *inhibit hepatocellular regeneration* such that nodules and ductules regenerate as the liver becomes atrophic. These are also *genotoxic* and *carcinogenic* so they might be involved in the occurrence of liver cancers in animals, as they are in humans.

At higher dose rates of aflatoxin, most periacinar hepatocytes disappear and are replaced by a mixture of inflammatory cells, fibroblasts, and primitive vascular channels. The liver may be much smaller than normal, particularly in young animals, due presumably to mitotic inhibition, and focal hepatocellular necrosis is more obvious or may be supplanted by zonal (periacinar) necrosis. Fatty change in these livers may be severe and uniformly distributed.

Acute, fulminating liver necrosis is sometimes seen in dogs that eat moldy bread, dog food, or garbage, which may contain very high concentrations of the toxin. Younger animals are much more susceptible and may die within a few hours; the gross postmortem picture is dominated by widespread hemorrhage and massive hepatic necrosis.

Fumonisin

Fumonisin B_1, a mycotoxin elaborated by certain strains of ***Fusarium moniliforme*** in infected corn, induces hepatocellular carcinomas in laboratory rats, and leukoencephalomalacia in horses. Hepatic toxicity has also been reported in horses, sheep, and baboons. Severe pulmonary edema and hydrothorax have been reported in swine fed contaminated corn screenings. More recent studies have shown fumonisin B_1 also to be a *primary hepatotoxin in pigs*. Experimental feeding trials with pigs have shown dose-related differences in pathology. Pigs intubated with a minimum of 16 mg fumonisin B_1/kg body weight per day developed interlobular edema, variable hydrothorax, and pulmonary edema, while pigs intubated with 8 mg/kg per day for 7–8 days, or fed diets containing 200 mg fumonisin B_1/kg of feed for 21 days, developed marked icterus. Histologic changes included hepatocellular necrosis without a zonal distribution, depletion of centrilobular hepatocytes, lobular disarray, and megalocytosis characterized by large numbers of swollen hepatocytes with abundant granular eosinophilic cytoplasm and occasional large nuclei, randomly interspersed with small angular hepatocytes and scattered necrotic cells. These pigs showed no evidence of pathologic changes in the lungs, whereas pigs given higher doses showed *hepatic necrosis in addition to pulmonary edema.* The liver changes appear to be reversible upon cessation of exposure. Gilts fed low levels of fumonisin B_1 for 90 days developed hepatic nodular hyperplasia, along with hyper- and parakeratosis and hyperplasia of the distal esophageal mucosa. Fumonisins are inhibitors of sphingosine and ceramide synthetase, and the subsequent inhibition of sphingolipid biosynthesis may be involved in the toxic hepatic effects.

Phomopsin

There are two distinct manifestations of toxicity associated with *Lupinus* spp.; discussed here is the condition formerly known as *"lupinosis," which is a true mycotoxic liver disease.* The teratogenic and neurotoxic effects of some of the isoquinoline alkaloids from the plants themselves are discussed in Vol. 1, Bones and joints and Vol. 1, Nervous system.

The fungus ***Phomopsis leptostromiformis*** is parasitic on green *Lupinus* plants, but it becomes saprophytic after the host dies. Phomopsins (A or B) are produced if the lupin stubble is moistened, and such stubbles may remain toxic for months. Severe acute liver damage has been described in sheep on very toxic stubbles in Western Australia, but in many of these cases it has been difficult to separate the toxicity of the lupins from that of copper, which in this area is often concentrated in ovine livers (see section on Copper, below).

The usual syndrome of phomopsin poisoning is subacute to chronic. Inappetance occurs soon after experimental administration of the toxin is begun; liver damage is clinically inapparent for several days, although there is early hydropic change and accelerated cell death among hepatocytes. Increased mitotic activity is soon apparent, although by this time the liver has become smaller. The mitotic activity is in fact largely ineffectual, as close examination reveals that many mitotic figures are abnormal (Fig. 2.72A). There is either clumping or dispersal of chromatin, and *there appears to be mitotic arrest at late metaphase.* Remaining hepatocytes swell, their cytoplasm becomes granular and their nuclei vesicular. With progression, hepatic fibrosis occurs, predominantly diffuse in distribution, and by this stage there is usually clinical icterus and anorexia. There will be variably severe fatty change, dependent to a large degree on the fat reserves of the animal (Fig. 2.72B). There is also accumulation of complex pigment in macrophages in portal stroma and about hepatic venules;

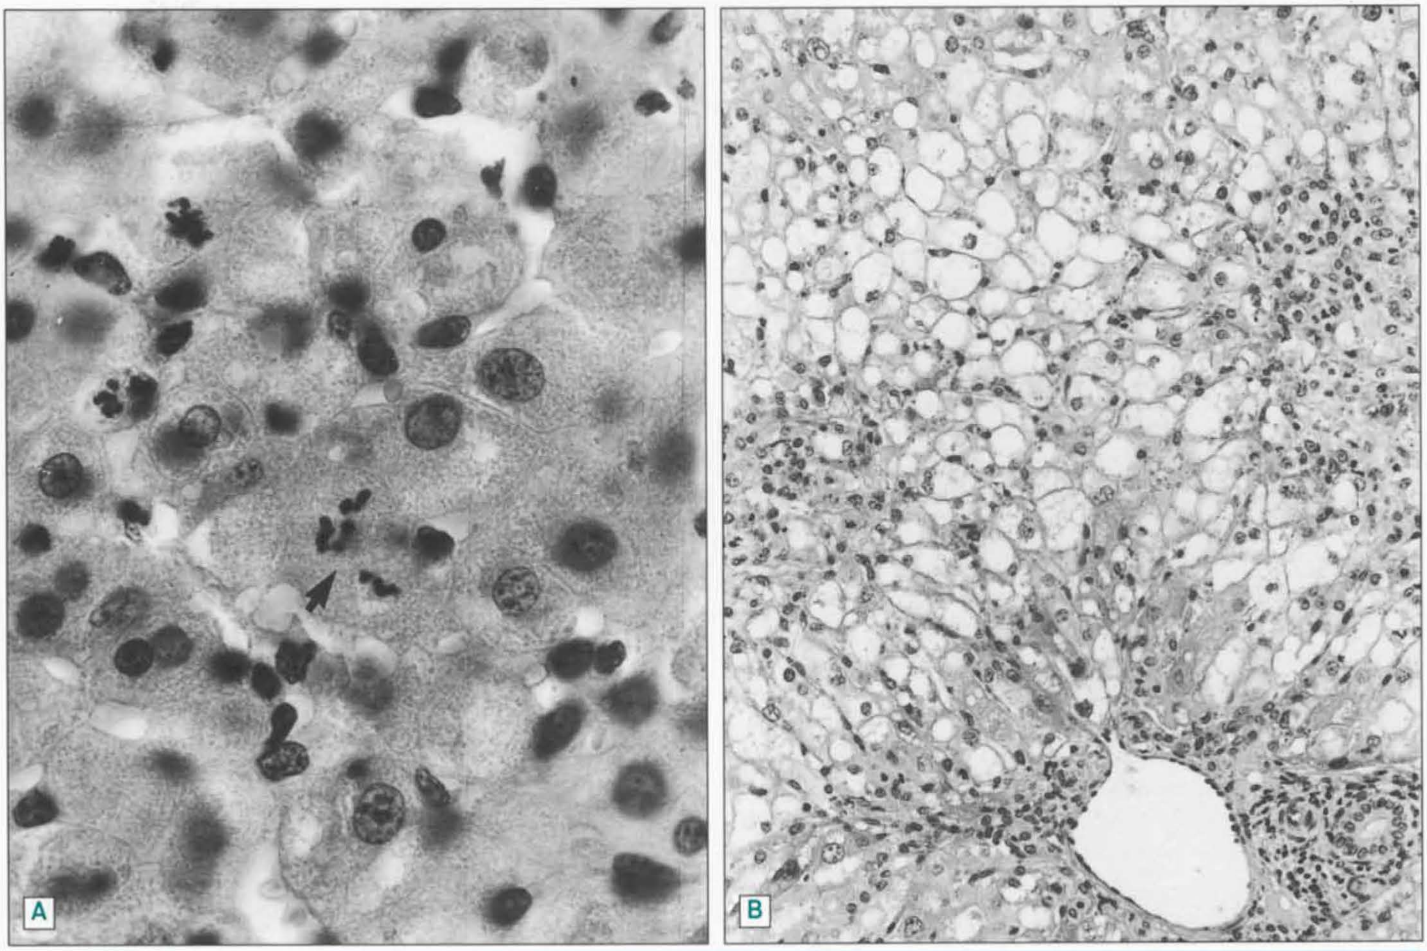

Figure 2.72 Phomopsin poisoning (lupinosis) in sheep. **A.** Numerous, and **abnormal, mitotic figures** (arrow) in subacute phomopsin poisoning. **B.** Zonal fatty change, periacinar collapse and periportal megalocytosis. (Courtesy of JG Allen.)

this granular material contains lipofuscin, ferric iron, and copper at least. Bile duct proliferation is also a prominent feature of the chronic disease.

The liver continues to shrink, presumably as a result of continued mitotic inhibition and progressive fibrosis. The organ is small, tough, and has a finely granular surface and texture. It is pale gray-orange but usually retains its shape. In naturally occurring cases, however, discontinuous intake of the toxin may produce a liver grossly distorted by asymmetric nodular regeneration and fibrosis. The atrophic changes are most severe in the left lobe.

Photosensitization occurs in phomopsin-poisoned sheep; it may be severe if the animals have access to green feed while under the influence of the toxin. Lupinosis in sheep has also been experimentally observed to induce mild skeletal myopathy, resembling nutritional myopathy.

Phomopsin poisoning in cattle causes most losses when the animals are lactating or heavily pregnant; in these animals the syndrome is essentially one of ketosis, to which such cows would be predisposed by the anorexia that is an obvious clinical feature of this intoxication. Pregnant sheep are less likely to have access to toxic lupin roughage during late gestation, otherwise ketosis triggered by phomopsin would be expected just as often as in cattle.

Chronic hepatic fibrosis with fine, nodular regeneration may occur infrequently in cattle due to chronic phomopsin poisoning. Similar liver changes may also be seen in horses, in which there may also be hemolytic anemia of unknown pathogenesis.

Sporidesmin

The mycotoxin *sporidesmin* is produced by the fungus ***Pithomyces chartarum***; the most important substrate is dead ryegrass (*Lolium perenne*) that has been moistened in warm weather. Intoxication causes *chronic liver damage and severe hepatogenous photosensitivity* ("*facial eczema*") and is a serious cause of loss of sheep and, to a lesser extent, cattle on the North Island of New Zealand. Sporadic and subclinical intoxication occurs irregularly on the South Island and in southern Australia and South Africa. Sporidesmin intake in conjunction with ingestion of *Tribulus terrestris* causes another hepatogenous photosensitivity (*geeldikkop*); this is similar to but distinct from facial eczema, and is described below.

Sporidesmin is concentrated in the fungal spores, and the toxigenicity of pasture is related to the density of the spores in it. Sporidesmin is not specifically hepatotoxic. Administration of the toxin does produce rapid disorganization of hepatic cell organelles and triglyceride accumulation, but these are mild and nonspecific changes. If administered in suitable dosage, the toxin causes permeability alterations in many tissues and will, for example, produce corneal edema on local application. *The hepatobiliary lesions are due* *to the excretion of unconjugated sporidesmin in bile and its concentration there.* Sporidesmin is also excreted in urine, and if the dose is high enough, edema and mucosal hemorrhage occur in the bladder. The hepatic lesion is due to irritation of mesenchymal tissues in the portal triads and surrounding the bile ducts. If the concentration of sporidesmin is high enough, the biliary epithelium undergoes necrosis, and diffusion of toxin produces irritative lesions and necrosis in the adjacent blood vessels.

The liver in acute forms of the disease is enlarged, with rounded edges, and is finely mottled and discolored yellow-green by retained bile pigments, although the discoloration may be blotchy. There is mild edema and congestion of the wall of the gallbladder, which may be distended with bile of normal quality or with mucin (white bile). The extrahepatic ducts are thickened and prominent, and there is edema of the adventitia. The ductal changes may extend to the papilla of Vater and can be traced by the naked eye deeply into the parenchyma. In more chronic cases, alterations of size and pigmentation of the liver are variable. Pale areas of capsular thickening, which may be elevated or depressed, are visible. On cut surfaces they extend deeply as wedge-shaped areas in which biliary fibrosis has produced an exaggerated acinar pattern, and the parenchyma is pale and atrophic; these areas are related to occluded bile ducts and are sometimes referred to as *biliary infarcts.*

The liver is firm and cuts with increased resistance. The intrahepatic ducts are conspicuous. There is irregular stenosis of their lumens, some are occluded by cellular debris and inspissated bile or mucin, and in some, cicatrization of the new fibrous tissue causes complete atresia. Occlusion of the ducts causes the parenchyma served by them to undergo atrophy, necrosis, and fibrosis. The livers of animals that have survived an attack of cholangiohepatitis of this genesis are distorted in shape and size by large nodules of regeneration and persistent areas of atrophy and fibrosis. The atrophy and fibrosis may affect either lobe, but usually the left most severely (Fig. 2.73).

Histologically, the changes are those of an *acute cholangitis or cholangiohepatitis* to which there is a minimum of leukocytic reaction. There is extensive necrosis of the lining of the larger intrahepatic ducts and the extrahepatic ducts, the epithelium being cast off as debris mixed with a few leukocytes. There is edema of the adventitia of the ducts, with active fibroplasia and scarring. Inflammatory cells are present, but not in large numbers, and they are chiefly lymphocytes and histiocytes. Injury to the smaller radicles of the bile ducts is less severe, but fibrosis and collagenization are active. The portal tracts are enlarged by fibrous tissue and by the active generation of new bile ducts that follows.

In more severe intoxications, there may be *coagulative necrosis of blood vessel walls in the portal triads*; when this is incomplete, the most damaged segment of the vessel tends to be that adjacent to the nearest injured bile duct. Both arteries and veins may be affected, and it is possible that the so-called bile infarcts are related to vascular insufficiency as well as to impaired bile drainage. Changes in the hepatic parenchyma are minimal and secondary to those in the portal triads. In acute cases, there may be extensive pigmentation of hepatocytes and Kupffer cells by bile pigments, but this is irregular in distribution in the liver. Inspissated bile can be found in the bile ducts and canaliculi. There is some necrosis of hepatocytes adjacent to inflamed portal areas, and other areas of necrosis, focal in type and distribution and probably the result of biliary obstruction, may be numerous.

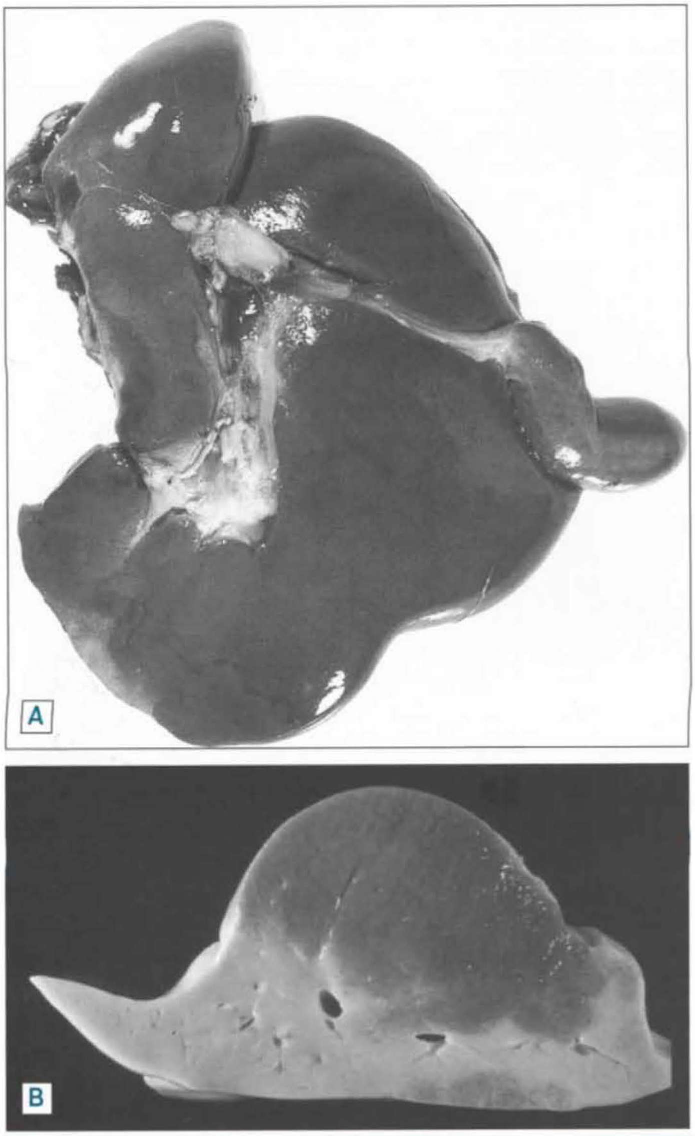

Figure 2.73 Chronic sporidesmin poisoning ("facial eczema") in sheep. **A.** Atrophy of left lobe with hypertrophy of right and caudate lobes. (Courtesy of WJ Hartley.) **B.** Cross section showing marked atrophy and fibrosis of left lobe, and hypertrophy of the right lobe. (Courtesy of KG Thompson.)

Other morbid alterations include great enlargement of the adrenals produced by cortical hypertrophy; sclerotic intimal plaques in the arteries, veins, and lymphatics in the hilus of the liver; and a tendency for the newly formed bile ductules to recanalize occluded ducts.

Pyrrolizidine alkaloids

Pyrrolizidine alkaloids have been identified from over 6000 plants of three families – the Asteraceae (Compositae), Leguminosae (Fabaceae), and Boraginaceae. The main genera responsible for plant toxicoses in domestic mammals are ***Senecio, Crotalaria, Heliotropium, Cynoglossum, Amsinckia, Echium***, and ***Trichodesma***, and are widely distributed around the world. More than 600 pyrrolizidine alkaloids have been identified chemically, and most of the toxic plant species contain more than one of the alkaloids. So far, only a small proportion of the known alkaloids have well-characterized toxicity; these are all esters of one of three amino alcohol bases (necines) or acids (necic acids). The *retronecine group* includes *monocrotaline, retrorsine, retronecine, ridelliine, senecionine, and jacobine*, and the *heliotridine group* includes *lasiocarpine and heliotrine.* These toxins must be metabolized to more reactive forms for toxicity. Cytochromes P450 mediate the N-oxidation of the esters or necine bases. They can also mediate the two-step hydroxylation of the necine bases at the C3 and C8 positions; this is followed by spontaneous dehydration to the *highly reactive dehydropyrrolizidine (DHP) derivatives (pyrrolic esters).* The toxic DHP metabolites are electrophilic and can bind covalently to proteins and nucleic acids at guanine and adenine residues. The DNA-binding activity is responsible for their genotoxicity; the DHP-derived DNA adducts are a common pathway for carcinogenic activity of pyrrolizidine alkaloids. The DHP metabolites can be detoxified by glutathione conjugation by glutathione *S*-transferases. Ester linkages at the C7 and C9 positions can be hydrolyzed by carboxylesterases to generate the necine or acid moieties; this is generally considered to be a detoxification pathway.

The toxicity of a pyrrolizidine alkaloid containing plant depends on many factors. For an individual pyrrolizidine alkaloid, toxicity depends on the amount of alkaloid that can be converted to reactive metabolites, the rate of cytochrome P450-mediated generation of the DHP, and the efficiency of detoxification by glutathione conjugation. Toxicity also depends on the species exposed, age, and sex of the animal intoxicated, the metabolic activity and the mitotic stage of its target cells. Grazing animals are more likely to consume plants that contain pyrrolizidine alkaloids, but since the toxins are produced by the plants to deter herbivores, it is unusual for an animal to consume large amounts. Ruminants, especially sheep and goats, are much less susceptible than pigs, in part because the toxins can be degraded in the rumen. However, sheep can graze out stands of *Senecio* that would be lethal to cattle. The seeds are also toxic and the small seeds of *Amsinckia* may, depending on harvesting technique, heavily contaminate other harvested grains used in prepared pig and poultry feeds.

Most pyrrolizidine alkaloids are hepatotoxic because they are metabolically activated to DHPs in the liver. However, monocrotaline is also bioactivated in the lung and is therefore pneumotoxic. There are three common expressions of pyrrolizidine poisoning. First, *acute periacinar zonal necrosis* occurs in animals ingesting large amounts of these alkaloids. Because the plants responsible are unpalatable, naturally occurring outbreaks of acute poisoning are generally restricted to circumstances where animals face starvation, such as grazing pastures affected by prolonged drought. Ingested dosages in grazing circumstances are usually too low for acute effects; however, acute hemorrhagic periacinar necrosis has been described after experimental exposures to high doses of pyrrolizidine alkaloids. The periacinar pattern of zone 3 necrosis produced is similar to that caused by many other hepatotoxins that are bioactivated by hepatic cytochromes P450. Second, phasic (usually seasonal) repetitive exposure to these alkaloids leads to *hepatic atrophy with formation of regenerative nodules. This is the most common expression of field exposure to pyrrolizidine alkaloids and affected livers show a characteristic pattern of hepatocellular polyploidy known as* **megalocytosis** (Figs 2.9 and 2.74). Third, prolonged exposure exclusively to *Heliotropium* induces *firm, fibrotic atrophic livers without nodular regeneration.* If seasonal exposure to these toxic alkaloids declines, then a remarkable degree of recovery is possible.

Pyrrolizidine alkaloids inhibit DNA synthesis and mitosis in hepatocytes, but some are able to replicate their DNA without undergoing mitosis, resulting in greatly enlarged hepatocytes with large convoluted polyploid nuclei. Some enlarged nuclei have cytoplasmic invaginations that can become entrapped as intranuclear inclusions. However, many hepatocytes in an affected liver do not become megalocytic. Those that are completely inhibited do not replicate DNA at all, whereas those that are more resistant can replicate more normally and give rise to nodular populations of smaller, more normal hepatocytes. Inhibited hepatocytes and megalocytes are long-lived but eventually many undergo apoptosis.

In *chronic pyrrolizidine alkaloid poisoning*, the liver can become atrophic as hepatocytes are lost faster than they can be replaced. The atrophy can be compensated to various degrees by megalocytosis and regeneration of small, less inhibited hepatocytes that proliferate in a nodular pattern. Concurrently, there is *usually proliferation of bile duct epithelial cells in the portal triads.* This is largely explained by the propensity of cholangiolar epithelia to proliferate in response to the regenerative stimuli that prevail when liver mass is inadequate. *There may also be some periportal fibroplasia that varies with species and exposure; typically it is minimal in sheep, moderate in horses, and may be marked in cattle* (Fig. 2.75). In **cattle**, the fibrous tissue can infiltrate along the sinusoids to dissect lobules, separate individual cells, and link up with the walls of efferent veins. In acute poisoning, in which there is

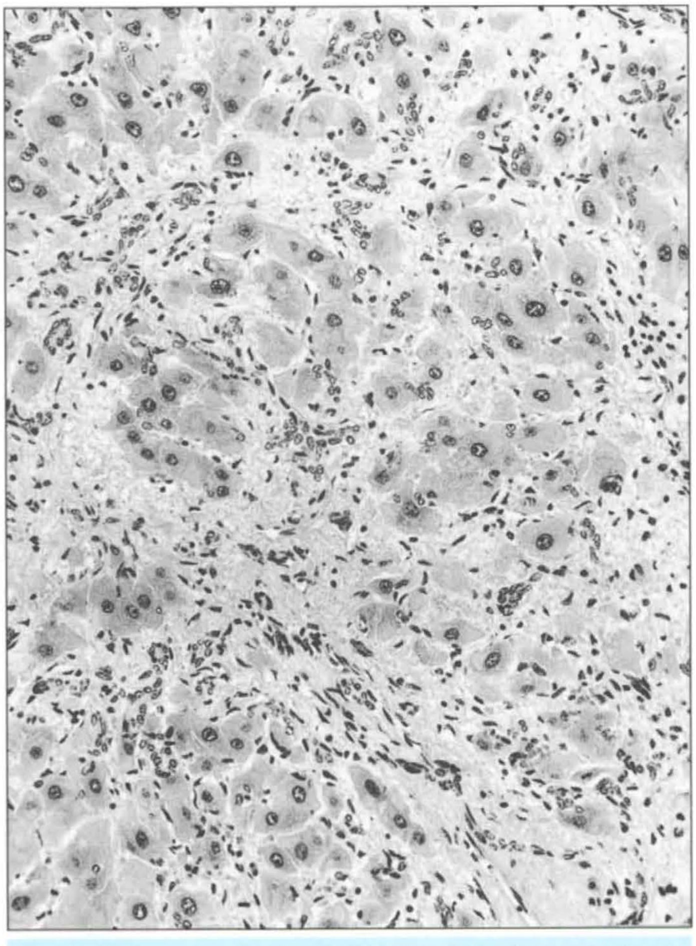

Figure 2.74 Megalocytosis and diffuse fibrosis in ***Crotalaria* poisoning** in an ox. Fibrous septa have subdivided the acini.

periacinar necrosis, fibrosis can also develop in a "veno-occlusive" pattern around and sometimes obliterating the hepatic venules. This pattern may occur in some field cases in cattle, but is more commonly observed in humans exposed to pyrrolizidine alkaloids in herbal preparations or "bush teas" and it can be produced experimentally after sublethal acute experimental hepatotoxicity. In fatal cases in cattle, the livers are very tough and nodular (Fig. 2.76), and the nodules have variably efficient biliary drainage and cytochrome expression, so there may be a very striking color pattern, ranging from fatty yellow through green and brown. These fibrotic livers can result in portal hypertension with ascites, severe mesenteric edema, and diarrhea. Excretory insufficiency with moderate jaundice and photosensitization can also occur.

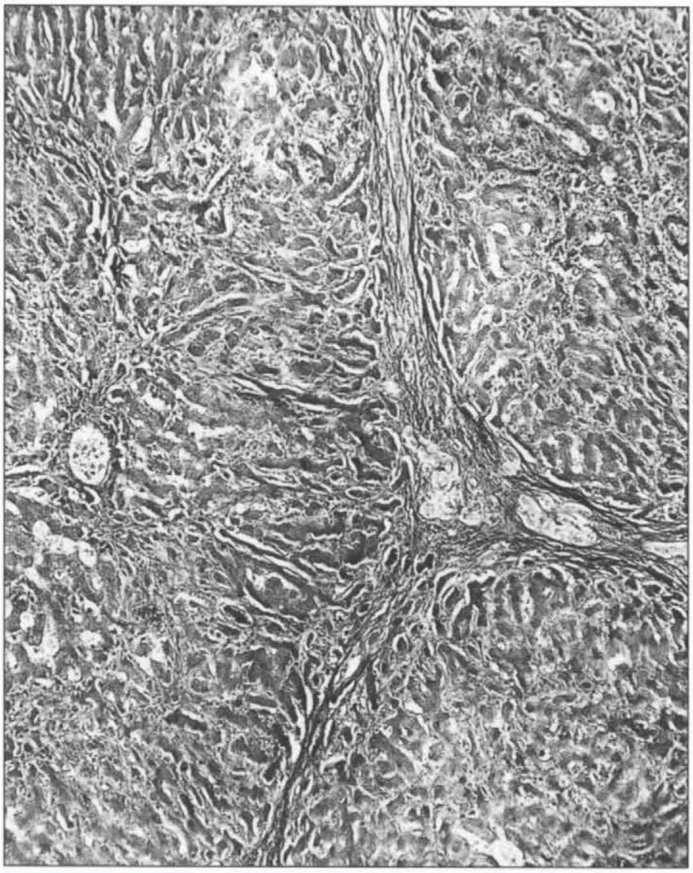

Figure 2.75 Diffuse fibrosis of liver in chronic ***Senecio* poisoning** in an ox.

The disease in **sheep** is always protracted as a consequence of the relative resistance of this species; indeed, clinical signs may not be seen until after a second season of exposure. The plants most often implicated are *Heliotropium europaeum* and *Echium plantagineum*. The shape of these failed livers is normal, but they are small, gray-yellow, fairly smooth, and toughened by condensation of normal stroma rather than by fibroplasia. If the liver copper content was high before intoxication, toxicity can culminate in copper release and an episode of intravascular hemolysis. In this case, the carcass will be intensely jaundiced, and the kidneys are stained with methemoglobin and bilirubin. The relationship of chronic copper poisoning to pyrrolizidine alkaloid poisoning is discussed below.

Horses are susceptible to both acute and chronic toxicosis, and liver failure produced in horses by these alkaloids is similar to that seen in cattle. Horses are more likely to manifest signs of hepatic encephalopathy with head-pressing and compulsive walking; in some places these nervous signs give rise to colloquial names such as "walkabout" and "walking disease." Administration of a high dose of *Cynoglossum officinale* resulted in severe liver disease within 7 days after dosing, with elevated serum enzymes, altered bile acid metabolism, and extensive hepatocellular necrosis with minimal periportal fibrosis and biliary hyperplasia, and little or no megalocytosis. Edema and infarction of the cecum and colon were also present at necropsy. Administration of a low dose to horses for 14 days resulted

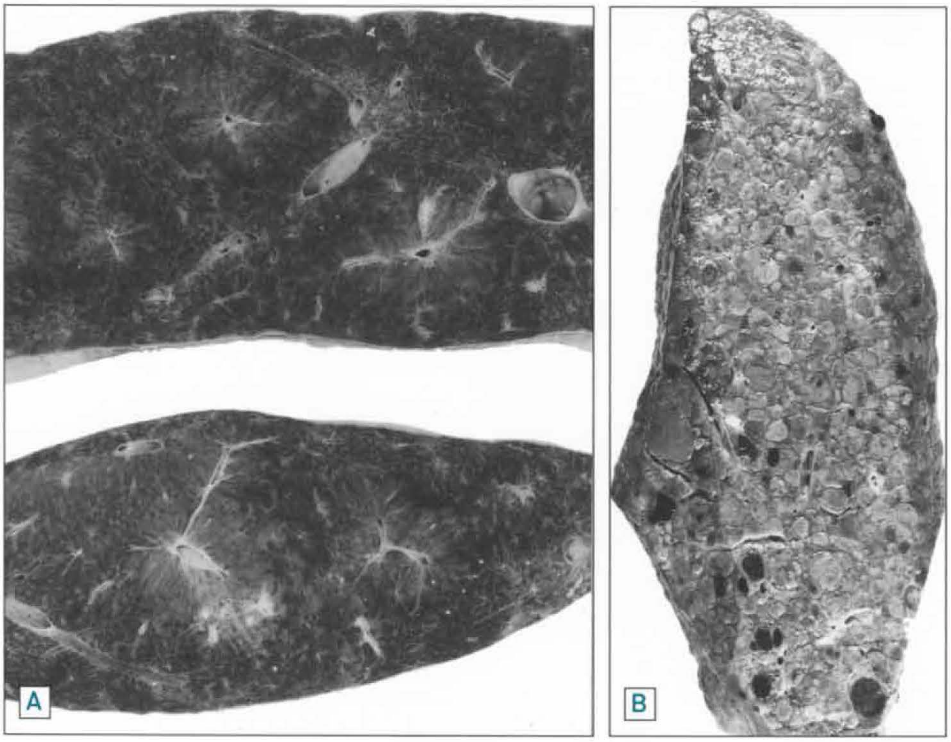

Figure 2.76 Pyrrolizidine alkaloid toxicity. A. Diffuse fibrosis, mimicking "nutmeg" liver of chronic congestion, in ***Senecio* poisoning** in a calf. **B.** Fibrosis and nodular regeneration, with some nodules stained by bile, due to ***Heliotropium* poisoning**, in a bovine liver.

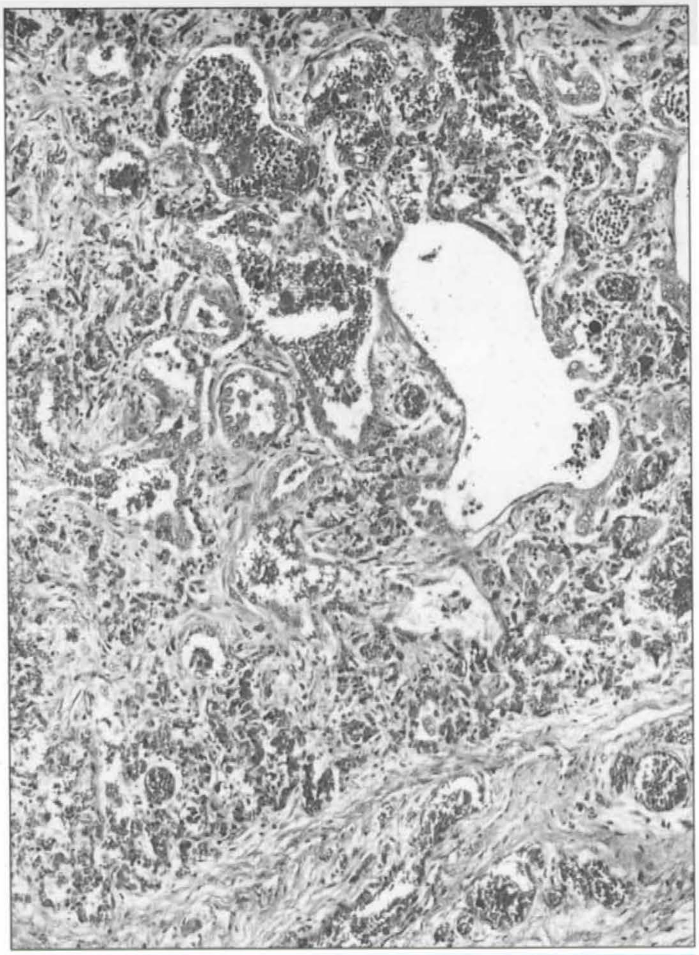

Figure 2.77 Pulmonary congestion and hemorrhage, septal fibrosis, and epithelial metaplasia due to ***Senecio* poisoning** in a pig.

in transient clinical depression and weight loss, transient elevations of serum enzymes and bile acids, and minimal periportal hepatocellular necrosis with fibrosis, developing extensive megalocytosis by week 14. The megalocytosis became the most prominent change 6 months after exposure.

The metabolites of pyrrolizidine alkaloids affect tissues other than the liver; death in some instances may be due to renal damage and in others to pulmonary vascular and interstitial lesions. Variation in the source of the toxin and in the species of target animals accounts for the differences in susceptibility of the different tissues. Alkaloids from *Crotalaria* affect the widest range of tissues in most animals; most notably, monocrotaline causes diffuse lung injury, leading to pulmonary edema progressing to fibrosis. Respiratory difficulty has been described in horses eating *C. dura*, and *C. crispata* produces similar lesions. Sheep develop pulmonary signs after eating *C. globifera* and *C. dura*, and pigs after eating *Senecio jacobaea*. The experimental feeding of *C. spectabilis* to rats or the injection of monocrotaline, extracted from the plant, produces progressive pulmonary disease, pulmonary hypertension, and cor pulmonale, with necrotizing vasculitis of the pulmonary arterioles. Emphysema occurs in pigs and is an outstanding feature of the pulmonary disease of horses. The essential reactive lesion is diffuse fibrosis of alveolar and interlobular septa, with patchy epithelialization occurring more slowly (Fig. 2.77).

Lantana camara

Lantana camara is an attractive ornamental shrub that grows readily in tropical and subtropical habitats. It contains various *toxic pentacyclic triterpenes*, the most abundant of which are lantadene A, B, and C. Other potentially toxic constituents have also been identified, but lantadene A appears to be the most toxic; at high doses experimentally it causes severe acute zonal necrosis of the liver. However, *L. camara* poisoning in grazing animals is *subacute or chronic cholestasis, characterized by severe icterus and photosensitization*, most commonly seen in cattle, but rarely in sheep and goats. The latter species are quite susceptible to the toxin, but are less likely to eat the plant.

Photosensitization is usually severe after 2 days, but jaundice is more severe in chronic cases. Heavily intoxicated cattle can die within 2 days, but most fatal cases run a course of about 2 weeks. Ruminal stasis and anorexia appear early and the large bowel contains dark, dry feces. The rumen is a reservoir of toxin that remains active and can perpetuate the intoxication after access to the plant is curtailed. The liver is enlarged, pale, and stained yellow, orange, or green-gray by bile pigment. The gallbladder is greatly distended with pale, sometimes slightly mucoid, bile.

The severity of the liver changes may be much less than expected from the intensity of the icterus and photosensitization. *The most consistent histologic finding in the liver is hepatocellular enlargement and fine cytoplasmic vacuolation, together with some degree of bile accumulation in canaliculi, hepatocyte cytoplasm, and Kupffer cells.* The canalicular cholestasis is usually more severe in the periacinar zones, while the cytoplasmic vacuolation is often more pronounced in the periportal hepatocytes. There is usually some bile duct proliferation, and in some cases there will be a high incidence of periportal apoptosis, focal coagulative necrosis, or hepatocellular dissociation.

Electron microscopy reveals an apparent increase in volume of smooth endoplasmic reticulum and a quite characteristic form of collapse of many bile canaliculi. Other canaliculi are distended and have damaged microvilli. Since much of the bilirubin that accumulates in the plasma of such animals is conjugated, it seems that the cholestasis is due in large measure to direct interference with canalicular transport of bile. The mechanisms of cholestasis have not been determined but damage to the contractile pericanalicular cytoskeleton or its associated cell adhesion molecules required for canalicular integrity are plausible targets (see section on Cholestasis and jaundice, above).

Animals are usually polyuric due to nephrosis, resulting in severe dehydration in part related to a disinclination to drink. The kidneys are slightly enlarged and wet on section, and, especially in the more chronic cases, the cortex is pale and the medulla hyperemic. The renal lesion is nonspecific nephrosis, ranging in severity from mild vacuolar change to patchy tubular necrosis and extensive tubular cast formation. The role of the hyperbilirubinemia in the production of the renal damage has not been assessed. Severe myocardial necrosis can be produced in sheep by *Lantana* poisoning, and may be responsible for the early deaths in cattle.

Tribulosis and related toxicoses

Consumption of ***Tribulus terrestris***, particularly by the grazing of young wilted plants or sometimes hay, causes cholangitis and photosensitization in sheep. This plant has caused enormous loss of sheep in

South Africa, where the toxicosis is known as **geeldikkop** ("yellow bighead," due to icterus and marked edema of ears and face). The disease has been reproduced by oral administration of crude extracts of *steroidal saponins* of *T. terrestris*, but which of the various saponins in the plant are responsible for the disease is unknown. The disease has also been reproduced experimentally by co-administration of sporidesmin and *T. terrestris*, but the liver lesions are histologically distinct from those produced by sporidesmin alone (facial eczema).

In geeldikkop, the most characteristic gross finding is the presence of a white, semifluid accumulation of fine, crystalline material that can be expressed from the cystic duct and larger intrahepatic ducts. The gallbladder mucosa is also partly covered with a fine, crystalline deposit. The gross lesions of geeldikkop are similar to those of facial eczema in that there is generalized icterus, and the liver is discolored by bile pigment and either slightly swollen or distorted, according to the duration of the disease. In poisoning by sporidesmin alone, however, there is more obvious edema and fibrosis of bile ducts, and bile infarcts in the parenchyma are more common. The acute lesion consists of swelling and feathery vacuolation of hepatocytes, and marked hyperplasia of Kupffer cells that may show similar cytoplasmic changes. In these acute cases, the presence of acicular crystals may be very difficult to detect (Fig. 2.78A). *With more chronic intoxication, the most consistent histologic abnormality is the presence in bile ducts of various amounts of crystalline material* (Fig. 2.78B). The crystals are fine, flat, and are deposited in affected ducts, and, less commonly, in hepatocytes themselves and in renal tubules. There may be associated bile ductular proliferation in severe cases, but often the degree of histological hepatocellular damage is mild compared to the severity of the photosensitization. The cholestasis is not solely due to mechanical obstruction by the crystals, since photosensitization can occur in such outbreaks in animals whose livers show very little cholangitis and contain very few crystals. The severity of peribiliary fibrosis is more variable and probably depends on the relative contribution of sporidesmin to the intoxication. There is some hepatocellular degeneration and apoptosis, and there is fairly uniform swelling of cytoplasm. Bile pigment accumulates in Kupffer cells and hepatocyte cytoplasm, but not to any marked extent in canaliculi. Focal necrosis of the gallbladder mucosa is often present. The severity of the hepatic lesion increases with the duration of exposure.

The biliary crystals from sheep with geeldikkop have been determined to be composed principally of *calcium salts of steroidal sapogenins* present in *T. terrestris*. Plant saponins are metabolized in the rumen and liver to episapogenin glucuronides, which in the presence of calcium may precipitate, forming the characteristic biliary crystals. Whether biliary occlusion by these steroidal plant saponins is the sole cause of the liver damage has yet to be determined. Other unidentified plant components may also play a role. *Hepatocellular damage likely also plays a role in phylloerythrin retention.* It has also been suggested that the toxins responsible may act primarily on the membranes of the bile canaliculi, in a manner similar to that of *Lantana* poisoning.

Crystal-associated cholangiohepatopathy is not specific for *Tribulus* intoxication. Similar changes occur in the hepatogenous photosensitivity disease, **alveld**, in sheep grazing pastures in Norway, the British Isles, and in the Faeroe Islands containing *Narthecium ossifragum*. Similar disease has been reported in ruminants intoxicated by *Agave lecheguilla, Nolena texana*, and the pasture species *Brachiaria decumbens* (signal grass) in Brazil and the *Panicum*, especially *P. coloratum*, kleingrass. In those cases studied (*T. terrestris, P. dichotomiflorum, P. schinzii, Narthecium ossifragum*), the characteristic crystalloid material deposited in the bile is principally composed of glucuronides derived from the metabolism of steroidal saponins present in the ingested plants. Foamy macrophages are also present in mesenteric and hepatic lymph nodes, and are also found in healthy cattle and sheep grazing *B. decumbens* in Brazil. With the exception of *Nolena texana*, steroidal saponins have been demonstrated in all of these

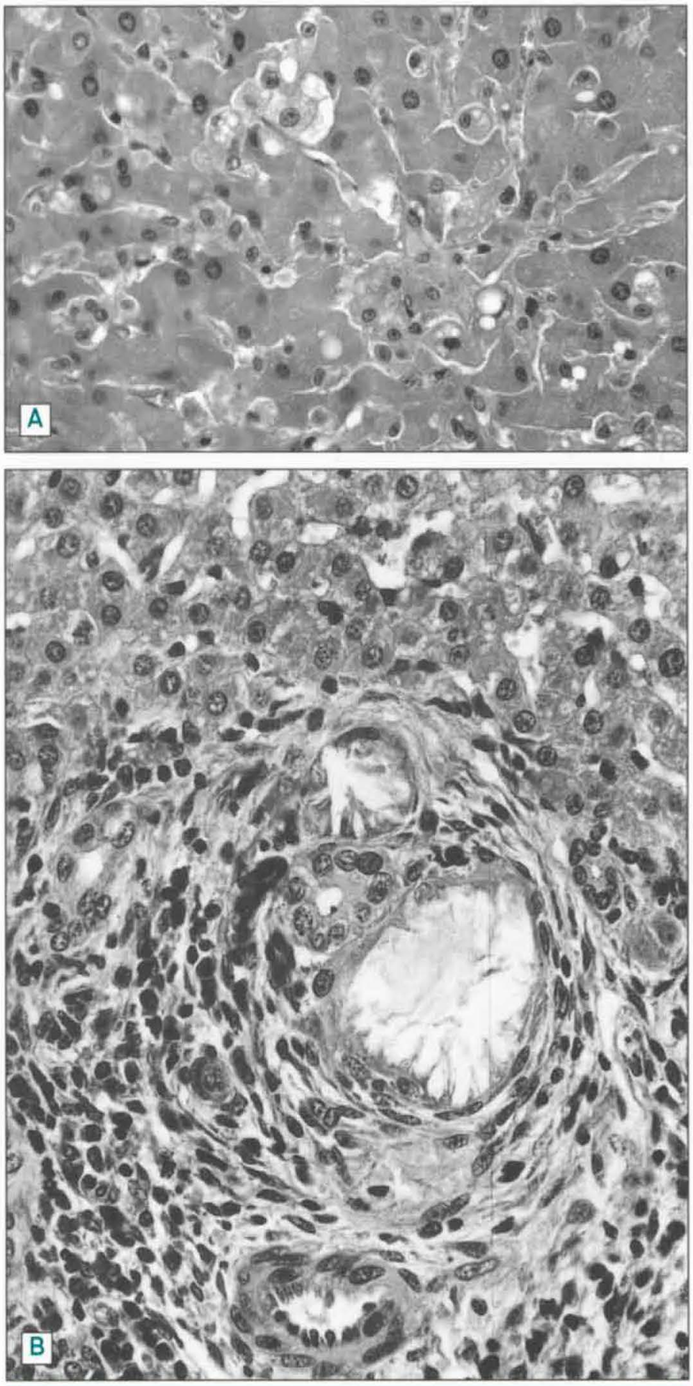

Figure 2.78 **A.** Hepatocyte swelling, feathery vacuolation and degeneration, with marked Kupffer cell hyperplasia – an early lesion of **geeldikkop** in a sheep. (Courtesy of RF Slocombe.) **B.** Chronic cholangitis and plugging of bile duct by lipophilic crystalloid material, in photosensitivity disease of sheep grazing **pangola grass**. Similar to reaction seen in geeldikkop.

plants. As with *T. terrestris*, extracts of *B. decumbens* containing steroidal saponins produced typical lesions of cholangitis with crystal deposition when orally administered to lambs, with *Pithomyces chartarum* spore counts below detectable levels. Similarly, analysis of samples of *B. decumbens* and *P. dichotomiflorum* on which cattle and goats had recently been photosensitized showed only low levels of *P. chartarum* spores, and all isolated obtained failed to produce sporidesmin. Despite this, it is also apparent that neither *Tribulus* nor *Panicum* stands are at all times dangerous. Levels of saponins have been shown to vary greatly within a species from site to site, and with the age of the plant. Additionally, the role of sporadic environmental conditions such as wilting, which might concentrate the saponins or other unidentified toxins, or the synergistic involvement of endophytic fungi, remains to be determined.

Other plants reported occasionally to produce unexpected photosensitivity include *Digitaria, Cooperia pedunculata, Nidorella foetida,* and *Chloris*, and such valuable pasture genera as *Medicago, Trifolium,* and *Avena*.

Nitrosamines

Epizootics of poisoning by **dimethylnitrosamine** occurred in Norwegian cattle, sheep, and fur-bearing animals, from 1957 to 1962. The toxin was present in herring meal and was thought to be a *reaction product of trimethylamine and other lower amines with sodium nitrite*, added as a preservative, the reacting amines being products of decomposition. Animals consumed several pounds of the toxic meal each day before becoming ill. *This intoxication has little importance in livestock now that it is easily prevented.*

At necropsy, there was moderate anasarca and signs of hemorrhagic diathesis. Livers affected acutely were enlarged and firm, with mottled discoloration and sometimes a nutmeg appearance. In chronic intoxication, the liver was small, granular, and very firm. A number of cases recovered after prolonged convalescence, and in these there was atrophy and fibrosis of the left and caudate lobes, and the right lobe was hyperplastic and hemispheric. Histologically, in acute cases, there was widespread hemorrhagic necrosis of periacinar distribution and an unusual degree of intimal and subendothelial reaction in sublobular and hepatic veins. The chronic lesion was dominated by extensive fibrosis of periacinar distribution, with obliterative changes in many central and sublobular veins. Sporadic cases of portal hypertension in Greyhound dogs have been recognized where hepatic veno-occlusive disease is the predominant lesion. In these cases, a history of feeding meat treated with large amounts of nitrites or sulfites in an attempt to preserve the color of fresh meat is common, but a causal relationship has not been established.

The *hepatocellular changes are not specific* for dimethylnitrosamine or other hepatotoxic nitrosamines. Nitrosamines are metabolized in the liver and other tissues to reactive alkyl groups that bind covalently to various macromolecules, especially guanine in nucleic acids. Hepatotoxicity develops more slowly than in response to toxicants that induce membrane peroxidation, as many hepatocytes with DNA damage undergo apoptosis when stimulated to replicate. There is some megalocytosis, nuclear vesiculation and nucleolar prominence, cytoplasmic intranuclear inclusions, and variable fatty change and cytoplasmic bile accumulation. The typical chronic effects of chronic experimental nitrosamine hepatotoxicity, such as hepatocellular fibrosis, nodules, and neoplasms, have not been evident in the accidental poisonings. Dimethylnitrosamine-induced hepatotoxicosis in dogs has been proposed as a model of toxin-induced progressive hepatic disease in this species.

Indospicine

Legumes of the genus ***Indigofera*** have for some years been known to contain the toxic amino acid indospicine (6-amidino-2-hexanoic acid), which is a structural analogue of arginine, and which was shown in early experimental work to be hepatotoxic for rats and other species. The dose rates necessary to cause chronic liver injury in these species were, however, quite high, and field cases of intoxications were only seen in cattle grazing *I. spicata*, which has the highest naturally occurring concentrations of indospicine. More recently, in Australia, a serious outbreak of fatal liver disease occurred in dogs that had been fed meat from horses that had been grazing *I. linnaei*, a plant native to the arid zones of Australia that has been known to produce in horses a chronic neurological disorder known as "*Birdsville horse disease*." The disease in horses is not associated with liver damage, although these animals do accumulate indospicine in most tissues, including muscle.

Dogs fed indospicine-contaminated meat for several weeks may develop *progressive liver damage*, which begins as vacuolation of a narrow band of periacinar hepatocytes, followed shortly by accumulation of mononuclear inflammatory cells in this zone and in the stoma of the hepatic venules. Progression of the lesion is marked by piecemeal necrosis of a widening zone of periacinar hepatocytes, disorganization, vacuolation due to hydropic and fatty change, and accumulation of ceroid pigment in macrophages (Fig. 2.79). Moderate periacinar fibrosis is seen in later stages, as well as pronounced canalicular cholestasis: by this stage, affected animals begin to show icterus, inappetance, and depression. Bile ductular proliferation is not a marked feature. Death is attended by the usual signs of hepatoencephalopathy and tendency to bleed spontaneously. There is no evidence of direct neurological damage as is seen in horses.

This intoxication is remarkable by virtue of its unpredictability. Experimental intoxication by pure indospicine has validly been shown to reproduce the naturally occurring intoxication caused by horsemeat feeding; however, liver failure can be produced by either means in only a small proportion of dogs so exposed. On the other hand, milder degrees of liver damage are reliably produced by both methods. Thus it seems an idiosyncratic response is superimposed upon a more consistent effect of the toxin; the nature of the accompanying inflammatory response suggests that the former may be immunologically mediated. This has yet to be established, as has the proposal that the mechanism of the intoxication is due to competitive inhibition of arginine.

Trifolium hybridum (alsike clover)

Alsike clover is a legume that grows well on wet clay soils in North America, where it is sometimes responsible for outbreaks or single cases of *cholangiohepatitis in horses* that consume it as pasture or hay. *The toxic principle has not been isolated*, but it likely is in highest concentrations in the flowering stage used for hay. However, there are evidently contributing factors because, while alsike clover is widespread in cultivation, *toxicity is rare*. Toxicity usually occurs when alsike clover is a major component of pastures or hay, but some horses are believed to graze it selectively in a mixed pasture.

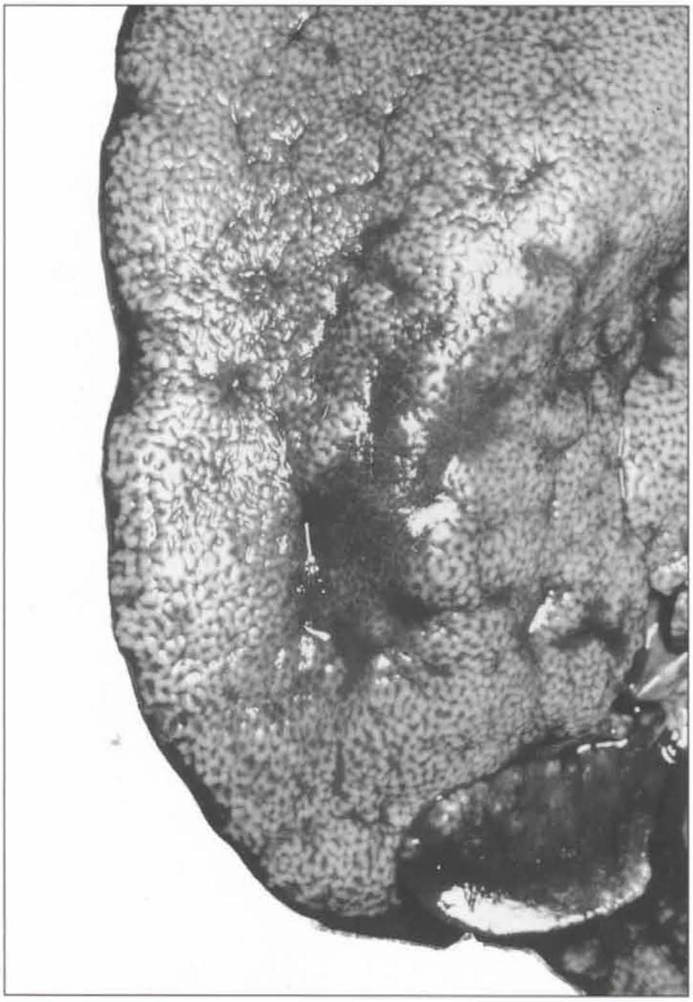

Figure 2.79 Acinar fatty and hydropic change, alternating with post-necrotic collapse, due to **indospicine poisoning** in a dog.

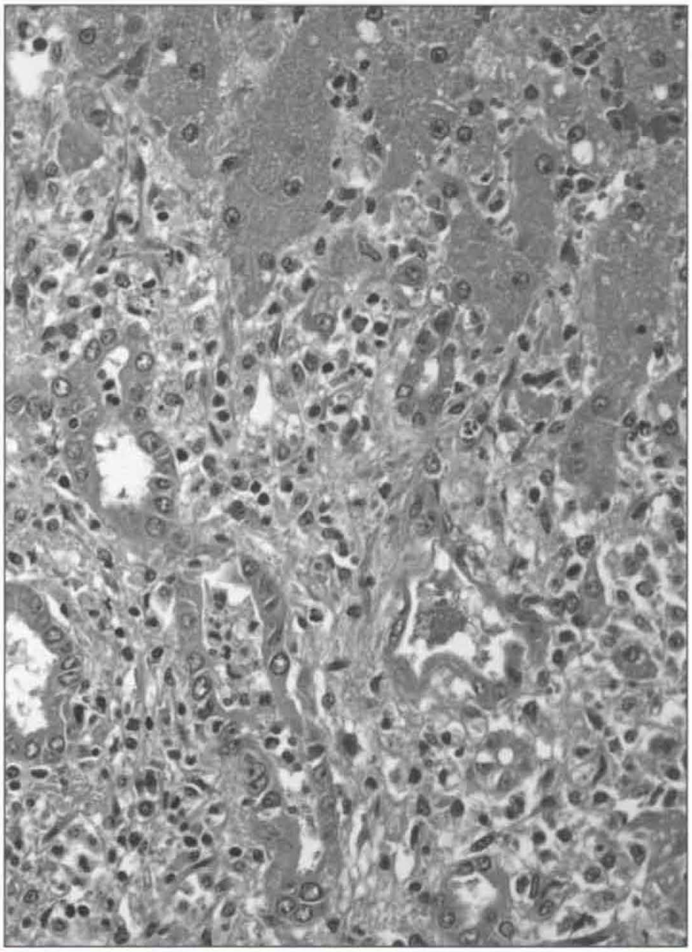

Figure 2.80 Chronic cholangiohepatitis due to **alsike clover poisoning** in a horse.

Clinical signs of poisoning initially include mild colic, ill-thrift, and anorexia, with increasing occurrence of signs of hepatotoxicity with cholestasis. In some there can be icterus and photodynamic dermatitis. Exposure to the plant can occur for a year or more before signs of hepatic insufficiency develop, but cholestatic liver disease can be detected biochemically before horses become ill. More severely affected horses display neurological disturbances, either excitement or mania in irregular episodes, or long periods of extreme dullness, anorexia, apparent blindness, forced wandering, head pushing, and yawning. Clinical problems related to hypoproteinemia such as coagulopathy or ascites are not a feature of this disease, probably because most of the hepatocytes are not directly affected.

The lesions of alsike clover poisoning are those of *diffuse subacute to chronic cholangiohepatitis*, with the major lesions within and adjacent to all intrahepatic biliary tracts. The liver is typically enlarged, sometimes greatly so, pale, and tough or rubbery in consistency. The surface is smooth, but its appearance is mottled. The mottling is clear on the cut surface and is caused by bands of gray fibrous tissue, distinctly visible to the naked eye, surrounding and compressing each lobule. Near the margins of the liver and in some other areas, scar tissue may completely replace the parenchyma. Areas of parenchymal atrophy may occur upstream of some occluded ducts. Microscopically, there is pronounced proliferation of fibrous tissue in and around the portal tracts associated with hyperplasia of well-formed bile ducts (Fig. 2.80). Some areas have prominent neutrophil infiltration into ducts but in many areas this does not occur. In the early stages, the proliferation of bile ducts is often greater than the proliferation of the fibrous tissue, but later the proportions are reversed. The proliferating tissue extends slowly to connect adjacent portal triads, circumscribing areas that correspond to conventional lobules. The fibrous tissue does not permeate along the sinusoids, and there is gradual and uniform constriction of the parenchyma.

This distribution of liver lesions suggests that the harmful factor in alsike clover is excreted into the bile in a form that damages the ducts. However the cholangiohepatitis is similar to that observed in areas of the liver that are drained by chronically obstructed bile ducts, so it seems likely some of the later changes are secondary to cholestasis. Agents that interfere with bile excretion have the potential to interfere with elimination of various potentially injurious substances. Thus it is possible that alsike clover ingestion might increase toxicity of other factors in the forage.

Copper

The heavy-metal copper is an essential trace element, facilitating electron transfer reactions by a number of key enzymes with critical roles in connective tissue cross-linking (lysyl oxidase), antioxidant defense (superoxide dismutase), cellular respiration (cytochrome C oxidase), and catecholamine biosynthesis (dopamine β hydroxylase). However, *copper's redox properties are also responsible for its toxicity at excess concentrations, through mediation of free radical production resulting in direct oxidation of cellular components.* The liver is the major organ involved in the regulation of copper levels, and homeostasis is maintained by the balance of dietary intake and copper excretion via the bile. *Hepatic copper toxicosis can result from a primary metabolic defect in hepatic copper metabolism, altered hepatic biliary excretion of copper, or from excess dietary intake of the element.*

There is significant variation in species susceptibility to copper toxicosis. Sheep as a species are most prone to copper poisoning, due to reduced biliary excretion of copper. Some breeds are more susceptible than others, reflecting differences in the efficiency of intestinal absorption of copper, rather than differences in efficiency of biliary excretion. Altered biliary excretion of copper in sheep does not appear to be associated with alteration in the structure or expression of the gene for ATP7B, the copper transporting P-type adenosine triphosphatase that is defective in Wilson disease, the human autosomal recessive disorder of hepatic copper metabolism, although functional analysis of the protein has yet to be performed.

Copper-associated hepatopathy has been reported as an *autosomal recessive disorder in Bedlington Terriers*, and as a *familial hepatopathy in West Highland White Terriers and Skye Terriers* (see the section on Chronic hepatitis in dogs, above). A single case of a hepatopathy associated with excess hepatic copper concentrations (4074 μg/g) has been reported in a Siamese cat. In dogs and sheep, toxic amounts of copper can accumulate in the liver while dietary copper levels are not excessive by standards for other species. Copper poisoning does occur in cattle and pigs, but in these species it is due to abnormally high intake of the element. Acute copper poisoning can occur following either the ingestion or injection of excess copper, and *animals deficient in vitamin E appear especially susceptible to acute copper poisoning.*

Chronic copper toxicosis in sheep occurs as a result of the presence of three environmental factors acting alone or in concert. First, *excessive copper intake* may occur as a result of contamination of water (naturally occurring or through the use of copper piping or fixtures), pasture or prepared feed; the latter is difficult to avoid when feed mills are preparing rations for different species and is probably partly responsible for the observation that housed sheep are more prone to copper poisoning than animals at pasture. Second, increased copper accumulation occurs as a result of increased availability of dietary copper; this happens when *dietary levels of molybdenum are unusually low.* Molybdenum, in the presence of sufficient sulfate, forms insoluble complexes with copper in the gut and liver, making the copper biologically inert. Subterranean clover growing on calcareous soils in southern Australia may be relatively deficient in molybdenum, and in these areas British breeds of sheep are known to be more susceptible than Merinos to chronic copper poisoning. *Other hepatotoxins* constitute the third environmental factor that predisposes sheep to outbreaks of chronic copper poisoning. The most important of these are pyrrolizidine alkaloids (from *Heliotropium* or *Echium*) in eastern Australia, and phomopsin from lupins in western Australia and, possibly, South Africa.

The basis for chronic copper poisoning in sheep is the peculiar avidity of the liver for copper, coupled with the very limited rate at which this species can excrete the element in the bile. After intraportal injection of a copper isotope, practically all the radioactivity is removed during the first passage through the liver. Most of the copper is sequestered in hepatocellular lysosomes, where it does little damage at concentrations of up to 200–300 μg/g dry weight. As the concentration rises, there is presumably more interaction between other cell components and the copper. There is some evidence that lysosomal membranes lose integrity and allow copper and lysosomal hydrolases to damage the rest of the cytoplasm. By the time the liver copper concentration has reached 300 μg/g or more, there is a histologically apparent increase in hepatocellular turnover, with single hepatocytes undergoing apoptosis within a dense knot of neutrophils. At still higher copper levels, the apoptotic rate increases, while all cells become swollen and their nuclei vesicular. The mitotic rate increases, presumably to keep pace with the accelerated loss of hepatocytes, and large macrophages appear in the sinusoids and stromal spaces about the vessels (Fig. 2.81). These cells contain eosinophilic or somewhat brown, granular debris, which consists of copper-containing lipofuscins.

Sheep with liver copper concentrations in excess of 1000 μg/g may be clinically and hematologically normal, so long as the increasing mitotic rate produces enough new hepatocytes to take up the copper released by dying cells. At this stage, however, there will be elevated levels of liver-specific enzymes in the plasma. If the rate of hepatocellular loss exceeds the capacity of the liver to phagocytose

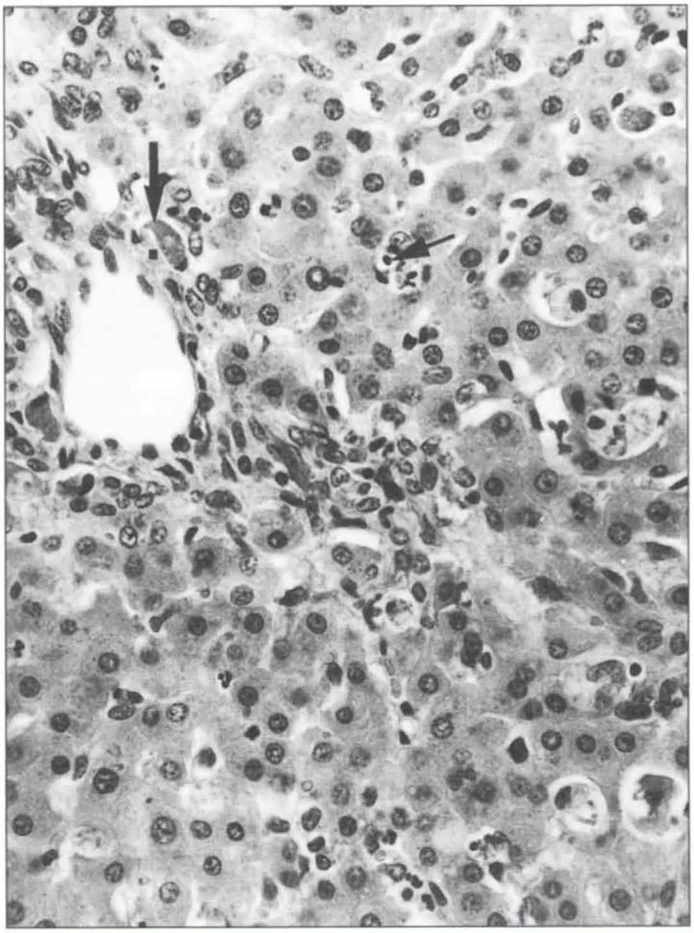

Figure 2.81 Apoptosis (smaller arrow), focal leukocyte aggregation, and pigmented macrophages in sinusoids and stroma (larger arrow) in the liver of a sheep in the prehemolytic phase of **chronic copper poisoning**.

and sequester cell debris quickly, the plasma copper levels can rise to levels that are high enough to damage circulating erythrocytes, and intravascular hemolysis ensues. *The effect of the hemolysis and anemia on the liver is to accelerate the rate of hepatocellular necrosis; thus copper enters the circulation at an increasing rate and acute copper toxic crisis is manifest.* The lethal clinical syndrome is then one of *paroxysmal intravascular hemolysis and liver failure*, in which a sheep may pass from apparent good health to death within ~6 hours. Stresses, such as brief starvation, may also precipitate the crisis in susceptible sheep but the mechanisms involved are unknown. During the hemolytic crisis, some of the copper is lost from the disintegrating liver; some passes into the urine, and kidney copper concentration rises to 1000 μg/g or more. *Blood or kidney copper levels* therefore give a truer indication of a prior hemolytic crisis due to chronic copper poisoning than does elevation of liver copper alone.

The gross lesions of fatal chronic copper poisoning are those of acute copper toxicity. The carcass is discolored by marked icterus, superimposed on which is the red color imparted by free hemoglobin. Often there is a brown hue as well, because a proportion of the hemoglobin is oxidized to methemoglobin. The spleen is engorged, dark, and soft. The kidneys are deep red-brown to black and the urine deep red, as a result of hemoglobinuria with oxidation to methemoglobin, and concurrent icterus. The liver is often slightly soft and swollen, and deep orange, but if the condition arises after long-term liver injury, atrophy and fibrosis may be evident. Other changes such as liver necrosis from various causes, including hypoxia due to anemia, heart failure, and shock, complicate the spectrum of liver lesions.

A breed of sheep from the Hebridean island of North Ronaldsay has apparently adapted to a seaweed diet low in both copper and molybdenum but rich in zinc. *Zinc is also capable of interfering with copper uptake*, and these sheep, while avoiding copper deficiency, are exquisitely susceptible to chronic copper poisoning when transferred to normal pasture. Hepatic disease associated with copper toxicity in this breed appears to differ morphologically from other domesticated sheep breeds. Copper accumulation begins in periportal hepatocytes, accompanied by a mixed inflammatory infiltrate and cholangiolar proliferation. Characteristic pericellular fibrosis, initially confined to the portal tracts and periportal zones, later extends to diffuse fibrosis and cirrhosis, associated ultrastructurally with numerous hepatic stellate cells. North Ronaldsay sheep have been proposed as a possible animal model for human non-Wilsonian hepatic copper toxicosis and cirrhosis of infancy, and for investigation of copper-associated hepatic fibrogenesis.

The events described in sheep also occur in **chronic copper poisoning in pigs and cattle**, and acute intravascular hemolysis may be seen, especially in calves. Usually, however, there is less of the acute terminal chain reaction in these species, and there is more evidence of chronic liver damage with extensive portal fibrosis and biliary hyperplasia within the triads.

Acute copper poisoning *is most often seen in ruminants after accidental administration of single large doses of copper*, by either the oral or parenteral routes. Iatrogenic copper toxicosis has been induced by administering copper oxide boluses to neonatal calves, and by injection with copper disodium edetate in weanling calves. Copper toxicosis has also been reported in veal calves fed milk replacer supplemented with various copper-containing hematinics. The liver lesion varies with chronicity of exposure, from nonspecific acute periacinar necrosis, to cholangiohepatitis with periportal fibrosis. Intravascular hemolysis may occur if plasma copper levels are sufficiently elevated. Acute gastroenteritis may be produced by oral dosage and may also be seen after sufficiently large parenteral doses of copper.

HYPERPLASTIC AND NEOPLASTIC LESIONS OF THE LIVER AND BILE DUCTS

In recent years, much has been learned about the multistep and multifactorial pathogenesis of neoplasia in the liver. This is the benefit of several circumstances that increased the need to understand responses of the liver to carcinogenic insults. Foremost is that *liver cancers are the most common fatal carcinoma in humans*, largely because of their association with endemic hepatitis B virus in Asia and Africa. Second, many xenobiotics have been found to increase the occurrence of liver neoplasms in laboratory rodents, increasing the concern that environmental, foodborne and medicinal hepatotoxins might be avoidable cancer risks. Third, the liver provides an exceptional model in which to observe and characterize the metabolic, cellular, and mutational events underlying the various stages of cancer development.

The available literature on liver neoplasms is immense and beyond the scope of this section, which will deal more with the usual conditions encountered by biopsy or necropsy of domestic mammals. Remarkably, *the occurrence of fatal liver malignancies is rather uncommon in aged dogs and cats*; this suggests that they are either less exposed, or they are more resistant to the etiological agents responsible for liver neoplasms in humans. Nonetheless, *atypical hyperplastic hepatocellular foci and nodules are common in older dogs*, and are increasingly encountered in the imaging and laparoscopic investigation of hepatic diseases in dogs. The reason why such lesions in dogs evidently do not progress to malignancies at the frequencies observed in humans, rodents, and fish remains intriguing and obscure.

Ectopic, metaplastic, and hyperplastic lesions

Ectopic and metaplastic lesions in the gallbladder have been reported. Ectopic tissue includes hepatocyte nodules attached to or within the wall, and pancreatic islands, which may include islets of Langerhans. Gastric ectopia, readily distinguishable by the presence of chief and parietal cells, may form plaques or large polyps. Ectopia of cardiac or pyloric mucosa is mimicked by metaplastic changes.

Hyperplastic nodules of hepatocytes are common in old dogs, but rare in other species. The lesions in dogs do not have a breed or sex predisposition, but their incidence increases sharply with age. Hyperplastic nodules typically develop in livers of normal mass, whereas **regenerative nodules** arise as a result of compensatory hyperplasia of surviving hepatocytes in a background of hepatic injury, atrophy, and fibrosis.

Hyperplastic nodules are usually multiple and randomly distributed throughout the lobes. The grossly visible nodules are spherical, well circumscribed, varying in size from 2 mm to 3 cm or more, and may bulge from the capsular surface. They may be sharply distinct from the surrounding parenchyma due to color differences, either lighter than the surrounding liver due to increased lipid or glycogen content or reduced expression of cytochromes within hepatocytes comprising the nodule, or darker because the sinusoidal vessels are distended with blood. Some nodules are the same color as the surrounding tissue and can only be identified by examination of a washed or blotted slice under a strong light.

The larger hyperplastic nodules grow expansively; they do not induce a fibrous capsule, but they can compress the surrounding parenchyma. The hepatocytes making up the focal hyperplasias are often phenotypically different from those in adjacent parenchyma. Old canine livers often have microscopic focal hyperplasia of similarly altered hepatocytes that can be distinguished from the surrounding parenchyma, but they evidently grow more slowly and do not compress their boundaries. These can be regarded as examples of the numerous atypical focal hyperplasias that arise as altered foci, nodules, plaques, or polyps in various tissues of old dogs. In more prominent paler nodules, hepatocytes can be enlarged and vacuolated with lipid or glycogen accumulation (Fig. 2.82). Mitotic figures are uncommon. The sinusoids of the nodules are often dilated and foci of hematopoiesis are occasionally observed. Necrosis and hemorrhage in hyperplastic nodules are rare.

The significance of hyperplastic nodules in old dogs is usually negligible. After acute liver necrosis, these atypical hepatocytes within preexisting hyperplastic foci and nodules may have phenotypic alterations that confer a survival advantage, and can survive and flourish as larger nodules amid regions of necrosis, so in these instances they can be beneficial. While hyperplastic nodules rarely progress to lesions with detrimental impact, they are often found during liver imaging, laparotomy, or biopsy and need to be differentiated from other focal lesions of more significance. Because they are atypically differentiated, they are the potential source of secreted products of clinical or diagnostic significance but their potential in this regard is unexplored. *The hallmark of the hyperplastic nodule, in contrast to the hepatic adenoma and hepatocellular carcinoma, is that it largely retains normal liver architecture, including a modified lobular structure with recognizable central veins and portal triads.* However this feature may be difficult to appreciate in small biopsies. The biological distinction between atypical hyperplasia and neoplasia is sometimes equivocal; in the latter,

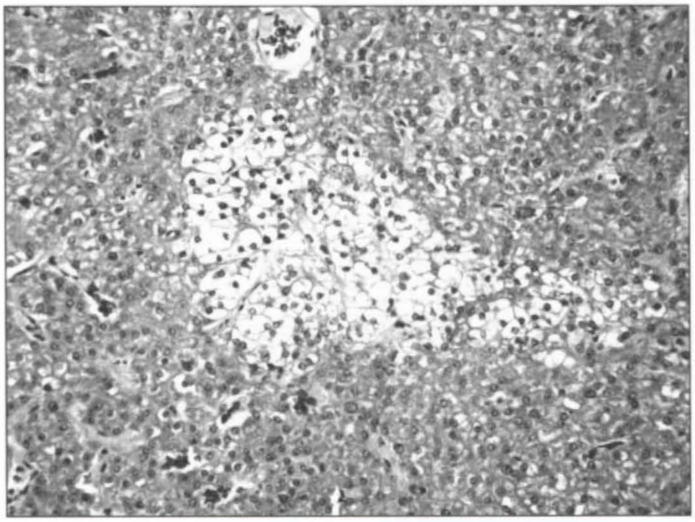

Figure 2.82 Vacuolated hepatocytes in a small **altered focus** in an old dog.

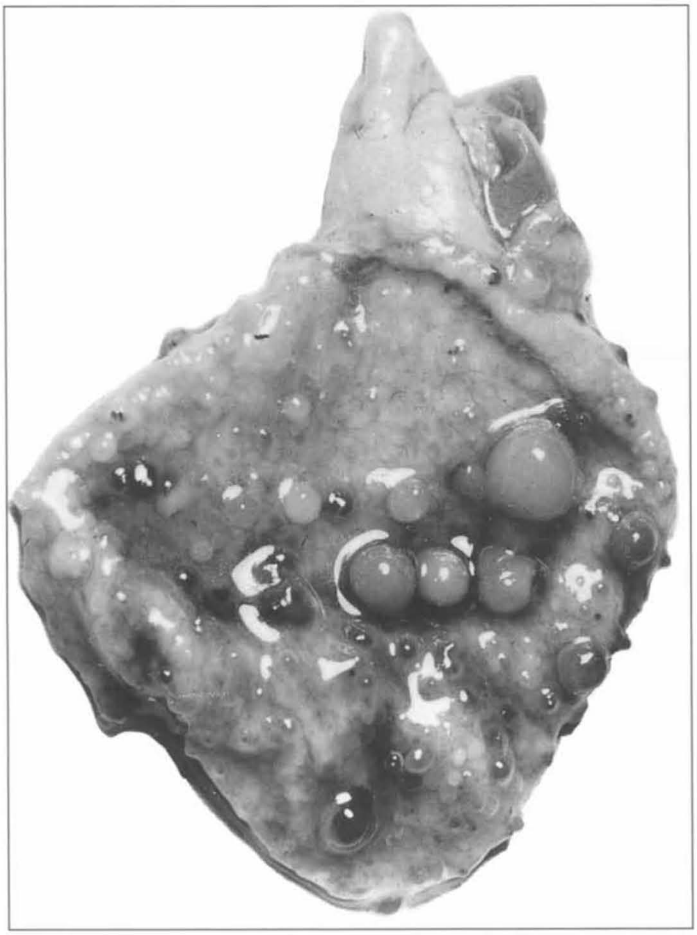

Figure 2.83 **Cystic mucosal hyperplasia** of the gallbladder in a dog.

continued growth that is independent of promoting influences is responsible for enlargement, and the designation of adenoma should apply to larger lesions that are enlarging.

Cystic mucinous hyperplasia *of the mucus-producing glands in the mucosa of the gallbladder* has been reported as an incidental lesion in dogs and sheep. These cystic hyperplastic nodules are often numerous, may be sessile or polypoid, and contain mucin (Fig. 2.83).

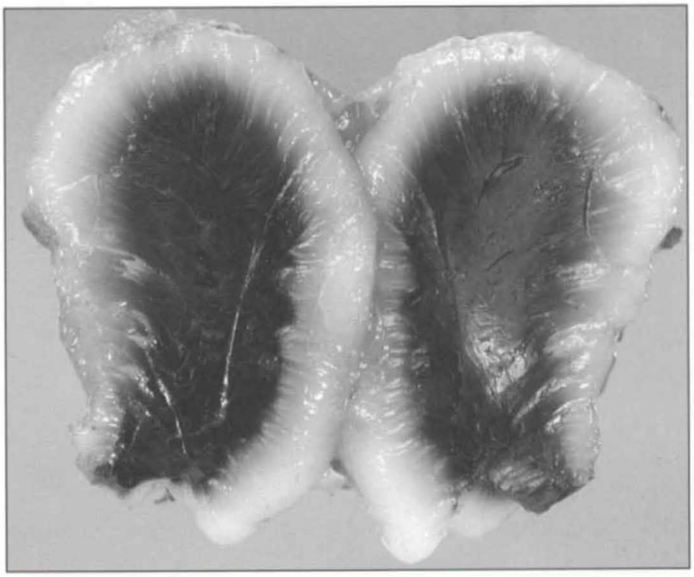

Figure 2.84 **Gallbladder mucocele** in a dog. (Courtesy of AR Vince.)

Dilation of the gallbladder with accumulated mucoid secretion (**gallbladder mucocele**) has been reported in dogs. Histologically, affected gallbladders display hyperplasia of mucus-secreting mucosal glands, as well as formation of mucus-filled cysts. Severely affected gallbladders may be distended with abnormal semisolid accumulations of mucus, and may undergo ischemic necrosis and rupture (Fig. 2.84). Bile-laden mucus may also extend into the cystic, hepatic, and common bile ducts, resulting in variable degrees of extrahepatic biliary obstruction. The etiology of this condition is unknown, and may be related to decreased gallbladder motility, bile stasis, and altered bile composition and viscosity.

Mucosal hyperplasia in the large bile ducts is frequently observed in the long-standing mild cholangiohepatitis of fluke infestation. The hyperplasia is of microscopic dimensions, but in some instances it appears histologically to be atypical. Localized, polypoid foci of cystic hyperplasia are specific changes in cattle poisoned by highly chlorinated naphthalene.

Hepatocellular tumors

Epithelial neoplasms of the liver and bile ducts include tumors of either hepatocellular or cholangiocellular origin, and have been reported much more commonly in dogs and cats than in cattle, horses, sheep, or pigs. *Hepatocellular neoplasms are reportedly more common in dogs, whereas cholangiocellular tumors predominate in cats.* Unlike the situation in humans, there are no clear associations in domestic animals between hepatobiliary tumors and viruses, chemical carcinogens, mycotoxins, or drugs such as synthetic steroids. With the exception of the occasional association of liver tumors with certain flukes or tapeworm larvae, and the rare adenoma seen in the bovine liver with chronic pyrrolizidine poisoning, *hepatobiliary tumors in domestic animals are not obvious successors to antecedent liver disease.*

Hepatocellular adenomas (sometimes termed *hepatomas*) are usually single and they may be 15 cm or more in diameter. The smaller ones project as smooth nodules, but some of the larger specimens are lobate, and some pedunculated (Fig. 2.85). They are soft

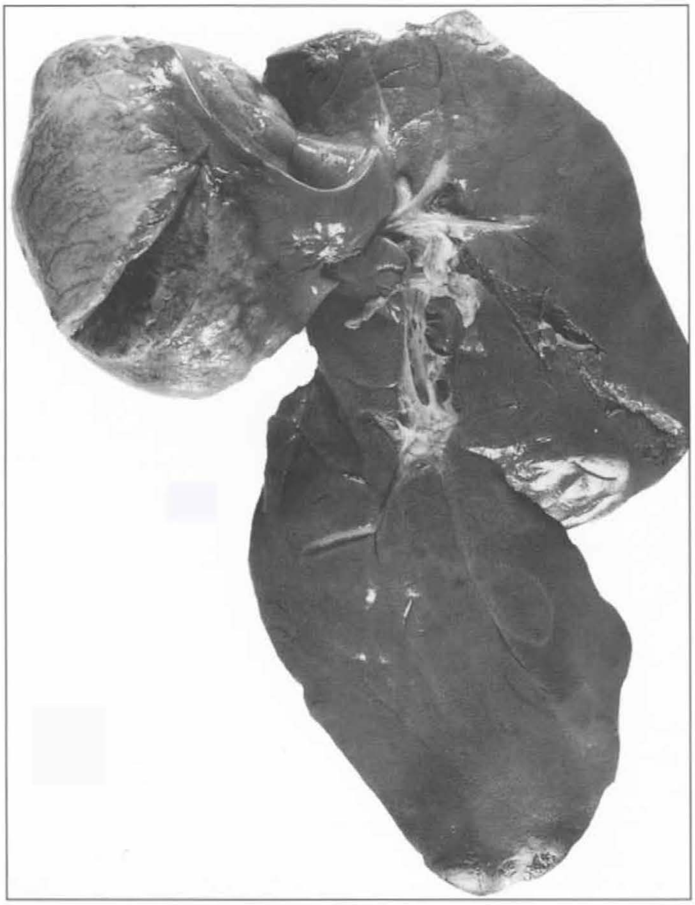

Figure 2.85 Pedunculate **hepatocellular adenoma** in the caudate lobe of the liver in a sheep.

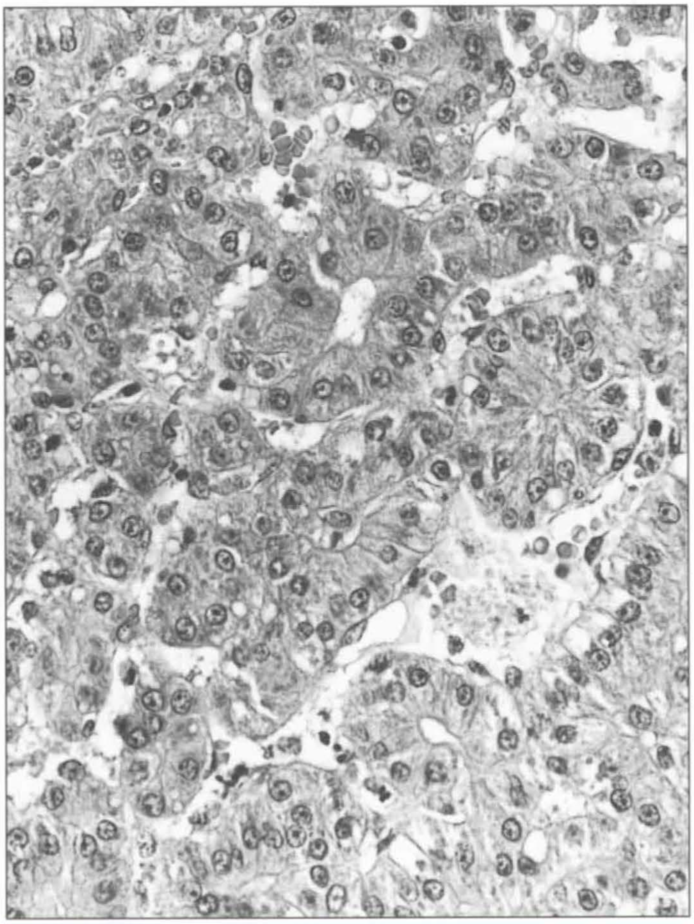

Figure 2.86 **Hepatocellular adenoma** in a dog.

and light brown or yellow; some are pigmented by bile, the remainder of the liver not being pigmented. Demarcation is fairly sharp, and while they compress adjacent parenchyma, they are not typically encapsulated. Histologically, the cells do not differ markedly from normal hepatocytes or hyperplastic nodules, and often contain lipid, glycogen, or occasionally protein secretory vacuoles. *Cells are arranged in cords or trabeculae, but typical acinar structures and vascular architecture are absent* (Fig. 2.86). *Adenomas usually lack central veins and hepatic venules, multiple portal tracts, bile ducts, or cholangioles.* Bile pigments may be present. In sheep, cattle, and dogs, hematopoietic foci may sometimes be found in the adenomas.

Hepatocellular carcinomas are uncommon, and may be single and massive, nodular or diffuse. Several features suggest malignancy, including the absence of pedunculation or clear demarcation and the presence of varied coloration of the cut surface produced by hemorrhage, necrosis, fatty change, and bile pigmentation. Invasion of portal vessels, sometimes clearly evident grossly, is decisive. Some of these tumors in cattle are scirrhous, hard, and white. Carcinomas occasionally penetrate the capsule to implant on the peritoneum. Hematogenous metastases occur first in the lungs, and some appear to arrive in masses to impact in relatively large vessels.

Free venous invasion is typical of the hepatocellular tumors and intravascular spread may extend to the large hepatic veins and vena cava. Retrograde growth in the portal veins may extend to the spleen and the stomach and the resulting portal hypertension and varicose venous shunts assist further spread in portal fields. Spontaneous rupture is common and may cause fatal hemoperitoneum.

Hepatocellular carcinomas may be quite variable in histologic appearance, and multiple patterns may occur within a single neoplasm. *Trabecular carcinomas are the most common histologic pattern.* Neoplastic cells resemble normal liver, and grow in plates or trabeculae that vary from few to many cells thick. Necrosis may be present, and sinusoids may be dilated. Other patterns include *adenoid carcinomas*, characterized by acinar arrangement of neoplastic hepatocytes within scant connective tissue stroma, and *solid carcinomas*, characterized by solid sheets of poorly differentiated, often pleomorphic cells that do not form sinusoids (Fig. 2.87). A feature of some hepatocellular tumors is the presence of giant cells, quite conspicuous by virtue of a large nucleus, multilobed nuclei, or multiple nuclei. Mitotic figures are more frequent in carcinomas than adenomas, but may not be a prominent feature of well-differentiated carcinomas.

Hepatoblastomas, rare benign tumors putatively originating from pluripotent small-cell precursors, have been reported in sheep, dogs, horses, and a bull. Hepatoblastomas in humans are neoplasms of infancy and childhood. Cases in domestic species have been reported in both young and adult animals.

Hepatic carcinoids, presumably arising from neuroendocrine cells, have been reported in both dogs and cats. These are aggressive neoplasms, with frequent intrahepatic spread, and metastasis to local lymph nodes and peritoneum. Like other neuroendocrine tumors,

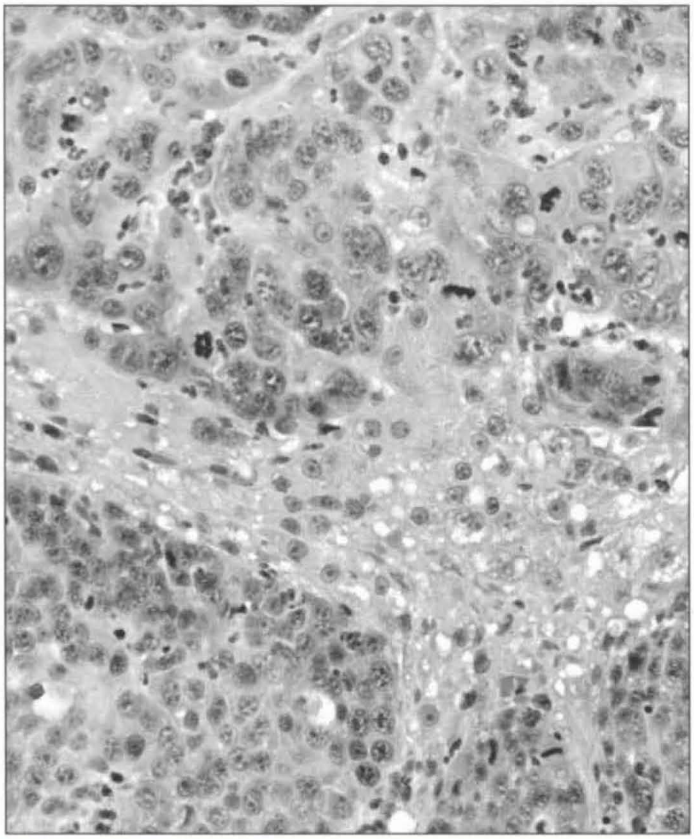

Figure 2.87 Invasive solid **hepatocellular carcinoma** in a dog.

hepatic carcinoids typically form nests of cells separated by a fine fibrovascular stroma. The cells are oval to spindle-shaped, and may form a rosette or pseudolobular pattern. Mitotic figures are usually frequent. Argyrophilic cytoplasmic granules may be detected by silver impregnation stains; more precise identification of carcinoids may require immunohistochemical stains for neurosecretory products such as glucagon or serotonin.

Cholangiocellular tumors

Cholangiomas (cholangiocellular adenomas) are mainly seen in old dogs and cats. Cholangiomas typically arise within the hepatic parenchyma. Extrahepatic cholangiomas are rare, with the exception of gallbladder adenomas reported in cattle in abattoir surveys. The smaller specimens may be solid on the cut surface and white, but the large specimens, and many of the small ones, are cystic, containing a clear watery to viscous fluid. Their volume may be greater than that of the lobe they occupy. The solid specimens are composed of a large number of tubules lined by a single layer of cuboidal biliary epithelium. The stroma varies in amount. There is no sign of active invasion of the parenchyma. **Cystic cholangiomas (biliary cystadenomas)**, a subtype commonly seen in cats, are multilocular and lined by atypical bile duct epithelia that may be flattened by pressure, or in some areas papillary. The septal stroma is collagenous.

Cholangiocarcinomas (cholangiocellular carcinomas) are reported in dogs, cats, sheep, cattle, horses, and goats. These tumors may be massive or multinodular (Fig. 2.88). In dogs and cats, the tumors are almost always multiple or diffuse. The multiple nodules of tumor might represent intrahepatic lymphogenous metastases, but the possibility of multicentric origin must be entertained. Hematogenous metastases are unusual, but metastases to the regional nodes are common. In cats especially, there is a tendency to invade Glisson's capsule and implant on the peritoneum.

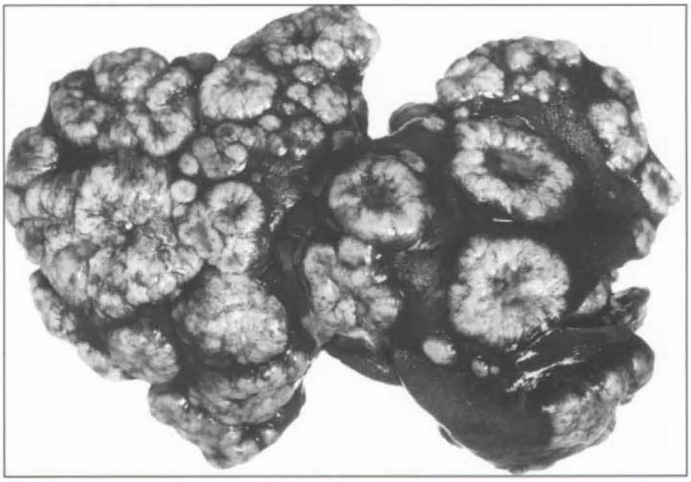

Figure 2.88 Multiple umbilicated foci of **cholangiocarcinoma** in a cat.

Affected livers are usually otherwise normal, with no suggestion as to an underlying cause. In humans, the relatively high incidence of bile duct carcinoma in some regions is related to chronic infestation with opisthorcid flukes, especially *Opisthorchis viverrini* and *Clonorchis sinensis*. Flukes and bile duct tumors have been observed in carnivores. The biliary change usually associated with these flukes is hyperplastic or adenomatoid proliferation of the epithelium and submucosal glands with goblet-cell (intestinal) metaplasia. There is minimal inflammatory change in the absence of superimposed bacterial infection.

Cholangiocellular tumors can usually be distinguished from the hepatocellular variety by their multiplicity, firmness, white color produced by more or less abundant stroma, and the typical umbilicate appearance of those that involve the capsule. The central depressed area can be due to necrosis or cavitation associated with insufficient neovascularization of the central parts of the tumor nodules. Even multiple nodules may not cause much enlargement of the liver, but the diffuse variety may cause great enlargement, although with retention of shape, and severe bile pigmentation.

Microscopically, cholangiocellular carcinoma is usually distinctly adenocarcinomatous, producing ductules and acini, and sometimes papillary formations. The cells are cuboidal or columnar, with a small amount of clear or slightly granular cytoplasm. The nuclei are small and fairly uniform, and nucleoli are not prominent. Mitotic figures are often abundant. The tubules do not contain bile, but in well-differentiated specimens may contain mucin. The epithelial components are separated by fibrous connective tissue stroma, which may have pronounced collagen deposition, the so-called *scirrhous response* that gives the tumor a firm texture. *Cholangiocarcinomas have a highly invasive growth pattern* (Fig. 2.89), and frequently metastasize to hepatic lymph nodes, lungs, and peritoneal cavity.

Primary intrahepatic cholangiocellular carcinoma can be difficult, and often impossible, to distinguish from metastatic adenocarcinomas, especially those of pancreatic origin. Mucus secretion and intrasinusoidal permeation

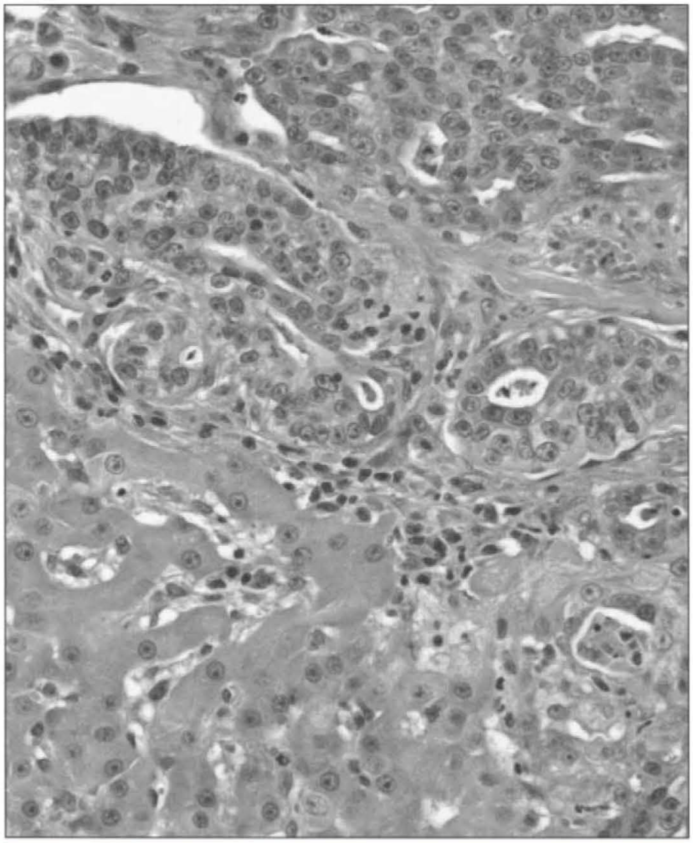

Figure 2.89 Invasive **cholangiocarcinoma** in a cat.

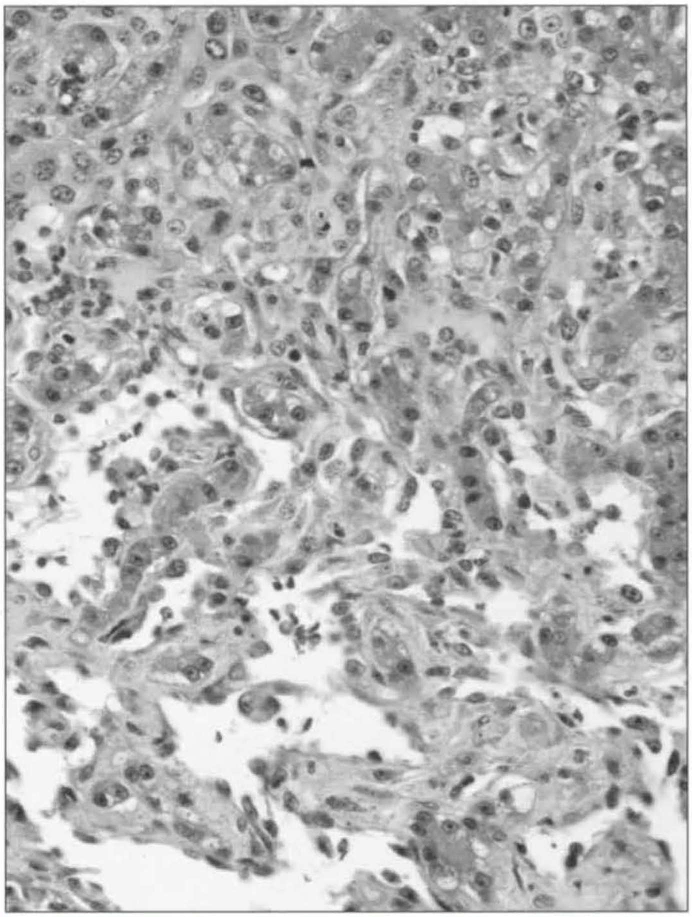

Figure 2.90 Neoplastic endothelial cells in this **hemangiosarcoma** are infiltrating hepatic sinusoids in a dog.

are more typical of biliary origin. Distinction from hepatocellular carcinoma of adenoid pattern may be assisted by demonstration of mucin, abundant mitotic figures, and presence of a prominent connective tissue stroma.

Extrahepatic bile duct adenocarcinoma has been reported in cats, as have adenocarcinoma of the gallbladder, and, more rarely, extrahepatic bile duct neuroendocrine carcinoma, and adenocarcinoma of the hepatopancreatic ampulla. Intramural mineralization of the gallbladder (so-called "porcelain gallbladder" in humans) has been reported in a dog, associated with an adenocarcinoma of the gallbladder neck.

Mesodermal tumors

Primary mesenchymal tumors of the liver are quite uncommon. Benign tumors of smooth muscle (**leiomyomas**) are occasionally observed in the gallbladder of dogs and oxen. **Leiomyosarcomas** and **fibrosarcomas** have been reported in the liver of cats and dogs; a single case of botryoid-type embryonal rhabdomyosarcoma has been reported in a cat. Hepatic **hemangiomas** have been reported in dogs and a pig. Primary **hemangiosarcomas** are seen in dogs, cats, and cattle; hemangiosarcoma of the liver should always be considered metastatic until proven otherwise by diligent search. Some of these tumors are solitary, large, and gray-white, with scattered hemorrhagic areas, and others are ill defined and cavernous. The latter may rupture into the peritoneal cavity to produce severe hemorrhage. Microscopically, it may be impossible to find malignant cells in or lining cavernous areas. At the margins of the tumor, there is a distinctive pattern or growth in which small, solid nodules of malignant cells may be found, or these cells can be found forming capillary structures or invading along preexisting sinusoids. The latter phenomenon is particularly characteristic (Fig. 2.90). As the cells invade along the sinusoids, perhaps in single file, they initially produce little distortion of the hepatic cords. Behind them the sinusoids are spread widely apart, and individual hepatocytes or portions of cords are isolated and appear to be floating freely, surrounded by a thin layer of connective tissue and neoplastic cells.

The **myelolipoma** is an unusual tumor that develops in the livers of domestic cats and wild felidae. The tumor develops as multiple growths in one or more lobes, varying from 0.5 to 5 cm in diameter; if they project above the surface of the liver, they are irregularly nodular. Myelolipomas are friable, and yellow to orange in color due to their high fat content. The neoplasm is composed of normal-appearing, mature adipocytes with a variable admixture of myeloid cells, including both mature and immature cells of the granulocytic, erythrocytic, and megakaryocytic series. In captive wild cats, similar lesions have been seen in the spleen. These were judged to be separate developments of the same process. Metastasis to other organs has not been reported.

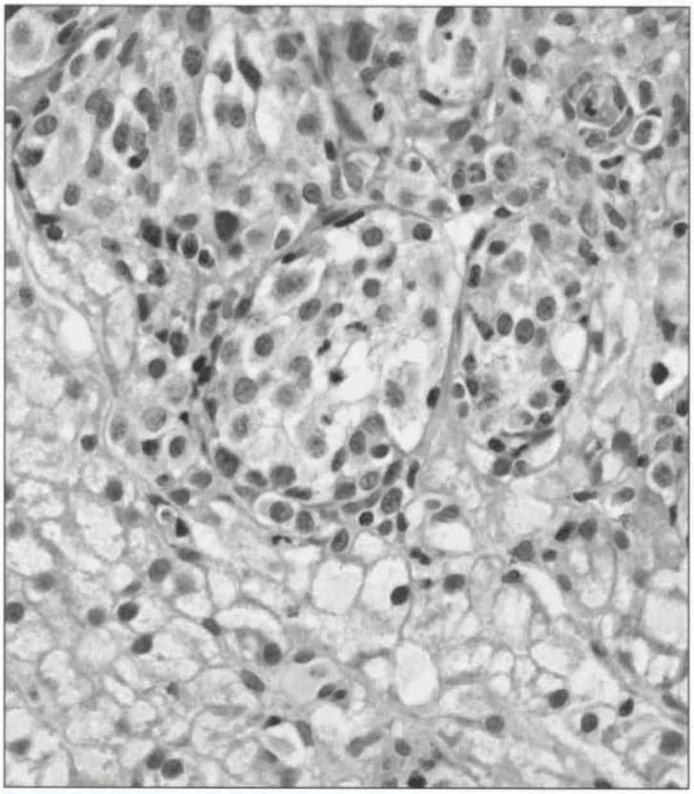

Figure 2.91 Histiocytic sarcoma in the liver in a dog.

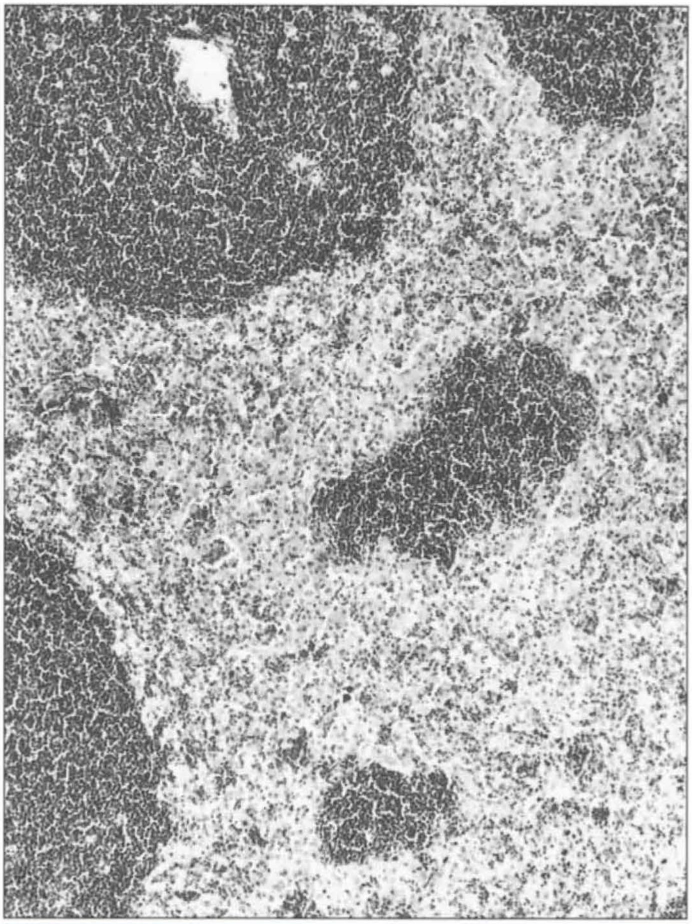

Figure 2.92 The malignant infiltrate in this **lymphoma** is heaviest in the stroma of triads and hepatic venules in a dog.

Metastatic neoplasms

The liver is particularly "fertile soil" that is readily accessible to most metastatic malignancies of the abdominal cavity. Metastatic solid neoplasms may be multiple but are usually not numerous and usually do not elicit clinical or biochemical evidence of hepatic injury or dysfunction. Malignancies arriving via the portal vein, such as pancreatic or gastric carcinoma or hemangiosarcomas, may practically replace the liver before producing clinical signs, one of which may be icterus caused either by extrahepatic bile duct obstruction, or by intrahepatic cholestasis, or both. Some of the carcinomas (e.g., thyroid, mammary), melanoma, and sarcomas from more remote sites also metastasize to the liver via the lungs and hepatic artery, and some (e.g., ovarian carcinoma or mesothelioma) implant on to the capsular surface from within the peritoneal cavity.

The hepatic perisinusoidal and periportal compartments are hospitable to various hematopoietic neoplastic cell types. Accordingly, disseminating lymphomas, malignant histiocytosis, myeloid and erythroid leukemias, and mast cell tumors often localize in the liver along hepatic sinusoids. Some lymphomas, histiocytic sarcomas (Fig. 2.91), and mast cell tumors also produce solid sarcoma masses in the liver. *Lymphoma in the liver is common* (Fig. 2.92), especially when the spleen is involved, and occasionally, the liver appears to be the major or primary site affected. Preferential involvement of the liver, spleen and bone marrow is characteristic of $\gamma\delta$ T-cell lymphomas in dogs. Diffuse infiltration of the liver in myeloproliferative disorders and mast-cell leukemia may cause extreme enlargement of the organ; the infiltrates localize preferentially in and around the sinusoids. Hepatic infiltration may be in discrete nodules 2 cm or more in size, but it is usually diffuse in the connective tissues of the portal triads.

Melanomas and hemangiosarcomas have characteristic gross features in the liver, but most metastatic tumors cannot be distinguished by their gross appearance. Sarcomas do tend to form a few large, smooth-surfaced nodules, and carcinomas do tend to form more nodules and to be umbilicate when in contact with Glisson's capsule. Hemangiosarcomas come from the spleen, usually, and may virtually replace the liver with small, blood-filled caverns. Their microscopic appearance is the same as that of the primary tumors (see above).

EXOCRINE PANCREAS

General considerations

The pancreas is a composite organ consisting of exocrine acinar lobules and endocrine cells. The endocrine cells are especially concentrated in the islets of Langerhans but are also dispersed as individualized cells. Interdependency between the exocrine and endocrine components is expressed anatomically in a *portal circulation* in which afferent blood flow follows a glomeruloid path through the islets before supplying the adjacent acinar tissue. This vascular arrangement enables different islet cell types to modulate the functions of each other and also the exocrine tissue.

Pathological processes of the pancreas, with the exception of acute pancreatic necrosis that may manifest as an acute abdominal crisis, are usually revealed as metabolic disturbances, maldigestion, or cholestasis. There are large reserves of endocrine and exocrine function, and *metabolic and digestive disturbances do not manifest until a large proportion of the organ or of the islets of Langerhans is lost.* Pancreatic disease that does not provoke abdominal pain or compromise biliary drainage can remain clinically silent for prolonged periods.

The pancreas develops from two separate diverticula of the endodermal lining of the portion of the embryonic gut destined to become the duodenum. Pancreatic growth is initiated at sites where the endodermal epithelium contacts endothelium of the vitelline veins and the fusing dorsal aortae. Following endothelial contact, dorsal and ventral buds begin to evaginate. Arising dorsally from the cranial duodenum, the dorsal diverticulum ultimately gives rise to the left lobe of the pancreas and the accessory pancreatic duct. The ventral diverticulum develops from the main stem of the hepatic diverticulum and gives rise to the right lobe of the pancreas and the pancreatic duct. Under the inductive influence of mesenchyme into which it grows, the proliferating epithelium arborizes to form the exocrine ductal system. Epidermal growth factor (EGF) promotes this ductal development. Secretory acinar cells arise directly as diverticula from the sides of the smaller terminal branches of developing ductal epithelium very early in organogenesis. The endocrine tissue is also of endodermal origin and its differentiation precedes that of the exocrine elements. Endocrine differentiation is promoted by transforming growth factor-β_1 (TGF-β_1) and by contact with vascular endothelium.

The early embryonic pancreas widely expresses the homeobox gene *pancreatic duodenal homeobox factor-1* (*PDX1*). This gene plays an essential role in pancreatic development. Its targeted mutagenesis in mice leads to arrest of pancreatic development at the bud stage, although insulin- and glucagon-positive cells still differentiate. In adult life, expression of this gene is almost exclusively restricted to β cells of the islets in which it is believed to act as a key transcription factor for insulin. The basic helix–loop–helix gene, *p48*, is thought to be responsible for committing pluripotent endodermal cells to exocrine pancreatic differentiation.

Rotation of the hepatic and the ventral pancreatic diverticula results in apposition and partial fusion of the dorsal and ventral pancreatic anlagen. The duct systems of the two pancreatic anlagen also fuse to produce an anastomotic network, although this process may fail so that pancreatic development is incomplete.

There are differences between and within species as to which of the embryonic ducts serves as the main conduit in the developed pancreas. The *accessory pancreatic duct*, which enters the descending duodenum at the minor duodenal papilla, does not persist in small ruminants and in the majority of cats; it is the major duct in the dog, the lesser duct in the horse, and the only duct in the pig and ox. The *pancreatic duct* is the only duct in small ruminants and most cats and is the main duct in the horse; in dogs, it is the lesser duct and is occasionally absent. It opens into the cranial duodenum at the major duodenal papilla, with or immediately adjacent to the bile duct.

The mature ductal system is in two compartments: the *main collecting and interlobular ducts* lined by columnar mucus-secreting epithelium, and the *intralobular ducts* to which the acinar and endocrine cells are ontogenetically related. The latter relationships may explain the mixture of cell types that may be observed in pancreatic adenocarcinomas. Some of the intralobular ductules (which are synonymous with intercalated ducts) may terminate in a single spheroidal acinus. However, in humans and dogs and probably other species, the intralobular ductules tend to form anastomotic loops in which multiple acini may drain via branches of the same ductule. This three-dimensional arrangement helps to explain some of the lesional patterns seen in the exocrine parenchyma in chronic ductal obstruction. There may also be continuities between acinar cells of adjacent acini. Acinar cells are electrically coupled through tight junctions to form functional units that are larger than single acini; this arrangement is often reflected in pathological processes of hyperplasia and atrophy in which the target unit may be a collection of acini.

The lobules of the pancreas are separated by fine connective tissue septa that extend from the capsule. In general, each lobule receives blood from a single arterial branch and much of the circulation to the acinar parenchyma is supplied by a portal system of capillaries that emerge from the sinusoids of the islets. In species other than the horse, exocrine tissue distant from islets is perfused directly from arterial branches. The acinar portal circulation allows the islet hormones to exert trophic or inhibitory effects on acinar cells. *Insulin, in particular, and pancreatic polypeptide are trophic for acinar tissue; somatostatin and glucagon are inhibitory.*

The pancreas receives extrinsic *innervation* from the sympathetic and parasympathetic nervous systems and axons of enteric neurons also project to it. An intrinsic neural component is also present, with ganglia being randomly scattered throughout the parenchyma. These ganglia are thought to operate as *pacemakers* controlling endocrine and exocrine secretion. Pancreatic neurons synthesize, store, and release several biologically active substances, including acetylcholine, norepinephrine, encephalins, nitric oxide, vasoactive intestinal peptide, gastrin-releasing peptide, galanin, and neuropeptide Y. Alterations to the neural network are known to occur in humans and cats with chronic pancreatitis and dogs with pancreatic acinar atrophy, possibly as a compensatory mechanism to support secretory function or to stimulate tissue repair. How the various neurotransmitters control the pancreatic microcirculation and modulate the function of the exocrine and endocrine cells in health and disease is incompletely understood.

The major function of the exocrine pancreas is the synthesis and secretion of **digestive enzymes**. Acinar cells secrete trypsinogens, chymotrypsinogens, proelastases, procollagenase, procolipase, prophospholipase A_2, and procarboxypeptidases as inactive proenzymes, whilst amylase and lipase are secreted in their active forms. The proenzymes and enzymes are packaged within acinar cells into membrane-bound zymogen granules. Stimulation of exocrine secretion is mediated via vagal innervation and by release of secretagogues by endocrine cells of the duodenal mucosa. Entry of gastric acid and fatty acids into the duodenum causes local release of secretin which in turn stimulates secretion of water and bicarbonate by pancreatic ductal epithelium, particularly by the centroacinar cells that line the initial part of the intralobular ductules. The bicarbonate contributes to neutralization of gastric acid in the duodenum. However, this is not essential for maintaining a neutral pH for optimal activity of the digestive enzymes as the duodenal mucosa itself has an enormous capacity to secrete bicarbonate and absorb hydrogen ions. The presence of undigested lipid and amino acid peptides in the duodenal lumen promotes release of *cholecystokinin* (CCK) by mucosal endocrine cells; this secretagogue promotes rapid discharge of digestive enzymes from zymogen granules into the ducts. CCK also has a direct, rapid, and substantial trophic effect on acinar cells, as does its analogue cerulein; this effect is normally inhibited by trypsin. The observation in the 1940s of pancreatic hypertrophy in animals fed diets rich in soybeans was explained by the presence of a trypsin inhibitor in the feed.

Within the duodenum, exocrine secretions also inhibit bacterial proliferation, exert a trophic effect on the mucosa, and contribute to the normal degradation of exposed mucosal brush border enzymes. The exocrine pancreas also produces *intrinsic factor*, which is essential for the absorption of cobalamin (vitamin B_{12}) in the ileum. In addition, the organ plays an important role in *zinc homeostasis*, accumulating zinc absorbed from the intestines and secreting it into pancreatic juice. This function is partly mediated by the zinc-binding protein, metallothionein, which is present in acinar cells and exocrine secretions.

Several mechanisms protect the pancreas from autodigestion. From the earliest stages of synthesis, digestive proenzymes and enzymes are segregated into the lumen of the rough endoplasmic reticulum of the acinar cells. This sequestration is maintained during processing in the Golgi apparatus, where packaging into zymogen granules takes place. Enzymatic cleavage of an activation peptide from trypsinogen is usually initiated in the duodenal lumen by enterokinase secreted by duodenal mucosal cells. The activated trypsin cleaves activation peptides from the other digestive proenzymes. Muscular sphincters in the pancreatic ducts prevent reflux of activated enzymes from the duodenal lumen. If normal acinar secretion is inhibited, lysosomal hydrolases within acinar cells are capable of degrading zymogen granules. Protease inhibitors are also important defences against autodigestion. Acinar cells synthesize pancreatic secretory trypsin inhibitor and α_1-protease inhibitor (α_1-PI) (which is synonymous with α_1-antitrypsin). These inhibitors are released with the zymogen granules into the ducts. α_1-PI is also present in circulation and in intercellular spaces and acts as a readily diffusible, transient inhibitor of serine proteases. Also in circulation are α_1-macroglobulin and α_2-macroglobulin, which irreversibly bind serine and other proteases prior to removal by macrophages.

The exocrine pancreas is a labile organ. It synthesizes much more protein on a weight-for-weight basis than does any other tissue and consumes a correspondingly large amount of precursor substrate. The response of the exocrine pancreas to changes in nutrient intake is rapid, and adaptation to new diets can produce dramatic alterations in the composition of pancreatic juice. *Secretion of proteases* is a reflection, in part, of dietary protein levels; *amylase secretion* is influenced by the level of dietary carbohydrate and by plasma levels of cortisol and insulin. The dietary influence on *lipase secretion* is less clear but secretion is to some extent dependent on dietary protein levels. Acinar cell hypertrophy and hyperplasia leading to organ enlargement occur in response to diets rich in protein and energy. When these substrates are withdrawn, the organ reverts to normal mass via autophagy and apoptosis. If dietary protein and energy become suboptimal, acinar cells and the exocrine organ atrophy.

Maternal malnutrition during gestation and lactation may retard maturation of the exocrine pancreas of the offspring. Paradoxically, the enzyme content of the pancreas may increase in the offspring; whether this increase enhances the ability of the offspring to resist malnutrition remains unclear.

The exocrine pancreas is normally functionally immature at birth, and synthesis of some digestive enzymes may not commence until several weeks postnatally. Enzymatic activity of milk and proximal intestinal secretions compensate for this insufficiency in suckling animals. The weight of the pancreas increases rapidly during the immediate postnatal period, chiefly because of an increase in the number rather than size of acinar cells. Colostrum, which contains growth-promoting factors such as epidermal growth factor (EGF) and insulin-like growth factors, plays a role in this early organ growth. Release of endogenous gut hormones such as gastrin that have trophic effects on the pancreas may also contribute. Glucocorticoids promote maturation of the acinar cells, and the enzyme activity of the organ increases with age in the perinatal period. At weaning, dietary and hormonal changes combine to cause abrupt increases in pancreatic enzyme synthesis and secretion. In animals weaned early, the surge in circulating glucocorticoids is considered to be more important than the dietary changes in triggering the alterations to enzyme output.

In aged humans, the weight of the pancreas declines and there may be intralobular fibrosis, degranulation and atrophy of acinar cells, and ductal epithelial hyperplasia. These involutionary changes are associated with decreases in the volume of pancreatic secretions and in their content of bicarbonate and digestive enzymes. The responsiveness of the human pancreas to such secretagogues as secretin and CCK also diminishes with advancing age. Altered exocrine pancreatic structure and function are likely in aged domestic animals but are yet to be described.

Acinar, ductal, and islet cells are all capable of **regeneration**. Rapid regeneration of exocrine parenchyma may follow acinar destruction. Slower regeneration of both exocrine and endocrine elements follows partial surgical ablation. Complete restitution of exocrine parenchyma by mitotic division and hypertrophy of viable acinar cells may follow minor cell loss. Extensive or persistent parenchymal injury may provoke proliferation of ductular epithelium and connective tissues. *The success of pancreatic repair following injury is influenced by the activity of various peptide growth factors, by the integrity of the blood supply and excretory ducts, and by competitive fibrogenesis.*

Ductular epithelium has the potential to differentiate towards acinar cells, islet cells, and even hepatocytes. Known stimuli of mitotic division of ductular epithelial cells include EGF, keratinocyte growth factor, and TGF-α.

Stellate cells akin to those of the liver have been identified in the normal pancreas in a periacinar location and appear to be the major mediators of pancreatic fibrogenesis. In the quiescent state, pancreatic stellate cells express desmin but not α-smooth-muscle actin (α-SMA). Following activation by injury, these cells acquire a myofibroblastic phenotype and express α-SMA. They proliferate in response to platelet-derived growth factor (PDGF), and, in response to TGF-β, synthesize fibrillar collagens, including collagen I. Macrophages may release both PDGF and TGF-β, but injured acinar cells adjacent to sites of fibroplasia appear to be a significant paracrine source of TGF-β. Activated stellate cells are themselves capable of producing TGF-β_1. They also express matrix metalloproteinases (MMPs), which are capable of degrading extracellular matrix components, and tissue inhibitors of these. As TGF-β_1 reduces the expression of MMP-3 and MMP-9, pancreatic fibrosis may be a consequence of both increased collagen synthesis and reduced collagen degradation.

Developmental anomalies of the exocrine pancreas

With a few important exceptions, anomalies of the exocrine pancreas and its ducts are usually of little clinical importance.

Agenesis or **aplasia** (complete absence) of the pancreas may be associated with more generalized and severe malformations incompatible with survival.

Pancreatic hypoplasia *occurs sporadically in calves.* The defect is in the exocrine tissue; the islets are normal in number and morphology. The hypoplastic organ is small, pale, and loosely textured. Its margins are poorly defined, but the parenchyma is centered on a normal duct system. Microscopically, acinar tissue is present as small scattered clusters of cells in glandular array. Some of the cells may appear well differentiated and contain zymogen granules, but most are small, basophilic, and of indifferent type. Affected calves have clinical signs of exocrine pancreatic insufficiency. Pancreatic hypoplasia was originally described in dogs, but the condition is now regarded as an atrophic rather than hypoplastic disorder.

Variations in the disposition of the ducts *are common in dogs.* Most dogs have two separate ducts opening into the duodenum, with interductal anastomoses within the pancreas, and with the accessory pancreatic duct the major conduit. A small percentage of dogs may have only an accessory duct entering the duodenum, and some may have three functional openings into the intestine.

Connection of the pancreas to the spleen by a band of pancreatic tissue has been described as a congenital anomaly in a piglet. An **annular pancreas**, *characterized by a thin flat ring of normal pancreatic tissue completely encircling the duodenum*, has also been observed in dogs and piglets; the annulus may cause duodenal stenosis. This anomaly probably reflects failure of normal embryonic rotation of the duodenal anlagen.

Congenital stenosis or **cystic dilation of a pancreatic duct** is occasionally reported in domestic animals, and *congenital intrapancreatic cysts* lined by squamous or low cuboidal epithelium are occasionally seen in lambs. Cystic dilation of intra- and interlobular pancreatic ducts accompanied by polycystic kidneys and cystic bile ducts is reported in piglets and goat kids. A primary inherited defect in epithelial cell growth and differentiation is suspected. Affected animals typically develop renal failure.

Saccular ductal distension to form a structure resembling a gallbladder and termed a **pancreatic bladder** occurs rarely in cats. Such cysts may be congenital or acquired. They are usually asymptomatic, but large cysts may compress the bile duct to cause jaundice. *True congenital duplication of the gallbladder* with the accessory organ arising from the ventral pancreatic bud has also been observed in cats.

Ectopic or **accessory pancreatic tissue** is rarely identified. In dogs, small pancreatic nodules may be found in the submucosa or muscularis of the stomach or intestine (especially in the duodenum), the mesentery, gallbladder, spleen, or liver. Ectopic pancreatic tissue has been described in the spleen in cats. The ectopic rests are of normal morphology, although islets are not always present. The rests are presumed to be functional but a ductal outlet may not be demonstrable. Ectopia may result from dislocation of portions of the duodenal buds during development, by persistence of an anlage that would normally regress, or by activation of pancreatic transcription factors within pluripotential endodermal epithelium. In humans, ectopic pancreatic tissue is increasingly recognized in association with abnormal gut peristalsis, with gut mucosal inflammation or ulceration, and as a site of neoplastic development. No such association has been made in domestic animals.

Intrapancreatic hepatocytes are occasionally observed as an incidental finding, especially in neonates. Hepatocytes may also appear in the adult pancreas during attempted regeneration after massive lobular injury. According to experimental data, the origin of the hepatocytes can vary. Transdifferentiation of acinar cells can occur directly, without intermediate cell division, and can be induced *in vitro* by administration of synthetic glucocorticoids. Alternatively, the hepatocytes may be derived from pancreatic ductular and periductular interstitial cells capable of multidirectional differentiation. Such pancreatic stem cell equivalents may be akin to the oval cells of the liver. The hepatocytes may be found as individualized or clustered cells within the exocrine parenchyma, ductal epithelium, or even islets.

Pacinian corpuscles are normally prominent in the interlobular connective tissues of the pancreas of the *cat*, and may be grossly visible as discrete nodules 1–3 mm in diameter.

Regressive changes of the exocrine pancreas

Degeneration, necrosis, and atrophy

The exocrine pancreas is a labile organ that is susceptible to many adverse influences. Degeneration or necrosis of individual acinar cells may occur in various local and systemic disorders, including febrile states, viral infections, intoxications, hypovolemic or septic shock, nutritional deficiencies and cachectic disorders, and with prolonged fasting. Degeneration of acinar cells is always a component of exocrine pancreatic atrophy, and is also expected when inflammatory, necrotizing, or neoplastic processes involve the pancreas.

Pancreatic degeneration should not be confused with postmortem autolysis. **Autolysis** is rapid and is accelerated by high temperatures and by rough handling of the organ at necropsy, with cell rupture and release of digestive enzymes. The color of the organ may grossly deepen to a dark red-brown or green as autolysis progresses. Postmortem hemorrhage into the interstitium of the body of the pancreas is frequently seen in dogs and horses. Patchy autolysis is common in histological material, with the affected areas appearing blanched, tending to resist eosin, and staining slate-gray with hematoxylin. Autolytic dissociation of exocrine cells and nuclear pyknosis may develop by 4 hours after death.

Apoptosis is accompanied by little or no inflammation. *Apoptosis is responsible for cell deletion during embryonic development, normal involution, pathological atrophy, and during regression of hyperplastic organs.* It can also mediate cell loss following mild cellular injury. Apoptosis often occurs in the pancreas but is infrequently described. It is a distinctive change ultrastructurally but can be easily confused with cell necrosis at the light microscopic level. Apoptosis has been observed as the principal means of acinar cell loss in zinc toxicity in ducklings, and is also reported in experimental duct ligation, after lipopolysaccharide administration, and in pancreatic involution following hypertrophy.

Acinar cells that have undergone degeneration are usually smaller than normal. The nucleus moves centrally and there is variable loss of zymogen granules. In fatty degeneration, the cytoplasm may contain single large clear vacuoles or numerous small vacuoles. In many conditions, degenerate and necrotic acinar cells are interspersed. Necrotic cells shrink and are often surrounded by narrow clear halos. The cytoplasm may be vacuolated or hypereosinophilic, and the nucleus appears pyknotic or karyorrhectic.

Multifocal pancreatic degeneration and necrosis *involving small clusters of acinar cells is a common microscopic finding in systemic infections with epitheliotropic viruses.* Associated inflammation is often minimal. In most cases, the lesions are incidental to the course of the disease unless release of digestive enzymes magnifies the process or significant injury is also sustained by islet cells. Agents responsible include adenoviruses in several species (Fig. 3.1), *Canine distemper virus* and *Canine parvovirus*, *Felid herpesvirus 1*, *Foot-and-mouth disease virus*, *Encephalomyocarditis virus*, *African swine fever virus*, and virulent strains of *Classical swine fever virus*. Low-virulence strains of *Classical swine fever virus* can be responsible in congenitally infected piglets. In both classical swine fever and African swine fever, necrosis of islets may be more pronounced than that of acinar cells. Multifocal degeneration and necrosis may also be seen in many intoxications, including trichothecene mycotoxicosis of pigs due to consumption of T-2 toxin, deoxynivalenol (vomitoxin), or diacetoxyscirpenol (anguidine) produced by *Fusarium* species. These mycotoxins may also cause pancreatic interstitial edema, hyperplasia of ductular epithelium, and necrosis of islet cells.

Acinar degeneration, necrosis, and resultant exocrine pancreatic atrophy may be produced experimentally in rodents by administration of ethionine or excess arginine, methionine, or phenylalanine. In some of these experimental models, massive necrosis of the pancreas may ensue and there may be necrosis of peripancreatic and more distant adipose tissue. Experimental selenium toxicity (particularly organic selenium) has produced pancreatic edema, hemorrhage, and necrosis in pigs. Intoxication by *Cassia occidentalis* may also cause necrosis of acinar cells in pigs.

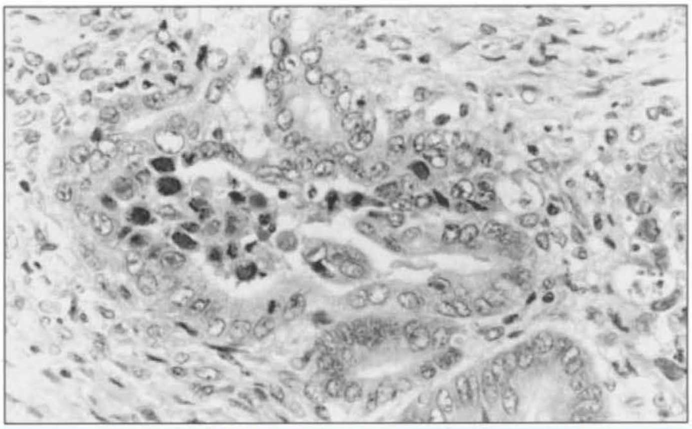

Figure 3.1 Intranuclear adenoviral inclusion bodies in the pancreatic ductal epithelium of a foal with combined immunodeficiency.

Zinc toxicity *causes striking pancreatic lesions in several species.* Pancreatic damage has been produced experimentally in cats, sheep, calves, chickens, and ducklings and has been observed in naturally occurring intoxications of caged birds, dogs, sheep, and calves and in piglets receiving total parenteral nutrition. Zinc toxicity may cause mild nephrosis in several species, bone and joint lesions resembling osteochondrosis in pigs, Heinz body hemolytic anemia in dogs, and necrotizing abomasitis and duodenitis in ruminants, but the pancreas bears the brunt of the injury in subacute and chronic exposure and is often the only organ in which lesions are found.

Toxicity may result from ingestion of zinc from zinc-plated or galvanized metal surfaces or recently minted pennies, from topical use of zinc oxide creams and lotions, from formulation errors in feed or milk replacers, or from prophylactic or therapeutic use of zinc salts for conditions such as facial eczema in sheep and cattle.

There are qualitative differences amongst species in the pancreatic lesions but, in all, *degeneration and necrosis of exocrine elements dominate, with exocrine atrophy and fibrosis developing in chronicity.* The islets are usually unaffected. In chronic stages, atrophic acinar cells without discernible zymogen granules may form dilated ductule-like structures embedded in scar tissue (Fig. 3.2). These structures are sometimes referred to as *tubular complexes* and are often mistaken for hyperplastic ductules. Some tubular complexes may be lined by attenuated ductular rather than acinar epithelium; these are thought to be a consequence of dilation or other modification of pre-existing intercalated ducts.

In piglets, the acinar cells appear to be targeted and undergo necrosis and progressive atrophy, with ultimate development of severe interstitial fibrosis. Acinar cells are also targeted in ducklings, but are deleted by apoptosis.

In sheep and, to a lesser extent, cattle, ductal epithelium appears to be the target of early necrosis. Inflammation, acinar degeneration and necrosis, and interstitial fibrosis are largely centered on the damaged ducts. In many respects, the lesions in ruminants resemble those of pancreatic duct obstruction and may in part result from obstruction

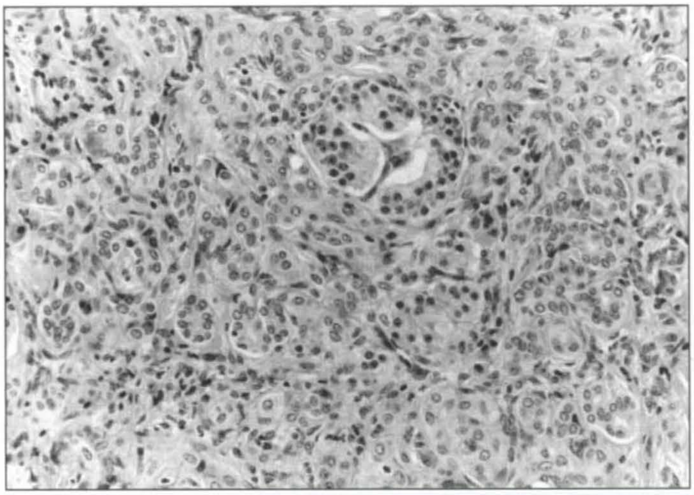

Figure 3.2 Tubular complexes (ductule-like structures) at the periphery of a lobule in a cow with **chronic zinc toxicity**.

of the ducts by debris and inflammation. However, the lesions of zinc toxicity tend to develop at a slower rate and there is less uniform involvement of lobules than is the case in duct obstruction.

Lipomatosis of the pancreas occurs occasionally in cats, pigs, and cattle, usually as part of generalized obesity but sometimes restricted to the pancreas. Adipose tissue accumulates in the interstitium and disperses the parenchyma to create a false microscopic impression of diminished exocrine mass with fatty replacement. Although there may be some pressure atrophy of the parenchyma, *lipomatosis is not functionally significant.*

Pancreatic lipofuscinosis is occasionally seen in *dogs deficient in vitamin E.* Accumulation of lipofuscin causes khaki to brown discoloration of the pancreas and of *intestinal smooth muscle* grossly; the urinary bladder and mesenteric lymph nodes may also be affected. The golden-brown pigment granules in the basal cytoplasm of pancreatic acinar cells and intestinal myocytes are periodic acid–Schiff-positive, sudanophilic, and weakly acid-fast. Microscopic pigment accumulation may occur in other tissues, including the pigmented epithelium of the retina.

Vacuolation of exocrine acinar, ductal epithelial and islet cells due to accumulation of substrates in lysosomes can be seen in *storage disorders* such as α- and β-mannosidosis and galactosialidosis. Vacuolation of ductal epithelium due to glycogen accumulation is a feature of *diabetes mellitus.*

Exocrine pancreatic atrophy is common but is often overlooked. It may be primary or secondary to other disorders of the pancreas or its ducts. Juvenile pancreatic atrophy of primary type is a common syndrome in dogs and is discussed separately below.

In **primary atrophy**, the organ is diffusely and uniformly affected. A decrease in mass is usually the only gross abnormality discernible, although fatty infiltration may occasionally be noted. Microscopic changes are often subtle.

Acinar cells undergo atrophy if dietary protein or energy levels are suboptimal. Diffuse atrophy of the organ is common in domestic animals in starvation, prolonged anorexia, cachexia, protein-caloric deficiency, and maldigestive and malabsorptive syndromes. In protracted starvation, the pancreas may be reduced to less than 10% of normal mass. Other tissues, particularly the liver, may also atrophy in these conditions. Diffuse pancreatic atrophy may also result from deficiencies of essential amino acids, vitamin A or trace elements such as zinc, copper, and selenium (Fig. 3.3).

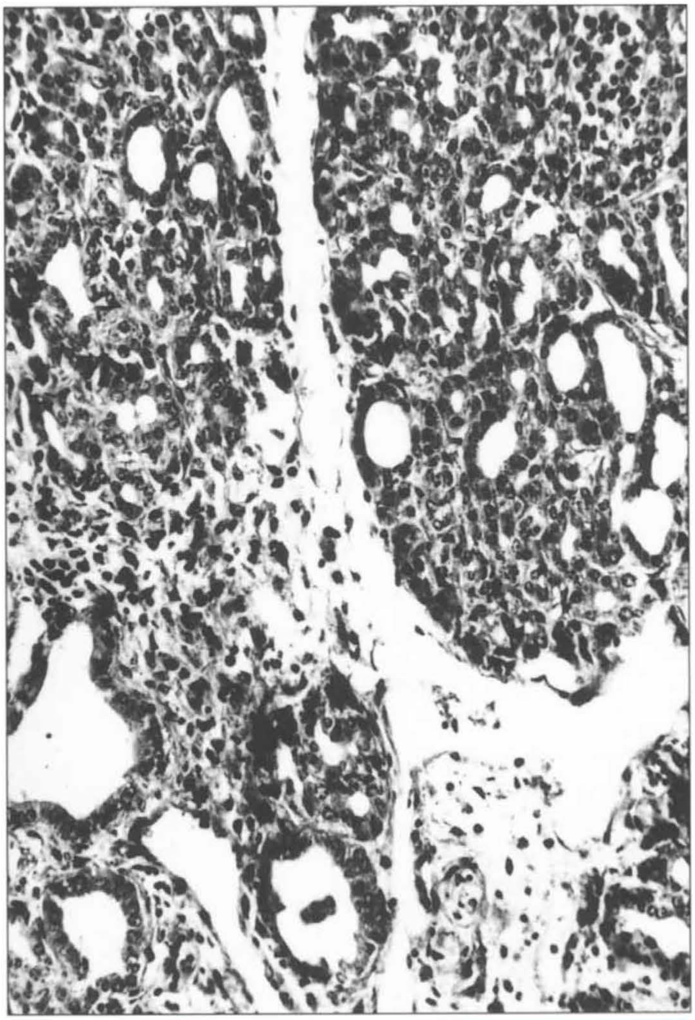

Figure 3.3 Atrophy of acinar parenchyma and dilation of ducts in **vitamin A deficiency** in a calf.

Acinar atrophy may be a consequence of altered intracellular metabolism or the cells may be indirectly affected by changes to the interstitium. The molecular pathogenesis undoubtedly differs according to the cause. In atrophy of copper deficiency, for example, experimental evidence suggests that the initial alteration may involve the basement membranes of acinar cells and the adjacent interstitium, leading to acinar cell dissociation. Irrespective of the cause, *acinar atrophy is characterized microscopically by progressive depletion of zymogen granules, cell shrinkage, and cytoplasmic basophilia* (Fig. 3.4A, B). Cytoplasmic vacuolation may be prominent. Ultrastructurally, autophagic vacuoles develop rapidly within acinar cells undergoing atrophy and residual bodies are freely extruded. Apoptosis may be widespread. The cells lose their polarity and dissociate so that the glandular arrangement is lost, with the small, darkly staining cells arranged into diffuse sheets. The reduction in number and size of acinar cells increases the prominence of the ductular system and of the interstitial connective tissue.

Secondary pancreatic atrophy is the result of local processes, particularly duct obstruction but also interstitial fibrosis, chronic

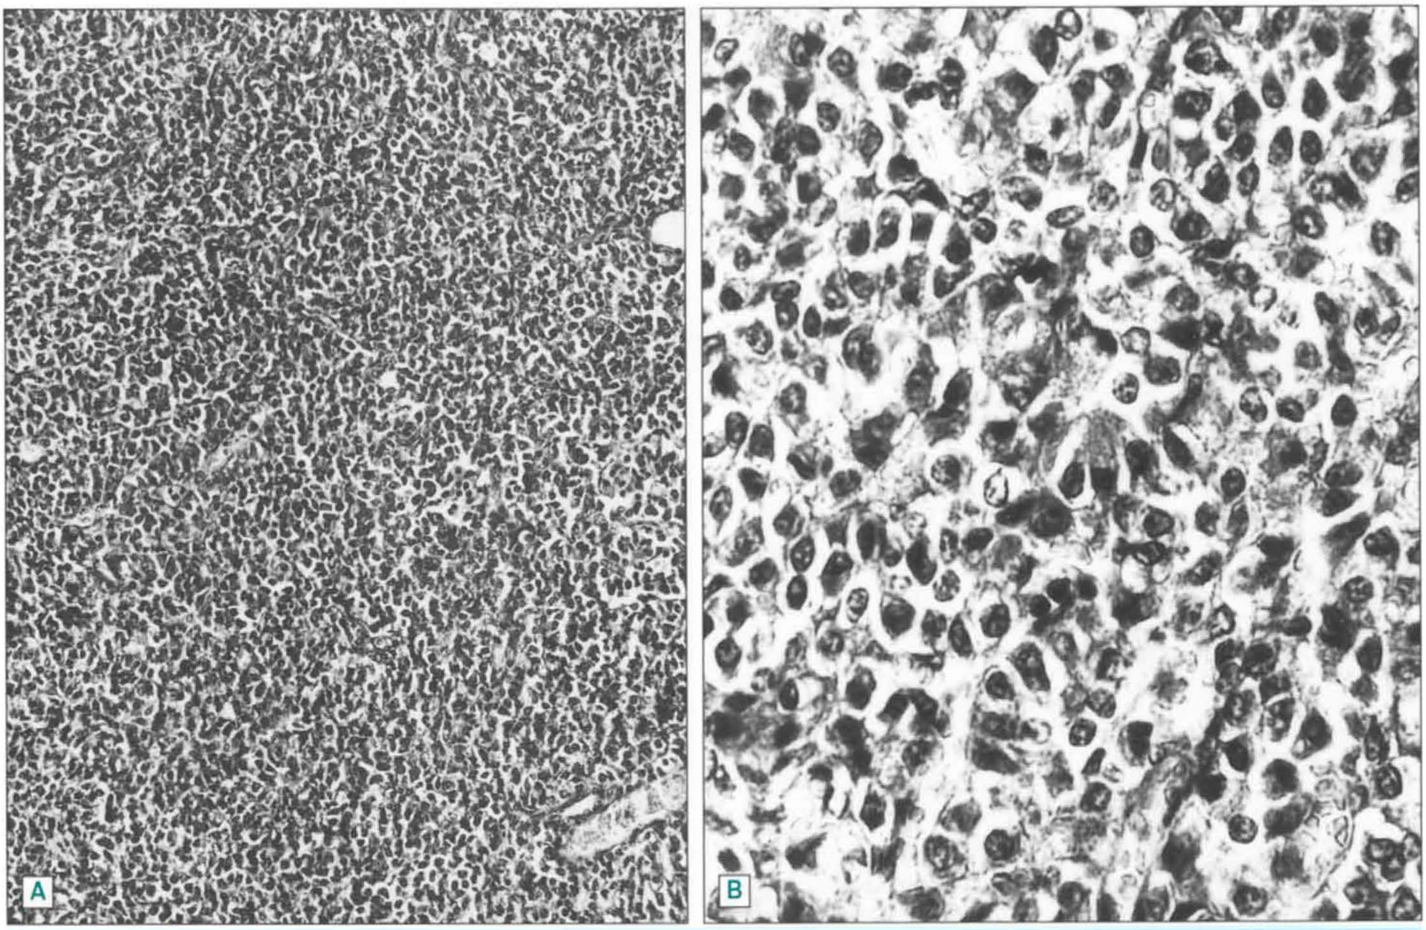

Figure 3.4 Severe chronic **nutritional atrophy** of the exocrine pancreas in a pig. **A.** Low-power view. **B.** Detail of (**A**) demonstrating loss of cell polarity and zymogen granules and cytoplasmic vacuolation.

inflammation, or neoplasia. Atrophy in these conditions is of nonuniform distribution. Affected areas are reduced in size, misshapen, coarsely nodular, and firm. Histologically, the atrophic areas contain few small acinar cells and consist largely of fibrofatty connective tissue in which islets, ducts, nerves, and blood vessels are condensed.

Obstruction of the pancreatic ducts may result from external compression by neoplasia or chronic inflammation and associated fibrosis or from luminal occlusion by parasites, inflammatory exudate, scar tissue, or pancreatoliths. Experimental ligation of the ducts causes ductal ectasia (with rupture of intercellular junctions between the lining epithelial cells), rapid atrophy, degeneration and loss of acinar cells by apoptosis and necrosis, mild interstitial edema and inflammation, and mild periductal fibroplasia (Fig. 3.5A, B). A later development is proliferation of ductular epithelium, particularly in the smallest ductules, and this may give rise to new ductules, acinar cells, or islet cells. Hyperplastic ductules need to be distinguished from tubular complexes formed by atrophy and dilation of acini or pre-existent ductules.

In experimental duct obstruction, discharge of digestive enzymes by acinar cells ceases despite continued synthesis, and the digestive enzyme concentration within the pancreas increases. Ultrastructurally, zymogen-containing organelles at the apices of the acinar cells enlarge and lysosomal enzymes become redistributed into them. The organelles then become more fragile and susceptible to rupture. It is postulated that duct obstruction may interfere both with zymogen exocytosis and with events in lysosomal enzyme transport from the Golgi complex to lysosomes so that lysosomal enzymes are diverted into secretory pathways. Such co-localization of lysosomal hydrolases and digestive enzymes is also a phenomenon of several diet- and secretagogue-induced models of acute pancreatic necrosis. Lysosomal cathepsin B can activate trypsinogen. Co-localization can therefore result in intracellular release of activated digestive enzymes and thereby mediate acinar cell loss. However, ductal obstruction alone is insufficient to provoke acute pancreatic necrosis.

Because endocrine tissue is spared from atrophy following temporary duct obstruction, duct ligation was the method experimentally employed initially to isolate insulin from the pancreas. However, more intense interstitial inflammation and fibrosis develop in spontaneous duct obstructions (other than developmental stenoses) than in experimental surgical models. Exocrine atrophy due to spontaneous ductal obstruction is therefore often compounded by ischemia and pressure atrophy induced by scarring, and the islets may also sustain injury.

Pancreatic acinar atrophy in dogs

Pancreatic acinar atrophy of juvenile onset is an important condition in dogs, but until recently was designated erroneously as "pancreatic hypoplasia." It is most commonly diagnosed in German Shepherds, in which an autosomal recessive pattern of inheritance has been demonstrated. A familial predisposition has also been noted in Rough-Coated Collies and is suspected in English Setters. The condition is reported sporadically in other breeds. In both the German Shepherd and the Collie, the prevalence of the condition has been estimated to be approximately 1%.

Atrophy of the exocrine parenchyma is preceded by intense but patchy infiltration by T lymphocytes in association with degeneration, atrophy, apoptosis, and necrosis of acinar cells. Cytotoxic CD8+-positive cells predominate over CD4+-positive cells in the pancreas as the disease progresses. The lymphocytes may be found both between and within acinar cells, and intraepithelial lymphocytes may also be observed within the ductal epithelium. Lymphoid follicles may form in the parenchyma, and plasma cells, macrophages, and eosinophils may also infiltrate. Plasma cells are more commonly observed in more advanced areas of parenchymal destruction. Reactive fibroplasia is not a significant feature of the process. This subclinical stage of the disease has been termed **atrophic lymphocytic pancreatitis**. *The nature of the lesion suggests that the condition may be an autoimmune cell-mediated process directed against acinar cells*; there is currently no evidence to incriminate autoantibodies in the pathogenesis.

Clinical signs of *exocrine pancreatic insufficiency* do not appear usually until affected dogs are 6–12 months of age. However, the natural course of the disease is highly variable. The subclinical phase may last years and, in some dogs, insufficiency may never manifest. In a significant proportion of dogs, the clinical onset may be immediately preceded by concurrent illness or by a change in the normal household environment or diet.

By the time clinical signs emerge, exocrine atrophy is advanced and there is usually little remaining evidence of the preceding degenerative and inflammatory events. At necropsy of clinically affected dogs, the intestines are distended by bulky ingesta. The peritoneal cavity is devoid of fat and the clearness of the mesenteries allows the flimsy tissue of the atrophic pancreas to be recognized (Fig. 3.6). The main ducts and their larger tributaries can be readily

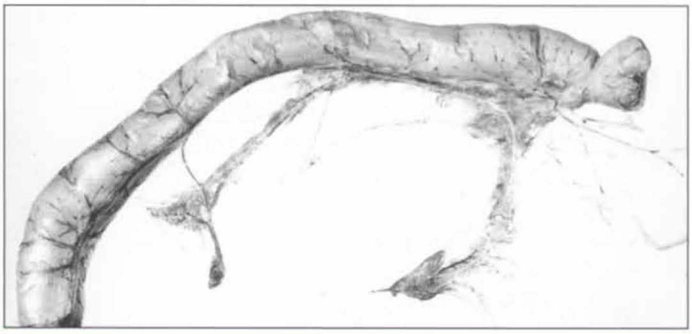

Figure 3.6 Condensation of exocrine and endocrine tissue around the normal duct system in advanced **juvenile pancreatic acinar atrophy** in a dog.

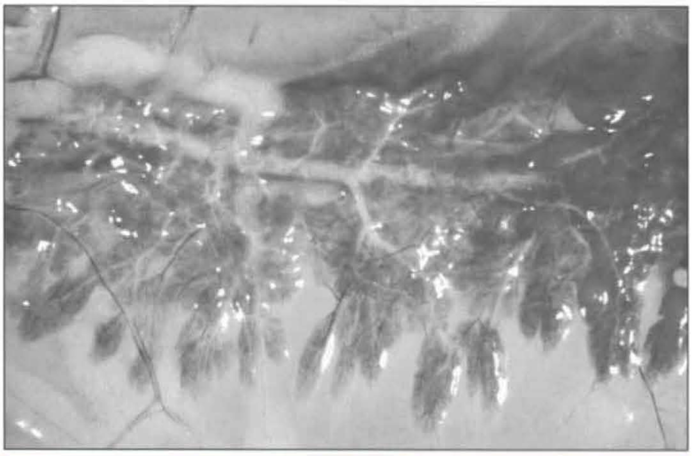

Figure 3.7 Residual parenchyma is condensed about prominent ducts in advanced **juvenile pancreatic acinar atrophy** in a dog.

discerned (Fig. 3.7) and many of the smaller ducts are recognizable grossly with the aid of transillumination. The ducts are of normal size, length, and configuration. Surrounding them is a thin pink veil of residual acinar parenchyma. Microscopically, the pancreatic lobules are small and composed of small acinar cells that stain darkly and do not assume a glandular arrangement. Tubular complexes may be identifiable within the atrophic lobules. Occasional isolated lobules of normal appearance may be present. There is increased prominence of the connective tissues, ducts, islets, blood vessels, and nerves of the pancreas due to condensation (Fig. 3.8). Mild interstitial and periductal fibrosis may be present, but fatty replacement of the organ is more common.

The islets are usually histologically normal. However, haphazard distribution of various islet cell types, hyperplasia of pancreatic polypeptide and delta islet cells, and emergence of a profusion of nerve fibers immunoreactive for enkephalins and vasoactive intestinal peptide within islets have been noted in dogs have with pancreatic acinar atrophy. The significance of these observations is uncertain.

Exocrine pancreatic insufficiency

Progressive loss of exocrine parenchyma ultimately leads to maldigestion of nutrients. The considerable functional reserve of the pancreas, however, delays the clinical onset of exocrine pancreatic insufficiency (EPI) until at least 85–90% of secretory capacity has been lost. Salivary, gastric, and intestinal mucosal enzymes may also assist in digestion in earlier stages of pancreatic disease, as may bile salt-activated lipase in milk in suckling animals.

EPI is most commonly diagnosed in dogs but occurs sporadically in other species. Juvenile pancreatic acinar atrophy is the most common *cause* in the dog, but the condition can also result from pancreatic necrosis, chronic pancreatitis, or exocrine pancreatic neoplasia. In cats, the most common cause of EPI is chronic pancreatitis. EPI referable to pancreatic hypoplasia is occasionally observed in calves. Infrequent causes of EPI include gastric hyperacidity leading to reduced activity of pancreatic enzymes (especially lipase) within the duodenum, and exocrine pancreatic atrophy referable to chronic ductal obstruction, or severe and protracted protein malnutrition. In any species, EPI may be accompanied by diabetes mellitus if the underlying pathological process has destroyed islets as well as exocrine parenchyma.

The most common clinical signs of EPI are diarrhea and chronic weight loss despite a normal to voracious appetite. The hair coat may be of poor quality and marked muscle atrophy may be apparent in some animals. Severely cachectic animals may be weak but, unless there is concurrent diabetes mellitus, animals with EPI are usually bright and alert. Some may display pica or coprophagia, and affected cats may vomit or be anorexic. Flatulence and marked borborygmus are common. The feces are commonly pale, soft, voluminous, and malodorous but may occasionally be watery or even of normal appearance.

Steatorrhea is not invariably present, but can lead to greasy soiling of hair of the tail and perineum, especially in cats. There may be a pot-bellied appearance due to bulky intestinal contents, and affected dogs are at increased risk of intestinal accidents, especially mesenteric torsion. Hepatic lipidosis may also develop in dogs and cats with EPI.

Malassimilation of nutrients in EPI is not simply due to failure of intraluminal digestion by pancreatic enzymes. Pancreatic proteases normally cleave proenzyme forms of small intestinal microvillar membrane enzymes and also inactivate or degrade exposed brush border enzymes. In several species, EPI is associated with increased activity of the jejunal brush border enzymes, sucrase, and maltase, and an increase in high-molecular-weight microvillar membrane proteins, which are thought to be intestinal proenzymes. These alterations may impair the intestinal phase of digestion and absorption. In spontaneous EPI, increased activity of enterocyte lysosomal degradative enzymes occurs, possibly to compensate for the above changes. Protein synthesis by the jejunal mucosa is also reduced in dogs with EPI. The mechanism is unclear but malnutrition and decreases in luminal trophic factors (such as pancreatic secretions and products of digestion) and humoral trophic factors (such as insulin, glucagon, and gastrin) may be implicated. Intestinal transport mechanisms for monosaccharides, disaccharides, fatty acids, and amino acids are also disturbed in EPI to contribute to malabsorption. These functional changes in the intestinal mucosa are not usually associated with histological lesions. However, dietary sensitivity leading to inflammatory bowel disease is also a potential consequence of EPI as there is increased intestinal mucosal exposure to antigenic macromolecules due to the deficiency of pancreatic proteases.

Small intestinal bacterial overgrowth (SIBO) *is a syndrome of bacterial proliferation in the upper small intestinal lumen associated with chronic or recurrent small-bowel diarrhea.* It commonly complicates EPI in dogs, especially German Shepherds, but has yet to be reported in cats with EPI. In SIBO, the feces are often foul-smelling and watery, and diarrhea is occasionally accompanied by vomiting. Alterations in the duodenal/jejunal microflora in EPI are chiefly a consequence of the presence of excess luminal substrates, but loss of the antibacterial properties of pancreatic secretions and abnormalities in intestinal immunity or motility may also contribute. The clinical signs reflect enterocyte damage caused by bacterial generation of alcohols, hydroxylation of fatty acids, bacteria-induced deconjugation of bile salts, and other mechanisms.

The effects of bacterial overgrowth depend on the type of bacteria and probably the duration of overgrowth. Pure bacterial cultures may be obtained from the duodenum of affected animals, but mixed infections are more typical, with *Escherichia coli*, enterococci, and anaerobes most commonly involved; clostridia predominate occasionally. When obligate anaerobes such as *Clostridium* or *Bacteroides* species are present in large numbers, the activities of many intestinal brush border enzymes may decrease and, in some cases, there may be villus atrophy. Proteases, glycosidases, or other products released by obligate anaerobes may inactivate or cleave the exposed brush border enzymes and this cannot be offset by increased protein synthesis. Lactase appears to be particularly susceptible. The intestinal microflora may also indirectly impair digestion and absorption by competing for nutrients or by decreasing the luminal concentration of bile salts.

Because adherence of bacteria to the brush borders of villus enterocytes is not an essential feature of SIBO, *small intestinal biopsies often reveal minimal lesions and are seldom diagnostic.* Quantitative culture of duodenal juice is currently regarded as the most accurate means of confirming SIBO, with counts of greater than 10^5 colony-forming units/mL generally being regarded as significant in dogs; however, higher counts can be found in clinically healthy animals.

A marked decrease in the serum cobalamin (vitamin B_{12}) concentration occurs in many dogs and most cats with EPI. The greater prevalence in cats may reflect the almost exclusive pancreatic origin of intrinsic factor in this species. Cobalamin deficiency can contribute in turn to nutrient malabsorption by promoting villus atrophy and it may also induce anorexia. The serum folate concentration is often increased in dogs with EPI, as a consequence of SIBO and increased bacterial synthesis of the vitamin. In cats with EPI, the serum folate level is often decreased, presumably reflecting concurrent proximal small intestinal disease, and occasionally a coagulopathy may develop as a consequence of malabsorption of fat-soluble vitamin K. Malabsorption of vitamins A, D, and especially E may also occur in EPI.

Confirmation of a diagnosis of EPI in cats and dogs is most accurately achieved via a species-specific assay of serum trypsin-like immunoreactivity. In other species, microscopic examination of fresh feces for undigested fat, starch, or muscle fibers and tests of fecal proteolytic activity can be utilized.

Acute pancreatic necrosis

Acute pancreatic necrosis is a common disease of dogs. A comparable condition occurs in humans and is occasionally seen in cats and rarely in horses and swine. The condition may manifest as an *acute and potentially life-threatening syndrome* or as a *chronic relapsing syndrome* that may culminate in exocrine pancreatic insufficiency and diabetes mellitus.

The **terminology** of the disease has been a source of confusion in the literature, with the condition being variably described as "pancreatic necrosis," "necrotizing pancreatitis," or simply "pancreatitis."

Clinicians tend to use the term pancreatitis to describe both this condition and also diseases in which inflammation is centered on the ducts and interstitial tissues, often qualifying only on the basis of whether clinical disease is acute or chronic. This is understandable because clinical manifestations of these disorders overlap substantially and distinction is often impossible without biopsy of the organ. However, these disorders have different etiologies, pathogenesis, and histologic characteristics. *The condition seen commonly in dogs is designated in these volumes as acute pancreatic necrosis because this term emphasizes the basic necrotizing nature of the process.* Pancreatic conditions in which inflammation rather than necrosis is the predominant process are discussed separately in the section on Pancreatitis, below.

The key event in the **pathogenesis** *of acute Pancreatic necrosis is activation of trypsinogen to trypsin within acinar cells.* Trypsin is then capable of activating the potent arsenal of pancreatic proenzymes to cause autodigestion of the organ. In experimental models of pancreatic necrosis that involve dietary manipulation, pancreatic hyperstimulation, or ductal obstruction, intracellular activation of trypsin follows fusion of zymogen granules with lysosomes. These structures are normally strictly segregated within acinar cells. Following co-localization, the trypsinogen activation peptide can be cleaved by lysosomal proteases such as cathepsin B. Pancreatic secretory trypsin inhibitor in zymogen granules is ineffective at inhibition at the acidic pH of the lysosome. In secretagogue hyperstimulation models of pancreatic necrosis, co-localization of zymogen granules and lysosomes is associated with a sustained rise in the cytosolic ionized calcium level and altered intracellular calcium signaling. Sustained elevation of intracellular ionized calcium also occurs with hypoxia, hypercalcemia, hyperlipidemia, and ductal hypertension, suggesting that this may be a common pathway by which various conditions initiate pancreatic necrosis.

The earliest lesions of acute pancreatic necrosis in most dogs are perilobular, with necrosis and reactive inflammation concentrated at the periphery of affected lobules and with more or less extensive involvement of adjacent adipose and other connective tissues. The duct system and centrilobular parenchyma are intact at this stage of the disease. Because the periphery of the pancreatic lobule is also the periphery of the circulatory field, hypoperfusion and possibly reperfusion may be important in the pathogenesis of necrosis and could account for its occasional onset after prolonged hypotension, following abdominal surgery or in conjunction with gastric dilation-volvulus.

Local release of the activated proteolytic and lipolytic enzymes induces necrosis, with liberated lipases initiating hydrolysis of peripancreatic fat. Activated elastase and phospholipase A appear to be particularly important in expanding the area of pancreatic necrosis. Trypsin, phospholipase A, elastase, lipase, and colipase damage the walls of local blood vessels to induce vasoactive amine release, increased vascular permeability, edema, hemorrhage, and thrombosis; enzymatic tissue necrosis may therefore be compounded by *superimposed ischemic necrosis.* There is local activation of the complement cascade and release of cytokines such as tumor necrosis factor α (TNF-α), interleukin-1 (IL-1), IL-6, IL-8, and platelet-activating factor (PAF). Some of these molecules promote chemotaxis of leukocytes into the area. The leukocytes amplify the pancreatic damage via the generation of oxygen-derived free radicals and additional cytokines. Products of inflammation may also directly activate digestive proenzymes. Cytokines, nitric oxide, and activated digestive enzymes are released into the circulation. Consumption of circulating protease inhibitors, such as α_1-protease inhibitor and particularly α_2-macroglobulin, permits systemic activation of the kinin, coagulation, fibrinolytic, and complement systems by proteolytic enzymes. The potential consequences include a systemic inflammatory response, hypotension, hypovolemic shock, disseminated intravascular coagulation (DIC), multiple organ failure, and death. These systemic consequences are not a feature of the clinically mild forms of the disease.

Release of activated enzymes, vasoactive peptides, inflammatory mediators, and embolic debris into the systemic circulation may lead to multifocal hepatocellular necrosis, pulmonary edema and acute interstitial pneumonia, myocardial injury, and development of cardiac arrhythmias. Acute renal failure may result from microvascular thrombosis in DIC or from nephrosis induced by hypotension. Other significant complications include portal phlebothrombosis, pulmonary thromboembolism, physical obstruction of the extrahepatic bile duct or duodenum and intestinal ileus. Glucagon released from the necrotic pancreas stimulates calcitonin release from thyroid C cells so that hypocalcemic tetany may also develop. Excess circulating free fatty acids may also depress serum calcium levels, and dystrophic mineralization of necrotic foci may contribute in a minor fashion to the hypocalcemia.

Mortality rates of 27–42% are reported in dogs with acute pancreatic necrosis, although most dogs with mild disease clinically recover within a few days. In humans with the condition, the extent of pancreatic necrosis and the presence of secondary bacterial infection of necrotic tissue are the most important factors determining the occurrence of multiple organ failure and subsequent mortality. Infection is more likely to occur in human patients with necrosis involving more than 50% of the organ. Although the extent of necrosis may well influence the outcome in dogs, secondary infection of the organ occurs rarely in this species. The greater prevalence of sepsis in humans reflects the fact that reflux of duodenal contents up the pancreatic duct is an important event in initiating pancreatic necrosis in that species. Factors that have been associated with mortality in affected dogs have included obesity, concurrent diabetes mellitus, hyperadrenocorticism, hypothyroidism, epilepsy, and prior gastrointestinal disease.

Although most dogs clinically recover from acute pancreatic necrosis, it is doubtful whether complete resolution of the pathologic process ever occurs. Rather, if the animal survives the initial episode, the necrotizing process smolders continuously and often asymptomatically until there is almost complete destruction of the pancreas. Recurrence of clinical signs of acute necrosis may occur intermittently throughout this period, and clinicians often refer to this pattern of disease as "chronic relapsing pancreatitis." There is seldom any difficulty in finding microscopic areas of acute necrosis in chronically affected organs. Whether the apparently relentless course is due to persistence of the primary pathogenetic mechanism or to a self-perpetuating property of the lesion is not known. The initial lesion is often localized to one portion of the organ, whereas the smoldering foci are often multiple, of random distribution, affect the periphery of the organ remnants, and tend to avoid any surviving parenchyma in the original focus, the latter being identifiable by fibrosis and atrophy. Clinical signs of exocrine and endocrine insufficiency may develop as a consequence of relentless destruction of the organ. *Pancreatic necrosis is a common cause of diabetes mellitus in dogs*, as the necrotizing process does not spare the islets.

Middle-aged to older dogs that are overweight or obese are at increased **risk** of acute pancreatic necrosis. Miniature Schnauzers, Yorkshire and Silky Terriers, nonsporting breeds, and perhaps Miniature Poodles are predisposed, and female dogs are more likely to be affected than males. There is often a history of recent dietary indiscretion, especially consumption of a large fatty meal, and experimentally the condition is more severe in dogs fed a high-fat, low-protein diet than in those fed a low-fat diet. These observations and the predisposition of Miniature Schnauzers with idiopathic hyperlipidemia to the disease may be a consequence of the elevating effect of hyperlipidemia on cytosolic ionized calcium levels in acinar cells. Alternatively, high-fat diets may promote excessive release of CCK and hyperstimulation of the exocrine pancreas. Dogs with hyperadrenocorticism, hypothyroidism, hypercalcemia, or uremia may also be at increased risk of acute pancreatic necrosis. Abdominal trauma may be the trigger in some animals and the condition has also been associated with the use of such drugs as azathioprine. In many cases, an inciting cause is not identified.

Mild cases of acute pancreatic necrosis in dogs may be clinically silent. *The most common* **clinical signs** *in more severe cases are anorexia, vomiting, depression, weakness, abdominal pain, and dehydration.* Diarrhea, fever, or jaundice may also be present. A cranial abdominal mass may be palpable and some dogs have mild ascites. Less often, affected dogs are presented in shock, DIC, or respiratory distress or with cardiac arrhythmia.

Cats *occasionally develop acute pancreatic necrosis*, but the condition is difficult to diagnose ante mortem and to distinguish clinically from the more common condition of interstitial pancreatitis. Older domestic shorthaired cats are most commonly affected and there is no sex predisposition. Affected cats are not usually overweight and some may be presented with weight loss. The condition has been reported following abdominal trauma (including that associated with falling from a great height) and in cats with lipodystrophy, acute hypercalcemia, ductal reflux of duodenal contents, and organophosphate poisoning. The most common clinical signs in affected cats are nonspecific and comprise anorexia, lethargy, and depression. Dehydration, tachypnea, and hypothermia are more commonly seen than vomiting, abdominal pain, or jaundice, and a palpable abdominal mass or fever is detectable in only a minority. Many affected cats are hyperglycemic and glucosuric and some may have ketonuria, hypocalcemia, and hypokalemia. Serious complications of acute pancreatic necrosis in cats are as described in dogs. Severe hepatic lipidosis may also develop in affected cats.

Grossly, in fatal cases of acute pancreatic necrosis, a small volume of turbid serosanguineous fluid containing free lipid droplets is usually present in the peritoneal cavity. Petechial and ecchymotic hemorrhages may be present in the pancreas and adjacent omentum and mesenteries but extensive hemorrhage is not usually a feature. Numerous small white chalky areas of fat necrosis, each with an intensely hyperemic border, are present adjacent to the pancreas and in the mesentery. In some cases, foci of necrotic fat are widely distributed throughout the peritoneal cavity and may be detectable as far away as the ventral mediastinum, to which digestive enzymes have been conveyed by lymphatics. The entire pancreas may be edematous, swollen, and soft or edema may be confined to localized areas. The necrotizing process may be confined to the central pancreas or one wing. Fibrin strands pass from the affected surface of the pancreas to the omentum, mesenteries, and the visceral surface of the liver. The cut surface of the pancreas has a variegated appearance due to merging of white areas of fat necrosis and gray-yellow areas of parenchymal necrosis; one or other appearance may predominate (Fig. 3.9). The texture is unusually greasy. Areas of parenchymal necrosis are soft and may liquefy.

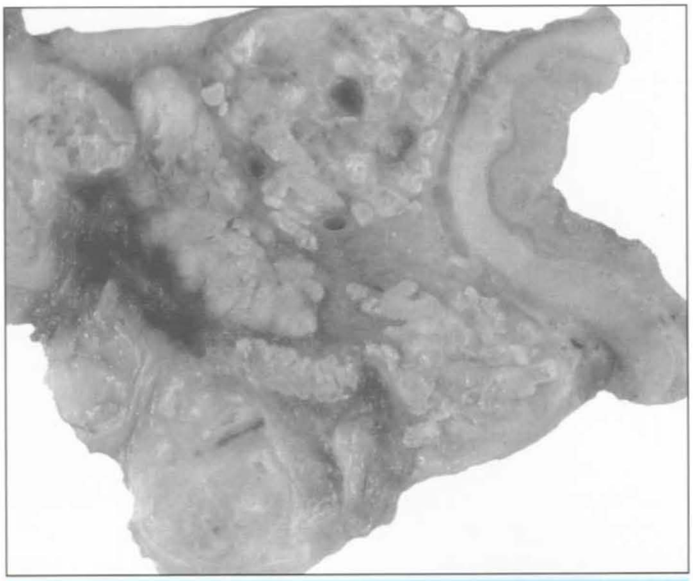

Figure 3.9 Cut surface of the pancreas after **repeated episodes of acute pancreatic necrosis** in a dog. Note the variegated appearance of the pancreas due to hemorrhage, necrosis, dystrophic mineralization, and fibrosis. Duodenal wall is at right.

Histologically, there is necrosis of peripancreatic adipose tissue and pancreatic parenchyma, edematous separation of the interstitium, mural necrosis, and thrombosis of blood vessels and reactive inflammation (Fig. 3.10A, B). Infiltrating leukocytes, chiefly neutrophils and macrophages, congregate at the boundary of necrotic and viable tissue. The necrotic fat saponifies and may undergo mild dystrophic mineralization. The initial parenchymal lesions at the periphery of the lobules are composed of small foci of coagulative necrosis in which the acinar cells become shrunken and acidophilic. These foci rapidly expand and liquefaction of the necrotic tissue leaves large lakes of debris. The collagenous stroma resists digestion for some time. Much fibrin may be precipitated in the edematous interstitium, and capillaries at the margins of necrotic areas may be occluded by fibrin thrombi. Phlebothrombosis, which may be associated with phlebitis or mural necrosis, may be apparent both adjacent to and distant from the parenchymal lesions; similar changes may occur in the small arteries but these vessels are less susceptible to injury. Widespread microvascular thrombosis may be apparent in multiple organs if DIC developed prior to death.

Infrequently, inflammatory masses such as abscesses, pseudocysts, or phlegmon may develop in the pancreas in the aftermath of acute necrosis. These lesions are discussed below in the section on Pancreatitis.

The duration of the disease influences the gross appearance of the pancreas. In chronic phases, the organ may be irregular in conformation and knobby or reduced to a few distorted lobules adjacent to where the ducts enter the duodenum (Fig. 3.11). In some cases, the remnants of the organ are too small to be visibly appreciated but they may still be palpable in areas indicated by a slight puckering of the mesentery. Scar tissue is usually not extensive and adhesions are

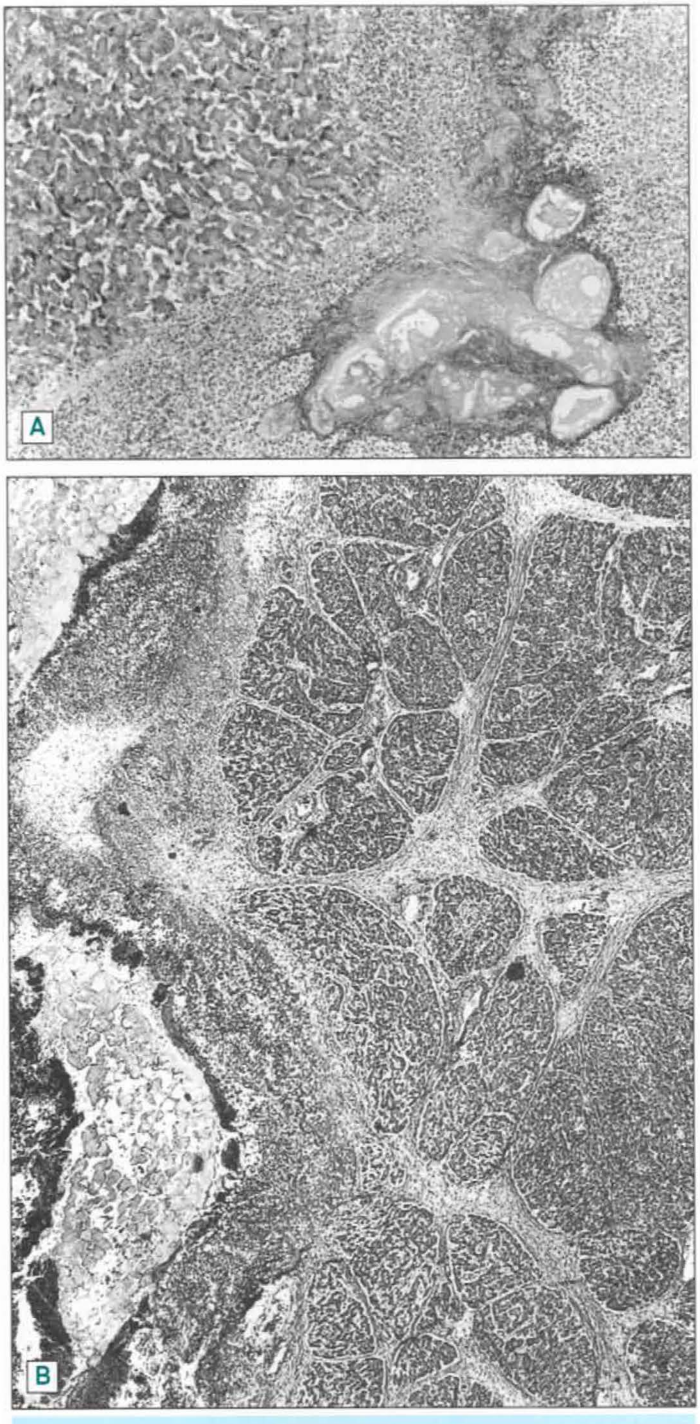

Figure 3.10 Acute pancreatic necrosis in a dog. **A.** Intense necrosis and inflammation is centered on peripancreatic fat (right), with relative sparing of exocrine parenchyma (left). **B.** Acute necrosis of the pancreas (left) with evidence of chronic postnecrotic interstitial scarring (right).

absent or minor. Microscopically, a few small rounded lobules remain and these are compressed and atrophic. Interstitial tissue is increased but this is probably due as much to condensation of stroma as to fibrosis. Blood vessels and nerves are also condensed into the small area of the pancreatic remnant. Islets often cannot be identified. Lesions of diabetes mellitus or intestinal abnormalities typical of EPI may also be present in advanced cases.

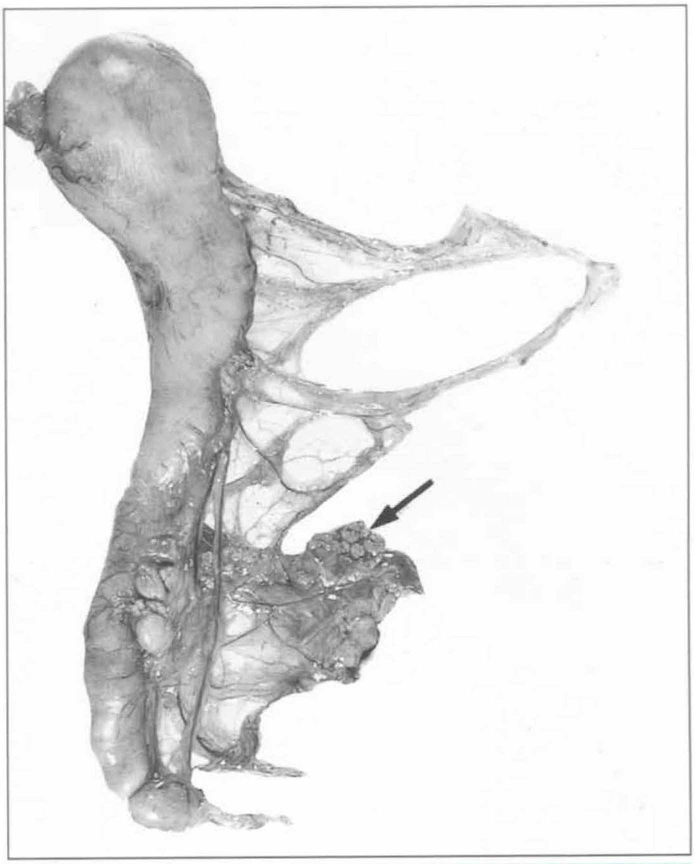

Figure 3.11 The pancreas is reduced to a nodular remnant (arrow) due to **postnecrotic scarring** in a dog.

A minority of dogs with pancreatic necrosis may develop multifocal necrotizing panniculitis and comparable subcutaneous lesions have been experimentally induced in cats by ligation of the pancreatic ducts. Release of activated enzymes, particularly phospholipase A, lipase, amylase, and trypsin, into the systemic circulation has been incriminated in the pathogenesis. In humans, the tendency to develop panniculitis in association with pancreatic necrosis is associated with a decrease in the serum concentration of α_1-PI or α_2-macroglobulin. A comparable association has yet to be demonstrated in small animals.

Acute hemorrhagic pancreatic necrosis, in which the necrotizing process is initially of centrilobular and periductal distribution, is a common subtype of acute pancreatic necrosis in humans, with approximately 80% of cases being associated with cholelithiasis or alcohol abuse. A similar lesion is occasionally observed in dogs. Predisposing factors in dogs are uncertain but the condition has been described in dogs envenomated by scorpions, following therapeutic use of asparaginase, and in association with necrotizing arteritis referable to visceral leishmaniasis. It is likely that in many affected dogs the initiating event is reflux of activated digestive enzymes and bile salts from the duodenum into the main pancreatic duct to cause ductal necrosis. Reflux may be encouraged by increased luminal pressures during severe vomiting. The initial periductal parenchymal lesions rapidly enlarge and may become confluent to involve most of the pancreas. The organ is initially edematous and hyperemic, and the parenchyma becomes friable and hemorrhagic. The extensive hemorrhage may obscure the parenchyma and necrotic foci in adjacent adipose tissue. Apart from the intensity of accompanying hemorrhage, this stage may be histologically indistinguishable from the more common pattern of acute pancreatic necrosis that commences at the periphery of the organ.

Life-threatening complications develop more commonly in the hemorrhagic form of pancreatic necrosis in dogs. In cases initiated by reflux of duodenal contents, enteric organisms may colonize the necrotic tissue and may cause abscessation.

Pancreatitis

Hematogenous infections may produce small, randomly distributed foci of pancreatic inflammation with necrosis of small clusters of acinar cells. **Multifocal pancreatitis** is commonly seen in systemic infections with epitheliotropic viruses, but inflammation is usually less prominent than degeneration and necrosis. These conditions have been discussed in the section on Degeneration, necrosis, and atrophy, above. Bacterial embolism to the pancreas is not

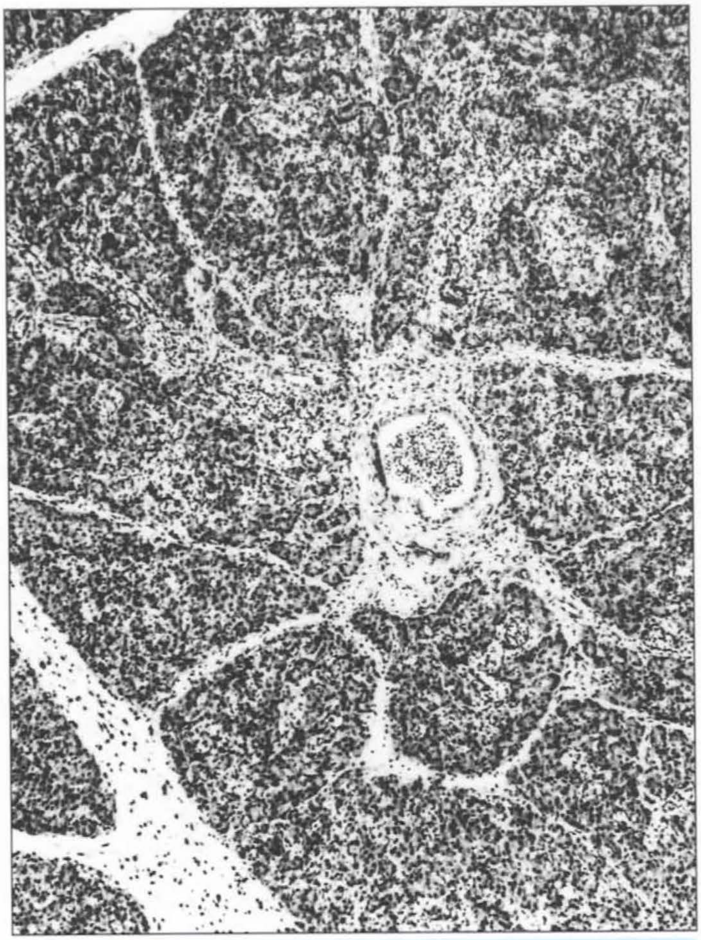

Figure 3.12 Inflammation is centered on a duct in **acute interstitial pancreatitis** in a cat.

uncommon in cats and dogs with septic peritonitis, but does not influence the outcome.

Acute interstitial pancreatitis is common in systemic toxoplasmosis, especially in cats (Fig. 3.12). Grossly, the organ is slightly swollen by diffuse interlobular edema, or there may be hemorrhage and necrosis with comparable lesions in the duodenum.

Chronic interstitial pancreatitis is the pattern of inflammation that is usually seen in domestic animals. It is seldom of clinical significance but may occasionally be responsible for pancreatic insufficiency. The lesion is not uncommon in cats, is occasionally observed in horses, and is rare in other species. *Chronic interstitial pancreatitis usually arises by extension of an inflammatory process that commences in the ducts.* The cause is usually an ascending infection involving intestinal bacterial flora, but may also be caused by intraductal trematodes. Pancreatic ductal malformations, intraductal parasites, duodenal disease, high luminal pressures in the duodenum arising from vomiting, and various miscellaneous causes may predispose to ascending infection. In horses, chronic interstitial pancreatitis may be provoked by the larvae of *Strongylus equinus* or, less commonly, *S. edentatus* that pass part of their developmental cycle in and about the pancreas. In cats, in which the pancreatic and bile ducts fuse before entering the duodenum, ascending cholangitis usually coexists with interstitial pancreatitis. Cholangitis may also develop in affected horses. Clinical signs referable to cholangitis may overshadow those of pancreatic involvement.

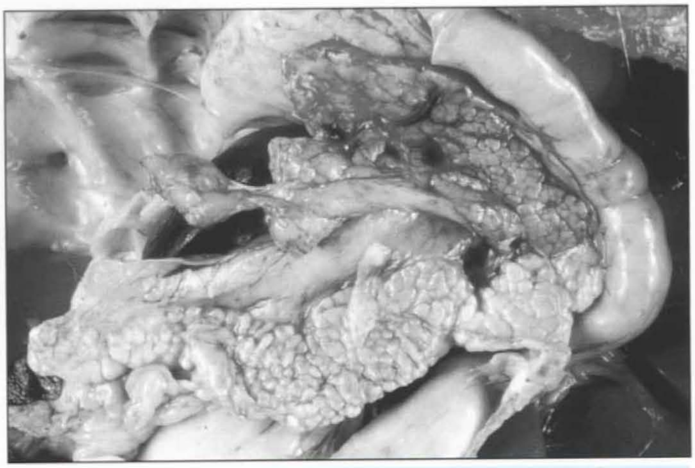

Figure 3.13 Exaggerated lobulation of the pancreas due to diffuse interstitial fibrosis in **chronic interstitial pancreatitis** in a cat.

In chronic interstitial pancreatitis, the organ may be enlarged or reduced in size. In horses, the tendency is for enlargement and the organ may be replaced by a tough mass of scar tissue with adhesions to adjacent structures. Flattened remnants of pancreatic tissue may be visible near the surface of the mass. Incision reveals tortuous and eccentrically dilated ducts that may contain purulent exudate or a large volume of slightly opaque mucus.

In cats, the pancreas is usually reduced in size and is firm, gray, and multinodular (Fig. 3.13). Clear retention cysts are often visible through the capsule and particularly on the cut surface. Fibrosis may not be recognizable on gross inspection, but there are exceptional cases in which the whole organ is converted into a shrunken, distorted, fibrous remnant. Histologically, the ducts contain catarrhal exudate and are enveloped by dense fibrosis (Fig. 3.14). Localized ductal stenoses and cystic dilations may occur. The epithelium of the ducts is hyperplastic and there may be squamous metaplasia. Fibrous tissue extends from around the ducts to the interlobular stroma and subdivides many of the lobules (Fig. 3.15). The interstitial tissues are permeated by leukocytes, chiefly lymphocytes and plasma cells. Acinar parenchyma atrophies as a consequence of fibrosis and ductal obstruction, but the islets are usually well preserved.

Inflammatory masses involving the pancreas and peripancreatic tissues are well-documented sequelae of acute pancreatitis in humans, but there are few reports of pancreatic phlegmon, abscess, or pseudocyst development in domestic animals. The masses can provoke clinical signs indistinguishable from those of pancreatitis and pancreatic necrosis.

A **pancreatic phlegmon** *is a solid mass of indurated pancreas and adjacent tissues that results from inflammation, edema, and necrosis.* A phlegmon may develop within a few days of onset of acute pancreatic necrosis and typically resolves spontaneously within 2–3 weeks, after the necrotizing process subsides. Necrosis may cause some cavitation of a phlegmon, but a fluid-filled pocket does not usually form.

Pseudocysts *are intra- or peripancreatic, fluctuant pockets of pancreatic enzyme secretions, necrotic debris, inflammatory exudates, and blood.* They are more common than abscesses as sequelae of acute or chronic

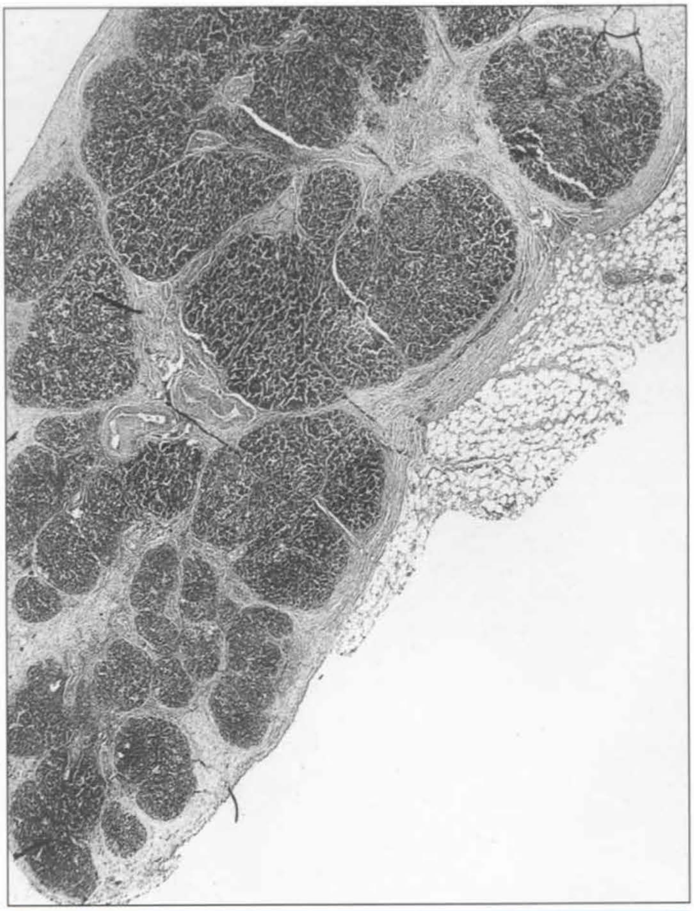

Figure 3.15 Marked interlobular fibrosis in **chronic interstitial pancreatitis** in a cat.

pancreatic necrosis. Rarely, they may result from trauma or neoplasia. Pseudocysts may develop within days to weeks of onset of pancreatic necrosis. Disruption of pancreatic ducts by inflammation or necrosis and duct occlusion contribute to their development. Pseudocysts are usually solitary and unilocular and may reach 10 cm in diameter. The wall may be thin or thick and formed by granulation tissue that matures to fibrous scar tissue. Unlike true cysts, there is no epithelial lining. Chronic inflammation may be intense in the fibrous capsule; hemosiderin, cholesterol crystals, and mineral deposits may be incorporated into the capsule. Small pseudocysts may spontaneously resolve over several weeks. Large, thick-walled, or mineralized cysts tend to persist or enlarge. Complications include compression of the extrahepatic bile duct, rupture causing severe hemorrhage or generalized peritonitis, and secondary infection leading to abscessation.

Pancreatic abscesses *are pockets of purulent exudate and necrotic debris within the pancreas or adjacent tissues.* Sterile abscesses may form within areas of intense liquefactive necrosis of parenchyma. Larvae of *Stephanurus dentatus*, migrating from the liver across the peritoneum to the perirenal area in pigs, may encyst in the pancreas and provoke abscessation. Septic abscesses may result from secondary infection of necrotic parenchyma or, less often, a pseudocyst. They can also arise by direct extension from a neighboring focus of infection, as they occasionally do from septic peritonitis and from perforated esophagogastric ulcers in pigs. Suppurative lesions of lymphohematogenous origin are rare. Enteric bacteria are usually isolated from abscesses in humans and are probably derived from the biliary tree or from adjacent inflamed or devitalized bowel. However, almost all reported pancreatic abscesses in dogs have been sterile. Some abscesses may track cranially as far as the mediastinum or caudally in the retroperitoneum to the pelvic inlet. Some may contain chyle as a result of lymphatic leakage, and gas bubbles may occasionally be present in septic abscesses. *Abscessation can be a serious and potentially fatal complication*, with death a result of rupture with severe hemorrhage or bacteremia; spontaneous resolution is rare.

Systemic **granulomatous infections** may involve the pancreas, but lesions are usually microscopic and less important than those in other viscera. Chronic sclerosing and granulomatous pancreatitis due to zygomycotic fungi has been reported in dogs, and pyogranulomatous pancreatitis occurs in feline infectious peritonitis. Disseminated cryptococcosis may occasionally involve the pancreas of cats, but is usually only associated with mild pyogranulomatous inflammation. Destructive granulomatous and eosinophilic pancreatitis can be a feature of multisystemic eosinophilic epitheliotropic syndrome of horses (Fig. 3.16); a proportion of these cases are examples of enteropathy-associated lymphoma.

In **pancreatolithiasis**, *concretions form within the pancreatic duct system* (Fig. 3.17). The calculi are occasionally detected in cattle at slaughter, being slightly more common in cattle over 4 years of age, but are rare in other species. The calculi are usually hard, white,

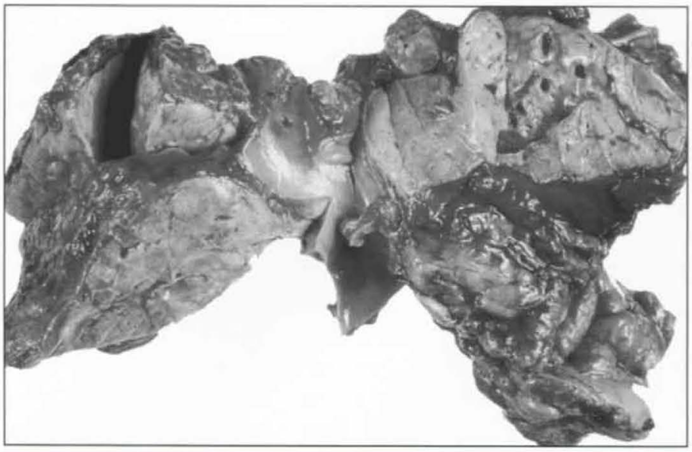

Figure 3.16 Chronic eosinophilic **interstitial pancreatitis** in a horse.

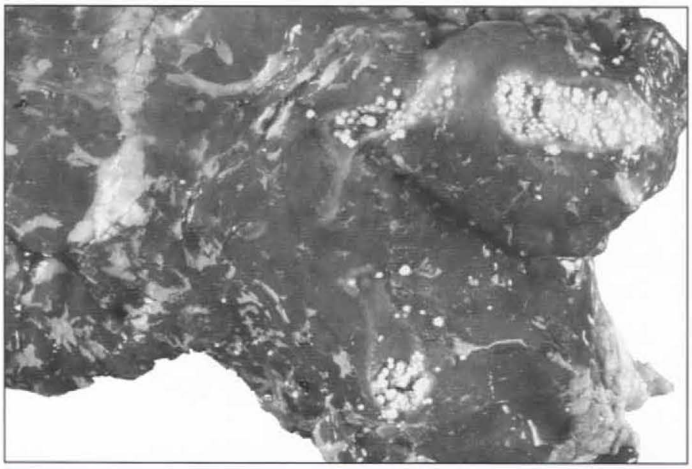

Figure 3.17 Pancreatolithiasis in a cow.

numerous, and small, often resembling sand grains, and are chiefly composed of carbonates and phosphates of calcium and magnesium. The calculi are associated with and may be a consequence of ductal inflammation, including that provoked by flukes. Affected ducts may be irregularly stenotic or dilated and there may be cystic dysplasia of the mucosal glands. The calculi are typically incidental findings at necropsy and are not a significant cause of complete duct obstruction. Obstructive pancreatolithiasis with concurrent pancreatitis has been reported in a cat.

Parasitic diseases of the pancreas

The pancreatic lesions of systemic toxoplasmosis and of migrating larvae of *Strongylus equinus, S. edentatus,* and *Stephanurus dentatus* have been described in the preceding section.

Various **metazoan parasites** may be found within the pancreatic ducts of domestic animals. Their significance depends on the extent to which they occlude the ducts, either by direct physical obstruction or by provoking inflammation and periductal fibrosis. Ascarids may invade the ducts from the intestine in pigs and dogs. *Thysanosoma actinioides*, the fringed tapeworm, may spill from the bile ducts of ruminants into the pancreatic ducts and small intestine. In heavy infestations in herbivores and carnivores, trematodes such as *Dicrocoelium dendriticum, Opisthorchis tenuicollis, O. felineus, O. viverrini, Clonorchis sinensis, Platynosomum fastosum, Metorchis conjunctus*, and *Amphimerus pseudofelineus* may be found in both the pancreatic and bile ducts. These parasites are described in Vol. 2, Liver and biliary system.

Dicrocoelid flukes of the genus ***Eurytrema*** may inhabit both the pancreatic and biliary ducts but prefer the former. *Eurytrema pancreaticum* is the most important species and is a common parasite of the pancreatic and bile ducts of ruminants and other herbivores throughout Asia and South America and is also reported in Madagascar and Russia. *E. coelomaticum* is common in Brazilian cattle and is reported in ruminants in China. *E. tonkinese* is found in cattle in Vietnam. Snails act as the first and grasshoppers the second intermediate hosts. The flukes are presumed to gain access to the pancreatic ducts directly from the duodenum following ingestion of an intermediate host.

Other species of *Eurytrema* are found in carnivores, wild herbivores and birds. Pigs may harbor *Eurytrema* flukes of either herbivore or carnivore origin. *E. procyonis* is a common parasite of the pancreatic ducts of raccoons in many parts of the USA, and has also been detected in red and gray foxes and domestic cats. In areas in which the fluke occurs, up to 14% of cats may be infected. The common garden snail, *Mesodon thyroidus*, and grasshoppers act as intermediate hosts. *E. procyonis* is infrequently reported in the bile ducts and gallbladder of cats.

Intraductal flukes may provoke only mild luminal and periductal inflammation, hyperplasia of the ductal epithelium, and periductal fibrosis. In other animals, however, there may be pronounced cording and dilation of the ducts and chronic interstitial pancreatitis, leading to near total loss of exocrine parenchyma and severe replacement fibrosis. Duct obstruction is thought largely to mediate the periductal fibrosis and the progressive atrophy of exocrine elements. Irritation of the ductal mucosa by the flukes and their ova and inflammation in response to dead flukes contribute to the progressive scarring.

E. pancreaticum preferentially targets the left pancreatic lobe in ruminants. Infestation of cattle with *E. pancreaticum* may cause progressive wasting; emaciation, recumbency, and death have been reported in heavily infested sheep. Although islets are preserved in most cases, progressive destruction culminating in diabetes mellitus has been reported in sheep. Glucosuria has also been noted in raccoons harboring *E. procyonis*. In cats, *E. procyonis* is found in the small- and medium-sized ducts of both pancreatic lobes, but the tail of the pancreas is usually more severely affected than the head. Duct obstruction in cats is thought to be responsible for the significant reduction in the volume of pancreatic secretions and in the content of digestive enzymes and bicarbonate. With heavy infestations, the major pancreatic duct may be greatly dilated and much of the organ is shrunken, pale, and fibrotic. However, most cats are asymptomatic and diagnosis is by identification of typical dicrocoelid eggs with a single operculum in the feces.

Hyperplastic and neoplastic lesions of the exocrine pancreas

Hyperplasia of ductular epithelium is occasionally seen, often in an environment of chronic pancreatitis, exocrine parenchymal atrophy, and interstitial fibrosis, or within foci of nodular hyperplasia of the exocrine parenchyma. It is also reported as an aging phenomenon, at least in humans. The hyperplastic lining epithelium may protrude as papillae into the duct lumina and the affected ducts may be dilated.

Nodular hyperplasia of the exocrine parenchyma *is common in older dogs, cats, and cattle*, but is of no clinical significance. In most cases, there is no evidence of a preceding pancreatic insult, so it is unlikely that the nodules reflect regenerative effort. Solitary foci are unusual, with *multiple small nodules scattered throughout the organ being typical* (Fig. 3.18). Individual lobules may contain multiple hyperplastic nodules; complete transformation of a lobule into a hyperplastic nodule is uncommon. The nodules are of variable size but do not usually exceed the size of normal lobules. Their gray-white color and firm consistency contrast grossly with the color and texture of normal pancreas. Where superficially positioned, the smooth-surfaced nodules barely project.

Histologically, there is a mosaic of normal and hyperplastic tissue within affected lobules (Fig. 3.19). Only the exocrine tissue is involved. *The hyperplastic foci are not encapsulated and usually do not compress the adjacent parenchyma, features used to distinguish a solitary hyperplastic lesion from an exocrine pancreatic adenoma.* The cells within each nodule tend to be uniform, with at least some attempt at acinar formation. They may closely resemble their normal counterparts except for altered staining intensity and cell size. The cells may be larger than normal, with expanded, brightly acidophilic cytoplasm, or they may be smaller and paler than normal, forming low cuboidal acini. Cells may be vacuolated and, in some nodules, arranged as irregular sheets or small clusters without an obvious lumen.

Exocrine pancreatic adenomas *are rare*, and some of those reported in older dogs, cats, and cattle may have been hyperplastic nodules. Adenomas are usually solitary and small. They are usually incidental findings at necropsy and their rarity suggests that they do

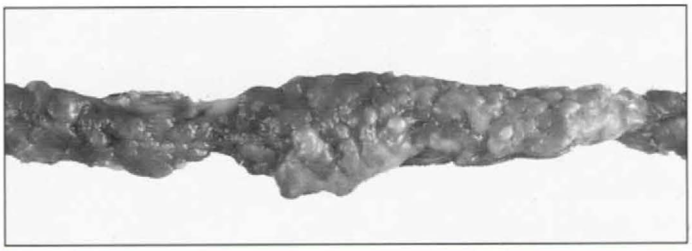

Figure 3.18 Nodular hyperplasia of the exocrine parenchyma in a cat.

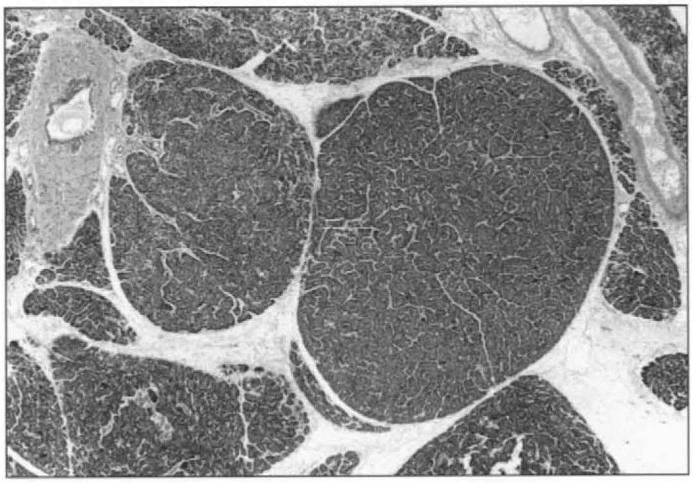

Figure 3.19 Nodular hyperplasia of the exocrine parenchyma in a cat.

not give rise to pancreatic adenocarcinoma. Adenomas may protrude from the surface of the pancreas, and grossly they more closely resemble normal parenchyma than do hyperplastic nodules. *Expansive growth causes compression of adjacent parenchyma from which the tumor is usually separated by a thin fibrous capsule.* The histological pattern of an adenoma may be predominantly tubular or rarely acinar. In the tubular type (which is thought to be derived from ductal epithelium), small or large cystic spaces are lined by cuboidal or columnar epithelial cells and may contain mucin. Mitoses are rare.

Exocrine pancreatic adenocarcinoma *is uncommon in all domestic animals.* Most cases are observed in dogs and, less commonly, in cats. A few cases have been reported in cattle and horses, and the tumor appears to occur rarely in pigs and sheep. The malignancy is largely one of older age but some affected dogs have been only 3 years of age. Female dogs may be at slightly greater risk than males. Whether the Airedale Terrier is genuinely predisposed remains unconfirmed.

The incidence of pancreatic adenocarcinoma in humans has increased over recent decades. Smoking, consumption of meat- and fat-rich diets, alcohol and methylxanthine compounds such as coffee, and exposure to radiation and to chemical carcinogens, including *N*-nitroso compounds produced by intestinal bacteria, are implicated in tumor development in humans. There is also a weak link between chronic pancreatitis and pancreatic malignancy. *Nitrosamines* are potent pancreatic acinar carcinogens in hamsters, mice, and rats, with exposure leading progressively through enzyme-altered foci and hyperplastic and dysplastic nodules to malignancy. Chemicals or other factors inducing spontaneous pancreatic adenocarcinoma in dogs and cats are yet to be identified. *Chronic pancreatitis* was speculated to have been a contributory factor in the development of pancreatic adenocarcinoma at a relatively young age in two gray Collies with cyclic hematopoiesis, but a genetic predisposition could not be excluded.

The most common clinical signs in dogs and cats with this neoplasm are nonspecific: anorexia, weight loss, depression, lethargy, and vomiting. There may be abdominal pain or a palpable abdominal mass. Ascites may develop if there is extensive peritoneal implantation. Occasionally, there may be signs of diabetes mellitus or exocrine pancreatic insufficiency due to extensive neoplastic destruction of the pancreas or complete obstruction of the pancreatic ducts. There is a tendency for these tumors to arise centrally within the gland or in the duodenal wing; these may provoke early clinical signs of biliary obstruction. Rarely, the first clinical signs reflect distant metastasis. Multifocal necrotizing panniculitis with mineralization of necrotic adipocytes has been observed in a few dogs with pancreatic adenocarcinoma. A rare syndrome of *paraneoplastic alopecia* affecting the ventrum, legs, and usually the face has been observed in cats with pancreatic adenocarcinoma. Pseudohyperparathyroidism leading to hypercalcemia has been reported in a dog with pancreatic adenocarcinoma.

Pancreatic adenocarcinoma may appear as a solitary, discrete, circumscribed mass or there may be multiple masses throughout the organ. The neoplasm is usually firmer than the adjacent pancreas. Some carcinomas are highly scirrhous and cannot be grossly distinguished from postinflammatory scarring (Fig. 3.20). The cut surface of the neoplasm is typically heterogeneous and yellow to gray-white; areas of necrosis, hemorrhage, and mineralization may be obvious. Necrotic foci are often found in adipose tissue within and adjacent to primary and metastatic nodules and there may be adhesions of the pancreas to adjacent tissues. Some tumors may contain mucin-filled cysts.

Three main morphological patterns of pancreatic adenocarcinoma are recognized histologically: *small tubular (the most common form), large tubular, and acinar.* In the *tubular forms*, glandular structures resembling pancreatic ducts are formed by mucus-secreting cuboidal or columnar cells (Fig. 3.21). Some tumors may contain localized

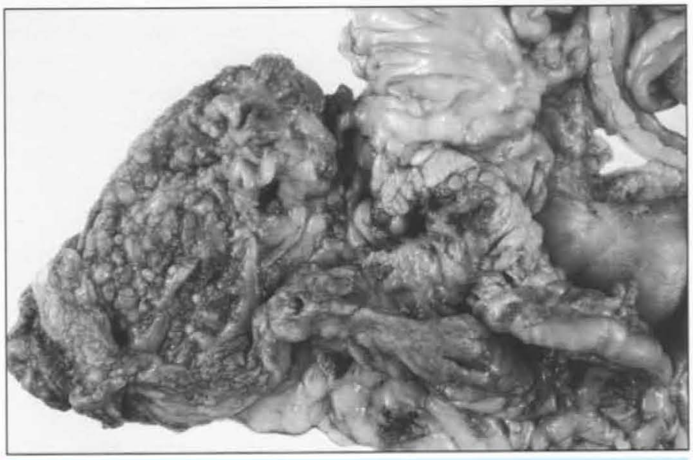

Figure 3.20 Pancreatic adenocarcinoma in a dog. The mass is scirrhous with extensive implantation on the gastroduodenal mesenteries and omentum.

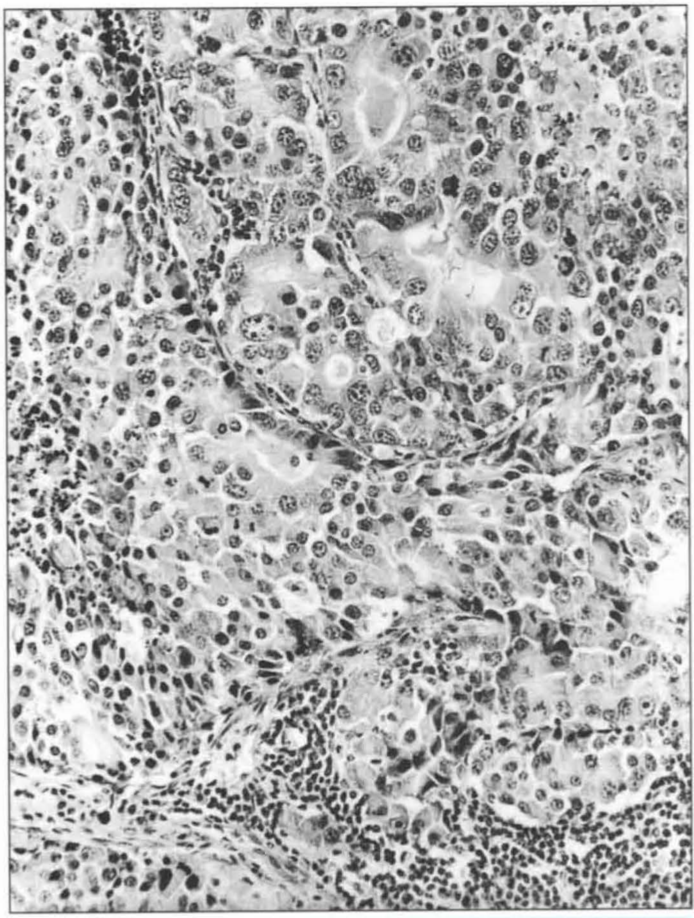

Figure 3.21 Pancreatic adenocarcinoma in a dog. Invasive neoplastic cells are forming tubular arrays and display karyomegaly and abnormal mitoses; lymphocytes are accumulating at the tumor margins.

ductular arrangements of well-differentiated cells that may be difficult to distinguish from the ductular response to incomplete obstruction. Well-differentiated *acinar tumors* are composed of small cells arranged into acini mimicking normal parenchyma.

The *histogenesis* of pancreatic adenocarcinoma has not been clarified in domestic animals. Traditionally, the tubular forms have been considered to be derived from ductal epithelium whilst tumor cells containing brightly eosinophilic zymogen granules have been interpreted to be of acinar origin. This distinction is often arbitrary and the histological pattern may vary considerably within a single tumor. Moreover, pluripotent ductular epithelium or endodermal stem cells could give rise to both tubular and acinar forms.

Undifferentiated carcinomas that do not form acinar or ductular structures are also seen. Some of these may be entirely composed of sheets of small anaplastic cells. Poorly differentiated tumors usually have a higher mitotic index and a more pronounced fibrous stroma.

The tendency of pancreatic adenocarcinomas to form tubules or acini usually permits their distinction from islet cell tumors. Detection of eosinophilic granules in tumor cells permits distinction of pancreatic adenocarcinoma from invasive or metastatic adenocarcinoma of gastrointestinal or biliary origin. Electron microscopy or immunohistochemical analysis for secretory products may be needed to clarify the origin of poorly differentiated tumors.

Pancreatic adenocarcinoma usually behaves aggressively and metastases are often established by the time of diagnosis. Local invasion into the wall of the duodenum is common and there may be obstruction of pancreatic or bile ducts. Neoplastic invasion of blood vessels and lymphatics may be obvious histologically in the pancreas, with tumor cells commonly tracking in the perineural lymphatics. Metastasis is most commonly to the liver, lungs, and local lymph nodes, but may also involve the spleen, kidneys, and diaphragm, and rarely the skin. Peritoneal implantation is common and there is also a propensity to extend along visceral nerves to the dorsal ganglia. Metastatic behavior cannot be predicted by the histological pattern as well-differentiated tumors can metastasize widely. The large tubular form is, however, purported to metastasize less readily than the other forms.

Only a single case of **hepatopancreatic ampullary carcinoma** has been recorded in domestic animals; the tumor arose from the junction of the common bile duct and main pancreatic duct within the wall of the duodenum in a cat. Such tumors may cause obstruction of either or both ducts. The neoplasm is discussed in Vol. 2, Liver and biliary system.

Nonepithelial neoplasms rarely arise in the pancreas. Those reported include fibrosarcoma, hemangiosarcoma, liposarcoma, neurofibroma, and neurofibrosarcoma. **Metastasis to the pancreas** from malignancies arising elsewhere appears to be rare but the paucity of reports may reflect lack of systematic examination and sampling of the organ at necropsy. The organ may become involved in hematopoietic malignancies and disseminated lymphoma. Neoplasms arising in the bile ducts, stomach, or duodenum, including intestinal lymphoma, may directly invade the pancreas.

ENDOCRINE PANCREAS

General considerations

The endocrine cells of the pancreas are chiefly aggregated within the islets of Langerhans, which are scattered throughout the exocrine parenchyma. There are four principal types of endocrine cells.

- **β cells** secrete *insulin* and an insulin-antagonist, *islet amyloid polypeptide* (IAPP or amylin), comprise 60–70% of all islet cells, and are present within all islets.
- **α cells**, which secrete *glucagon*, are the next most numerous cells.
- **δ cells** are present in small numbers in all islets and secrete *somatostatin* and, in some species, IAPP.
- **PP (or F) cells** secrete *pancreatic polypeptide* (PP); these cells are particularly numerous in sheep.

α cells in dogs and both α and β cells in pigs contain dopamine and serotonin. In cats, both α and PP cells may synthesize serotonin. Other cell types that may be present in islets of some species include *enterochromaffin (EC) cells* (that secrete serotonin), *D_1 cells* (that secrete vasoactive intestinal peptide, VIP), *P cells* (that secrete bombesin and are only reported in fetal islets), and *G cells* (that secrete gastrin in fetal islets). Insulin-secreting cells are confined to the pancreas, but the other islet cell types have functional counterparts in the gastrointestinal tract.

In most mammalian species, β cells are clustered at the center of islets. However, in the horse, islets of the left and intermediate lobes of the pancreas typically have α cells at their core, with β cells and a few δ and PP cells at their periphery. In cats, β cells are also largely situated at the periphery of the islets. Ultrastructurally, the secretory granules of the various cell types are distinct, but islet cells are most accurately distinguished by immunohistochemical techniques that label specific hormone products (Fig. 3.22). β cells can also be readily highlighted by histochemical stains such as aldehyde fuchsin.

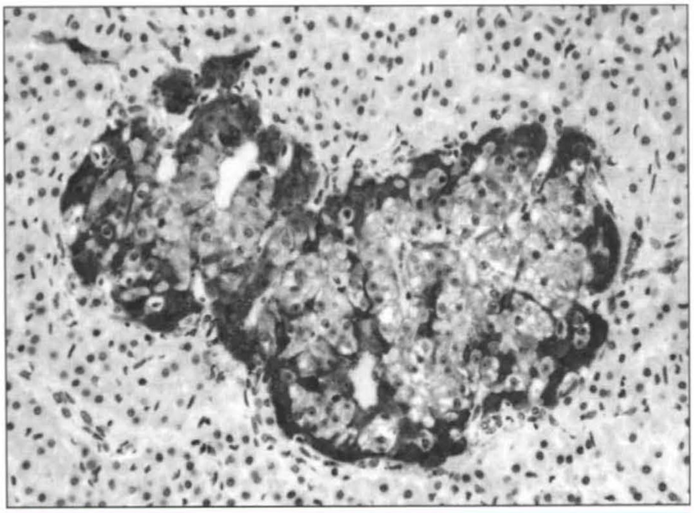

Figure 3.22 Positive immunoperoxidase staining of **insulin-secreting islet cells** in a horse. Note that the distribution of insulin-secreting cells within the islet is not random.

Secretory granules of all islet cells stain positively with chromogranin A and neuron-specific enolase.

Insulin *has both metabolic and mitogenic effects on target tissues.* The insulin receptor, which has tyrosine kinase activity, is widely distributed throughout the body, but the main target cells are hepatocytes, striated myocytes, fibroblasts, and adipocytes. *The principal function of insulin is to increase the rate of transfer of glucose into target cells to form intracellular glycogen*, thereby lowering the blood glucose concentration. It also enhances glucose oxidation and formation of ATP. Hyperglycemia causes immediate release of stored insulin from β cells, whilst sustained hyperglycemia promotes synthesis of the hormone. Insulin also increases the transfer of other monosaccharides, some amino acids, fatty acids, potassium, and magnesium into target cells. It directs amino acids into protein synthesis rather than gluconeogenesis, and promotes uptake of fatty acids by adipocytes to form storage triglycerides. *Insulin is a major anabolic hormone.* In concert with insulin-like growth factors (IGF-1, IGF-2), it promotes DNA and RNA synthesis and stimulates growth and differentiation of cells. Indeed, insulin and IGFs can bind to and activate their heterologous receptors. Growth retardation has been observed in mouse pups genetically rendered insulinopenic throughout development. The effects of insulin on cell growth and differentiation afford one explanation for the commencement of insulin synthesis so early in embryonic development, despite insulin not being required for glycemic control in the fetus.

IAPP is stored in the same secretory vesicles and is co-secreted with insulin in response to glucose and other secretagogues. The amount of IAPP secreted in response to glucose stimulation is usually approximately 1% of the amount of insulin released on a molar basis. However, expression of the two peptides is at least in part independently regulated, and β cells are also heterogeneous in their content of IAPP and insulin and in their response to glucose signals, so that this molar proportion may alter. The ratio is reduced during fasting. The ratio is increased in obesity and glucose intolerance, which has been incriminated in the pathogenesis of type 2 (non-insulin-dependent) diabetes mellitus.

The *biological actions of IAPP* are incompletely understood, but experimental evidence supports a role in glucose metabolism, calcium homeostasis, and control of blood pressure and appetite. At least some of its effects may be mediated via binding to cell receptors for calcitonin gene-related peptide, with which it shares approximately 45% amino acid sequence homology. IAPP inhibits basal and glucose-stimulated insulin secretion by β cells; it also inhibits basal and insulin-stimulated glycogen synthesis in skeletal muscle and promotes muscle glycogenolysis. Hepatic uptake of lactate released from skeletal myocytes as a result of glycogenolysis stimulates gluconeogenesis and boosts the blood glucose concentration. In promoting hepatic gluconeogenesis, IAPP acts synergistically with glucagon but via a different mechanism. IAPP also induces hypocalcemia by inhibiting osteoclast-mediated bone resorption. IAPP shares substantial sequence homology with the hypotensive peptide, adrenomedullin, and, when administered intravenously, provokes tachycardia and lowers systemic blood pressure via vasodilation. IAPP also acts as a satiety hormone on the hypothalamus to suppress appetite.

Glucagon *is released from α cells in response to hypoglycemia.* It acts to boost the blood glucose concentration by stimulating hepatic glycogenolysis and gluconeogenesis. It also stimulates lipolysis. **Somatostatin** has potent inhibitory effects on the secretion of insulin, glucagons, and PP but its role within the islet remains largely enigmatic. Conversely, insulin appears to have a major regulatory effect on somatostatin secretion by δ cells. Hypertrophy and hyperplasia of δ cells have been demonstrated in insulinopenic humans and animals. Very little is known about the function of **PP** apart from its capacity to inhibit exocrine pancreatic secretion and intestinal motility, and to stimulate secretion of gastric and intestinal enzymes. **VIP** induces glycogenolysis and hyperglycemia and stimulates gastrointestinal fluid secretion.

Islets are *innervated* by sympathetic, parasympathetic, and peptidergic nerves. Activation of the sympathetic nervous system in hypoglycemic states stimulates glucagon release from α cells and epinephrine release from the adrenal medulla to boost blood glucose.

Islets are *richly vascularized* and may receive up to 10% of pancreatic arterial blood flow. Small arterioles penetrate the β cell-rich core of the islets and then form a glomeruloid network of fenestrated capillaries that drain into collecting venules either within or external to the islets. This portal arrangement permits high concentrations of insulin to be carried to endocrine cells situated in the islet mantle and exposes acinar cells to hormones.

β cells are polarized, with one domain facing an arterial capillary and another a venous capillary. Numerous microvilli project from the β cells into canaliculi that lie between the lateral surfaces of contiguous cells. Interstitial fluid is thought to flow through the canaliculi in an arterial to venous direction, with glucose uptake by β cells occurring by means of transporters (particularly glucose transporter-2) on the microvilli. Glucose sensing by the β cell is via the products of glucose catabolism. It is therefore dependent upon the rate of intracellular glycolysis and especially upon the rate-limiting glycolytic step that is catalyzed by glucokinase.

Electrical activity of β cells is synchronized within individual islets, possibly via intercellular gap junctions. An increase in these gap junctions is associated with enhanced insulin secretion. There also appears to be synchronization of activity of endocrine cells in all islets, permitting periodic oscillations in serum insulin and glucagon concentrations; such synchrony may reflect intrinsic neural coordination. Nevertheless, the population of β cells appears to be heterogeneous in function. Thresholds for glucose stimulation of insulin secretion and synthesis vary amongst β cells and there also appear to be differences in the response of islets in different regions of the pancreas and of β cells within individual islets to glucose stimuli.

Interactions *among different types of islet cells are complex and incompletely understood.* An increase in the blood glucose concentration normally simultaneously stimulates insulin secretion by β cells and suppresses glucagon secretion by α cells. Suppression of the α cells is thought to be largely a consequence of the high concentration of insulin carried by the portal vascular system from the β-cell core of the islets to α cells in the islet mantle. Somatostatin release by δ cells may also contribute to inhibition of glucagon release by adjacent α cells. Studies in dogs, rats, and primates reveal that islet hormones carried via the portal system have a paracrine effect on downstream islet cells, in a sequence from β to α to δ cells. α and δ cells are therefore influenced by insulin carried centrifugally by the portal system, but β cells are not influenced by glucagon or somatostatin, and α cells are not influenced by somatostatin via the portal blood. Although glucagon at pharmacological doses stimulates insulin secretion, there is no convincing evidence that glucagon plays a significant physiological role in regulating β-cell function. Somatostatin, in contrast, acts physiologically to inhibit insulin release from β cells. δ cells are of dendritic shape, and granule-containing projections of these cells lie adjacent to α, β, and PP cells. This arrangement may afford an anatomic basis for paracrine-inhibitory effects of somatostatin on the latter cells. Glucose appears to be the chief stimulus for somatostatin release by δ cells. Gradual somatostatin release from endocrine cells in the proximal intestine during the late phases of nutrient absorption may also act to slow postprandial insulin release, thereby permitting a smooth return of the blood glucose concentration to a fasting level.

β cells have receptors for numerous peptides other than insulin, glucagon, and somatostatin. These include arginine vasopressin, oxytocin, prolactin, placental lactogen, growth hormone (GH), glucocorticoids, estrogens, progesterones, cholecystokinin (CCK), secretin, gastrin, galanin, nerve growth factor, glucose-dependent insulinotropic peptide (GIP), and glucagon-like peptide 1 (GLP-1). Gastrin, CCK, and secretin are known to stimulate insulin release from β cells, but the physiological roles played by many of the other peptides in the islets remain to be established.

The insulin response to ingested glucose is greater than that to intravenously administered glucose. The augmented response to ingested glucose is largely attributable to insulinotropic effects of gastrointestinal hormones released during nutrient absorption. These so-called *incretins* are responsible for rapid insulin release soon after a meal and prior to a major increase in the blood glucose concentration. Both GIP and GLP-1 have been identified as significant incretins with additive insulinotropic effects. GLP-1 also appears indirectly to inhibit glucagon release and to stimulate somatostatin release, whereas GIP appears to be capable of stimulating glucagon release. GIP is chiefly synthesized by K cells in the mucosa of the duodenum and proximal jejunum and released in response to ingested carbohydrates and lipids. GLP-1 is produced by L cells in the mucosa of the distal small intestine and colon. These incretins are thought to play a critical role in glucose tolerance. A sluggish early insulin response to ingested carbohydrate has been demonstrated in humans with glucose intolerance, and the insulinotropic effect of GIP is lost in patients with type 2 diabetes mellitus. Whether the impaired incretin effect in diabetes reflects decreased sensitivity of β cells to GIP, decreased endogenous GLP-1 activity, or a combination of both is uncertain.

In **pregnancy**, there are substantial changes in maternal metabolism to meet increasing fetal metabolic demands. Increased caloric intake, enhanced insulin secretion, peripheral insulin resistance, and increased lipid metabolism in the dam result in sparing of glucose and amino acids for utilization by the fetus whilst lipids are used as an alternative maternal fuel. Crucial to these changes in maternal metabolism during pregnancy, at least in rodents and humans, are *hypertrophy and hyperplasia of β cells within existing islets and enhancement of their secretory response to glucose.* These adaptations, particularly the lowering of the threshold for secretion and, to a lesser extent, mitotic division of β cells, permit maternal islets to maintain elevated insulin secretion in the face of normoglycemia. Failure of these adaptive processes leads to *gestational diabetes mellitus.* In normal pregnancy, there is also decreased glucose tolerance, which reflects peripheral insulin resistance with a reduced rate of glucose clearance. Placental lactogens appear to be responsible for the upregulation of β-cell function in rats and humans during pregnancy; in humans, prolactin may also play a significant role. Progesterone may be responsible for counteracting the stimulatory effects of lactogenic hormones in the latter stages of pregnancy when insulin secretion returns towards normal levels.

β cells also have receptors for 1,25-dihydroxycholecalciferol and the latter is thought to modulate insulin secretion. Many in vivo studies have demonstrated that vitamin D administration improves insulin secretion in vitamin D-deficient animals but, rather than a direct effect of the vitamin, this may be but a consequence of restoration of normocalcemia and removal of the inhibitory effect of high levels of parathormone on insulin secretion. Moreover, some studies have demonstrated an inhibitory rather than stimulatory role of 1,25-dihydroxycholecalciferol on both β-cell growth and insulin secretion in vitamin D-deficient rodents.

The hypothesis that the endocrine pancreas is of neural crest (ectodermal) origin has been refuted by multiple studies. *Islets are now understood to develop from primitive endodermal epithelium of the embryonic foregut and their differentiation precedes that of exocrine elements.* Experimental studies indicate that endocrine differentiation is dependent upon interactions of endodermal epithelium with vascular endothelium, and that these interactions may be promoted by expression of vascular endothelial growth factor by the endodermal cells. Insulin expression first appears at sites where endoderm of the dorsal pancreatic diverticulum contacts endothelium of the portal vein. Although islet cells typically first appear as individual cells associated with the ducts, their development is not dependent on prior formation of the ducts. The four major islet cell phenotypes are derived from a common stem progenitor cell and, during early maturation, there may be transient stages of expression of multiple islet hormones and co-expression of enzymes involved in catecholamine synthesis.

Several *regulatory genes* expressed in endocrine cells of the embryonic pancreas have been identified. They include the homeodomain genes, *PDX1*, *Hlxb9*, *Nkx6.1*, *Isl-1*, *Pax4*, and *Pax6*, and the basic helix–loop–helix genes, *BETA2 (NeuroD)* and *neurogenin3 (ngn3)*. *ngn3* appears to act as a genetic switch that specifies differentiation of pluripotent endodermal cells into endocrine cells. Mice that are homozygous for a null allele of *ngn3* lack all endocrine cell types and die of diabetes mellitus within a few days of birth. Conversely, overexpression of *ngn3* results in premature differentiation of progenitor cells into endocrine cells at the expense of exocrine pancreatic development. The other regulatory genes appear to function in controlling proliferation, differentiation, and survival of precursors of the four major islet cell types once *ngn3*-induced commitment to an endocrine phenotype has occurred.

Insulin production by β cells is not essential for normal endocrine pancreatic organogenesis. However, insulinopenia throughout embryonic and fetal development in mice results in the emergence of hyperplastic islets, suggesting that insulin may function as a negative inhibitor of islet cell growth in utero.

Factors implicated in **growth and maturation of islet cells** include GH, prolactin, TGF-α, gastrin, and nerve growth factor (NGF). TGF-α and gastrin act in concert to induce the differentiation of ductular precursor cells into β cells. GH and prolactin act together to promote expression of receptors for NGF on β cells. In response to GH, both fetal and adult β cells release IGF-1, which in turn stimulates β-cell replication.

Islet cells may constitute up to 10% of the total cells of the early embryonic pancreas, and the first to form may co-express insulin and glucagon. Initially, the islet cells are individualized but later they appear in small nonvascularized clusters. Formation of typical islets by aggregation of cells occurs at a relatively late stage of gestation and vascularization of the islets occurs independently of that of the exocrine parenchyma. Individualized and clustered islet cells may persist, especially at the periphery of lobules. Islet cells lying outside acinar tissue in association with ducts may give rise to tumors in adult animals.

Differing rates of contribution of the dorsal and ventral duct anlagen may account for regional variations in the density of islets and for the variety of cell types present within islets. The distribution of β and δ cells is relatively constant throughout the pancreas in cats, dogs, cattle, and horses, but the density of α and PP cells is variable. In these species, islets rich in α cells are derived from the dorsal pancreatic primordium and its accessory pancreatic duct and are therefore concentrated in the left pancreatic lobe. Islets rich in PP cells are derived from the ventral primordium and its pancreatic duct and are concentrated in the right lobe. Islets rich in both cell types may be found in the body of the pancreas.

Glucose does not stimulate insulin synthesis and release by fetal β cells, although they are capable of responding to other insulin secretagogues. Glucose sensitivity of β cells is only acquired after birth, even though both glucokinase and glucose transporter-2 are both expressed in fetal β cells. Insulin gene expression increases between birth and weaning, and regulation of insulin secretion in response to glucose matures after weaning.

Two morphological types of islets can be identified in ruminants in the late fetal and neonatal periods. *Small islets* (which correspond to conventional islets of other species) are 25–200 μm in diameter and are embedded in exocrine parenchyma. *Large islets* (which diminish in size with age and are rarely observed in adulthood) are 100–1600 μm in diameter, lie in interlobular connective tissue, and chiefly consist of β cells. Endocrine cells of the large islets of fetal calves in the third trimester of pregnancy co-express insulin and galanin, with a surge in galanin synthesis occurring shortly before parturition and reaching a peak by day 5 postnatally. During the same period, there is a marked increase in the number of galanin-releasing nerve fibers innervating the exocrine acini and ducts. The significance of galanin production in the perinatal period in cattle is uncertain, but this peptide is known to inhibit insulin secretion and to have an inhibitory effect on smooth-muscle contractility, gastrointestinal motility, and release of several gastroenteric neurotransmitters and hormones.

Islets have been estimated to comprise 20–30% of fetal pancreatic mass. Formation of new endocrine cells and islets normally ceases in mice after weaning, but the mechanism responsible for this cessation is unknown. Postnatal expansion of the exocrine parenchyma results in a gradual proportional decrease in islets to less than 5% of organ mass by adulthood despite an increase in the volume of islets and the size of individual islet cells.

Islet cells in adults are capable of mitotic division. Replication of β cells can be experimentally stimulated by exposure to glucose, D-mannose, essential amino acids, glucocorticoids, gastrin, CCK, GH, prolactin, IGF-1 and IGF-2, platelet-derived growth factor (PDGF), epidermal growth factor (EDF) and indeed by insulin itself via stimulation of the IGF-1 receptor. The response to amino acids is important in the fetus, in which islets lack sensitivity to glucose, but is less prominent in the adult. Notwithstanding these observations, most β cells have been shown in postnatal rats to have entered an irreversible G_0 phase of the cell cycle and only a small fraction of the population is capable of mitotic division. This fraction declines from approximately 10% in the perinatal period to less than 3% in early adulthood. An alternative to division of pre-existent islet cells is replacement of islet cells by stem cells.

Various hypotheses exist regarding the location of *islet stem cells* in adult animals. Some researchers have proposed that these cells reside in the ductal epithelium, the interstitium, or within islets or even within the bone marrow or spleen. Others have suggested that replacement of β cells in adult animals may occur via transdifferentiation of acinar cells or islet cells expressing hormones other than insulin. Irrespective of their location, facultative stem cells are postulated to proliferate following pancreatic injury, differentiate into β cells, and thence migrate to replenish existing islets or cluster to form new islets. Budding of acinar and islet cells from hyperplastic ductules has been observed histologically in many experimental models in a variety of mammalian species, with expression of *PDX1* occurring concomitantly with the β-cell neogenesis. Following experimental surgical removal of 90% of the pancreas in rats, the mitotic index of pre-existent islet cells increases, but only for a few weeks. Sprouting of ductules occurs from the cut surface of the organ and new islet and acinar cells may be generated from these hyperplastic foci. Similarly, ductular hyperplasia with budding of new islet cells can be experimentally induced by provoking chronic inflammation within the pancreas. Indeed, studies in rodents have indicated that *the entire pancreatic mass of β cells can be replaced every 30 days by processes of programmed cell death and formation of new islet cells from progenitor cells located in the ductal epithelium.* Toxic ablation of β cells in rodents by administration of alloxan or streptozotocin is usually associated with permanent cell loss. Lack of significant cell replacement in the latter model may reflect destruction of both stem cells and mature β cells. Nevertheless, during the period of partial recovery from streptozotocin-induced injury in mice, there is evidence of expression of *PDX1* in δ cells and subsequent transformation of these cells into β cells. The capacity for transformation of ductal or non-β islet cells into insulin-secreting islet cells is not surprising, given that any cell, if altered to allow transcription of the insulin gene, can produce proinsulin. In fact, processing, packaging, and regulated secretion of insulin are possible in endocrine cells that have been so altered.

Notwithstanding these observations that support the concept of islet stem cells in adult animals, a study that used a genetic cell lineage tracing technique demonstrated no stem cell replacement of β cells in adult mice, even following substantial pancreatectomy. Rather, new β cells appeared to be replaced entirely by mitotic division of pre-existent β cells. One explanation that could reconcile this finding with previous observations is that there may be unipotent pancreatic endocrine stem cells in which the insulin gene is transcriptionally active so that these stem cells are indistinguishable from differentiated β cells.

Reduction in pancreatic insulin content with **age** is recognized in rats and mice. However, although smaller islets may lose their ability to respond rapidly to glucose, this appears to be compensated by a normal insulin response from larger islets. Experimental data in rodents indicate that release of insulin, glucagon, and somatostatin is maintained throughout the lifespan. Alterations in endocrine pancreatic structure and function with advancing age are not well documented in domestic animals.

Developmental anomalies of the islets

Aplasia and **hypoplasia of islets** are reported in dogs as causes of insulin-dependent diabetes mellitus, often manifesting in the first few months of life. *In aplasia, no islets are identifiable.* As islets are irregularly distributed in the normal pancreas, many parts of the organ must be examined microscopically to establish the diagnosis. *Hypoplasia of β cells is predominantly identified in purebred dogs.* It is inherited as an autosomal recessive trait in Keeshonds and a similar disorder has been reported in a Chow Chow pup and as a probable inherited disorder in Golden Retrievers. In the Keeshond, β cells are absent from islets but individual β cells remain scattered throughout the acinar parenchyma. In other cases of islet hypoplasia, a few small islets may be present. The exocrine pancreas shows moderate atrophy consistent with withdrawal of trophic influences but is otherwise normal.

Degenerative lesions of the islets

Atrophy, necrosis, amyloidosis, and sclerosis

Atrophy of the islets may occur as a result of fibrosis in chronic interstitial pancreatitis, but diabetes is seldom a complication. Atrophy may also be observed in insular amyloidosis.

Vacuolar degeneration of β and sometimes α cells due to glycogen accumulation is a common finding in diabetes mellitus.

Necrosis of the islets occurs in *acute pancreatic necrosis*. Their progressive destruction in this condition is a common cause of diabetes mellitus in dogs. Insular insufficiency may also arise from extensive neoplastic destruction of the pancreas. Although several viruses can replicate within the pancreas and provoke insulitis and necrosis of islet cells, most are not known to provoke clinically significant islet injury. The exceptions are *Bovine viral diarrhea virus* and *Foot-and-mouth disease virus*, both of which may lead to type 1 (insulin-dependent) diabetes mellitus in cattle.

Amyloidosis of the islets occurs in humans, other primates, raccoons, and domestic and wild cats and is a *characteristic lesion of type 2 (non-insulin-dependent) diabetes mellitus* in more than 90% of affected humans and cynomolgus macaques and in more than 80% of affected cats. Insular amyloid may also be detected in clinically healthy cats, with the amount deposited increasing with age, but the prevalence is significantly lower in age-matched nondiabetic animals than in diabetics. The amyloid is a useful morphological marker of disturbed β-cell function and, when detected in normoglycemic cats, is indicative of a potential prediabetic state. Islet amyloidosis has not been reported in diabetic dogs, but may be found in islet cell tumors in this species.

Although the extent of amyloid deposition in diabetes is not directly related to the severity of impairment of glucose tolerance, the amyloid may contribute to dysfunction and degeneration of islet cells by acting as a diffusion barrier. Although the deposits are typically extracellular, amyloid may form intracellularly within β cells as a consequence of intracellular digestion (crinophagia). Such deposits are directly toxic; they disrupt cell membranes and may induce apoptosis or necrosis of β cells.

Islet amyloidosis is a localized primary form of amyloidosis, in which the amyloid deposits are restricted to the islets. The major constituent of insular amyloid is islet amyloid polypeptide (IAPP) produced by β cells. In the species in which insular amyloidosis occurs, IAPP has a central amyloidogenic amino acid sequence (residues 20–29), and a high local concentration of the hormone favors the formation of amyloid fibrils. Increased IAPP secretion occurs in obesity and has been demonstrated in normoglycemic cats with impaired glucose tolerance. However, studies in transgenic mice overexpressing human IAPP indicate that overproduction of the hormone is insufficient alone to induce amyloid formation. An accompanying defect in β-cell synthesis, processing, transport, secretion, or degradation of IAPP may also be necessary. It is postulated that, in insulin resistance, constant overstimulation of insulin and IAPP secretion may lead to IAPP fibrillogenesis via the depletion of factors required to process and secrete IAPP. Alternatively, fibril formation may be promoted by an increase in β-cell synthesis and secretion of IAPP relative to insulin. There is experimental evidence that an increase in the IAPP-to-insulin ratio may occur in response to hyperglycemia, hypertriglyceridemia, and to corticosteroid excess. Insulin itself appears to inhibit IAPP amyloidogenesis.

In **cats**, amyloid deposition occurs particularly in peripheral parts of the islets, in the immediate vicinity of β cells. Extracellular fibril formation is initiated in close association with the β-cell membranes. A perivascular orientation of amyloid around islet capillaries may be obvious in some cases. In cats with advanced diabetes, most islets are affected and may be remarkably enlarged. Most of the islet space is occupied by amyloid and islet cell numbers are severely depleted (Fig. 3.23). Unlike secondary systemic amyloid derived from serum amyloid A, the affinity of insular amyloid for Congo red dye and its birefringence characteristics on polarization are retained after exposure to potassium permanganate and dilute sulfuric acid.

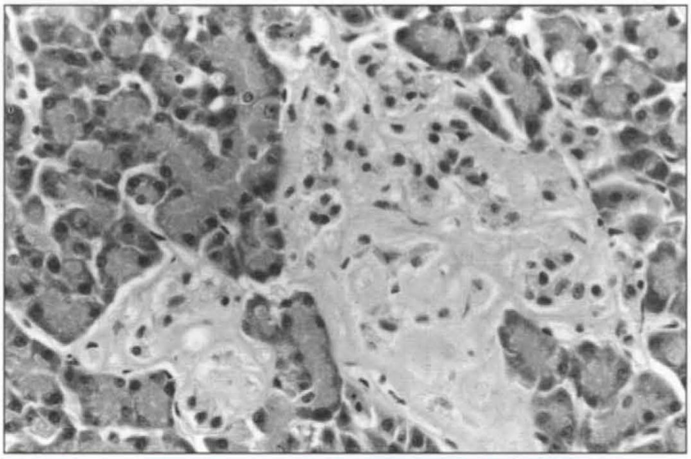

Figure 3.23 Amyloidosis of islets of Langerhans in diabetes mellitus in a cat.

In **dogs** with diabetes mellitus that is not the result of pancreatic necrosis, various degrees of *sclerosis of the islets* may occur. Mild sclerosis is, however, occasionally observed in aged nondiabetic dogs, so its diagnostic significance is difficult to assess. The sclerotic process may be focal or diffuse within affected islets and the collagen deposits commonly appear hyalinized. Mild fibrosis and focal mineralization have also been observed in conjunction with lymphocytic insulitis in **cattle** with type 1 diabetes mellitus.

Diabetes mellitus

Diabetes mellitus is a common metabolic disorder of dogs and cats, but is rarely seen in cattle, small ruminants, pigs, or horses.

The clinical syndrome of diabetes is caused by failure of the β cells to provide sufficient insulin to meet the metabolic demands of the body. The insulin deficiency may be absolute or relative, and a consequence of inadequate synthesis and release by β cells, decreased sensitivity of target organs to insulin, antagonism of insulin by other hormones or drugs, or a combination of these mechanisms. Although the etiopathogenesis of diabetes mellitus may vary, all cases share some common metabolic, clinical, and pathologic features.

The most common *clinical signs* of uncomplicated (nonketoacidotic) diabetes mellitus are weight loss despite a normal to increased appetite, polydipsia, and polyuria. *A relative or absolute deficiency of insulin leads to a generalized catabolic state.* Persistent hyperglycemia reflects a combination of decreased glucose entry into cells, diminished glucose oxidation, increased glycogenolysis, and increased gluconeogenesis from amino acid sources. Diversion of amino acids from protein synthesis into gluconeogenesis contributes to muscle atrophy and weight loss. Hyperlipidemia results from increased lipolysis and diminished uptake of free fatty acids by adipocytes. The hepatocytes are presented with a large excess of mobilized fatty acids that cannot be adequately processed and exported as lipoproteins because of reduced glucose availability and a shortage of ATP. Hepatic lipidosis results and there may be palpable hepatomegaly. Hyperglycemia increases the filtered load of glucose in primary urine to a level that exceeds the renal tubular threshold for resorption, leading in turn to glucosuria, osmotic diuresis, polyuria, and compensatory polydipsia. Dehydration may develop if water intake does not match urinary losses. Electrolyte disturbances, particularly hypokalemia, largely reflect solute loss in urine. Glucosuria represents a significant caloric loss that contributes to weight loss. Polyphagia despite persistent hyperglycemia reflects decreased entry of glucose into neurons of the hypothalamic satiety center.

Diabetes mellitus is of insidious onset. The normal pancreas contains a substantial reserve of β cells, and insulin-secreting capacity may have to be reduced to 20% of normal before the catabolic processes become dominant. The anabolic effects of insulin are exerted on many tissues and through numerous metabolic steps, not all of which are deranged equally or simultaneously as the insulin deficiency develops. *Impaired glucose tolerance develops early in the condition, and is a feature that is common to all types of diabetes mellitus.*

Classification of diabetes mellitus

The classification of diabetes mellitus into its various subtypes continues to evolve as new knowledge is gained. The reference classification is that used for the human condition, although it is not directly applicable to domestic animals.

In the human classification, **type 1 diabetes mellitus** *is generally consistent with juvenile-onset and insulin-dependent diabetes mellitus.* Patients with type 1 diabetes have a *severe absolute deficiency of insulin* due to autoimmune destruction of β cells. They have negligible insulin response to secretagogues such as glucose and are dependent upon insulin therapy for survival.

Type 2 diabetes mellitus *is generally consistent with adult-onset and non-insulin-dependent diabetes mellitus.* However, some patients may develop this form of diabetes when young and insulin dependence may emerge over time. Type 2 disease is characterized by both *impaired insulin action (insulin resistance)* and *inadequate insulin secretion* to meet metabolic demands. The capacity of β cells to secrete insulin and the number of β cells decline as the disease advances. Depending on the stage of the disease and the functional capacity and number of β cells present, affected patients may be hypo- or hyperinsulinemic. Islet amyloidosis develops in the majority of patients.

Complex genetic traits and environmental influences influence the occurrence of both type 1 and type 2 diabetes in humans.

A third category (previously termed type 3 or secondary diabetes mellitus, but now referred to in the reference classification as **specific types of diabetes**) includes all cases of diabetes mellitus arising as a consequence of insulin antagonism or nonspecific destruction of islets in pancreatic inflammatory, necrotizing, or neoplastic processes.

Glucose toxicity and lipotoxicity

Irrespective of the mechanism underlying diabetes mellitus, once persistent hyperglycemia develops, insulin secretion by β cells becomes suppressed. In both type 1 and overt type 2 diabetes, there is profound unresponsiveness of β cells to changes in blood glucose concentration. This is thought to be due to the deleterious effects of chronic hyperglycemia on β cells, a phenomenon known as *glucose toxicity.*

Glucose normally stimulates transcription of the insulin gene by causing phosphorylation of *PDX1* to enhance binding of the latter to the insulin gene. Glucotoxicity of β cells following prolonged hyperglycemia is mediated by downregulation of glucose transporters on the membranes of β cells and hence downregulation of expression of both the insulin and *PDX1* genes. As well as impairing β-cell secretion of insulin, the persistent hyperglycemia contributes to induction of peripheral insulin resistance.

Glucose toxicity is initially reversible if glycemic control is improved (termed *glucose desensitization*). If hyperglycemia persists for more than 2 weeks, however, it leads to glycogen accumulation in islet cells and cell death. The susceptibility of β cells to glucose toxicity is thought to be greater if β cells are hyperfunctioning, as they may well be if β-cell loss has preceded the onset of hyperglycemia.

Persistent increases in serum fatty acids may also suppress insulin secretion by β cells in a phenomenon termed *lipotoxicity*. Lipotoxicity and glucotoxicity may suppress insulin secretion via a common pathway, as both are associated with an increase in the intracellular concentration of long-chain acyl-coenzyme A molecules.

Secretion of other islet hormones in diabetes mellitus

Impaired responsiveness of α and δ cells to glucose also occurs in diabetes mellitus. In type 1 diabetes, there is a relative or absolute increase in the serum glucagon concentration. This contributes to hyperglycemia by promoting hepatic glycogenolysis. It may also promote development of ketoacidosis by stimulating hepatic oxidation of fatty acids. The glucagon concentration also fails to rise in response to episodes of insulin-induced hypoglycemia. Glucagon responses to hyper- and hypoglycemia are also impaired in type 2 diabetes. One hypothesis is that deficient intraislet secretion of insulin is responsible for both failure of suppression of α-cell secretion in the face of hyperglycemia and failure of glucagon release in the face of hypoglycemia. Whether or not chronic hyperglycemia has a direct deleterious effect on α cells is unknown. Cats with type 2 diabetes have been shown to have mean fasting and glucose-stimulated serum glucagon levels that are significantly higher than those of normoglycemic cats.

Type 1 diabetes mellitus in humans and cattle

Although the initiating triggers are often not identifiable, the absolute hypoinsulinemia of type 1 diabetic humans is a direct result of depletion of β cells by selective autoimmune destruction. Genetic linkages confer high and low levels of susceptibility to this type of diabetes and an association with certain human lymphocyte antigen (HLA) haplotypes has been confirmed. The complex phenotype that is highly susceptible is characterized by poor β-cell defense mechanisms, efficient antigen presentation, and dysregulated cytokine production.

Exposure of genetically susceptible individuals to foreign antigens structurally similar to components of β cells is thought to be an important mechanism by which a cell-mediated immune response becomes directed against β cells. Viruses are the most likely candidate sources of foreign protein and several viruses of humans (group B Coxsackie, mumps, Epstein–Barr and rubella viruses, cytomegalovirus, influenza virus, herpesvirus, and enteric rotavirus) are suspected to play a role in the pathogenesis of type 1 diabetes in genetically predisposed individuals. Group B Coxsackie viruses and *Encephalomyocarditis virus* have also been incriminated in the development of type 1 diabetes in mice. The concept of molecular mimicry being important in triggering autoimmune attack has been supported by the finding that there is substantial sequence and epitope homology between Coxsackie B viral proteins and glutamic acid decarboxylase (GAD); GAD is the enzyme responsible for the synthesis of GABA and is expressed at high levels in β cells. Sequence homology between bovine milk casein and p69 protein of islet cells has also been demonstrated, lending support to the hypothesis that consumption of bovine milk by human infants may potentially lead to autoimmune islet attack.

β-cell apoptosis in type 1 diabetes appears to be largely mediated by perforin released by infiltrating cytotoxic CD8+ T lymphocytes. However, there is evidence in spontaneous animal models of diabetes and in prediabetic humans that the period of lymphocytic insulitis is preceded by a prolonged phase during which local synthesis and secretion of cytokines may contribute to β-cell dysfunction and/or loss. Intracellular proteins derived from any dying β cells may be taken up by islet dendritic cells. The latter respond by synthesizing and releasing cytokines that may damage additional cells.

β cells appear to be particularly susceptible to injury by cytokines and free radicals. IL-1, interferon-γ (IFN-γ), and TNF-α can all interfere with normal β-cell function and integrity via induction of free radicals. β-cell proteins damaged by free radicals may be presented to the immune system in a more antigenic form so that a self-perpetuating cycle of islet injury may be initiated. When acting in concert, IFN-γ and TNF-α almost completely abolish glucose-stimulated insulin secretion. The latter two cytokines can independently upregulate expression of class I major histocompatibility complex (MHC) molecules on β cells and, in combination, they can induce the de novo expression of class II MHC molecules on β cells. Increased expression of MHC molecules in turn promotes homing of autoreactive lymphocytes to the pancreas; homing may also be promoted by IL-2. IFN-γ may also activate quiescent autoreactive T lymphocytes so that they become responsive to antigens encountered in their vicinity. β-cell destruction may also involve Fas ligand, either directly or via generation of cytotoxic molecules such as nitric oxide. Although differentiation of helper T lymphocytes becomes shifted in type 1 diabetes towards the helper T lymphocyte type 1 (Th1) pathway, Th2 pathway cytokines such as IL-10 may also play a role in β-cell destruction via effects on the local vasculature and by promoting local release of other cytokines.

The immune destruction of β cells in humans proceeds slowly and years may elapse between the triggering event and the onset of clinical diabetes. In most patients, this period is characterized by the presence of circulating autoantibodies that serve as predictive markers of the disease. Autoantibodies may be directed against β-cell membrane or cytosolic antigens or even insulin, but appear to reflect an epiphenomenon rather than being directly implicated in the pathogenesis of islet destruction. During the asymptomatic phase, some islets will have lost all β cells, some will contain degenerating islet cells and lymphocytic infiltrates, some will be normal, and others may be hyperplastic. Ultimately, all β cells are lost and the inflammatory infiltrates disappear.

The islets of humans in advanced stages of type 1 diabetes are characterized by marked depletion of β cells, normal δ cell numbers, and normal to moderately reduced numbers of α cells. Such patients have reached a permanent state of insulin dependence.

Diabetes mellitus in cattle appears to be of comparable pathogenesis to type 1 diabetes in humans. Both *Bovine viral diarrhea virus* in persistent infections and *Foot-and-mouth disease virus* are capable of provoking autoimmune lymphocytic insulitis, leading to insulin-dependent diabetes in young cattle.

A comparable pathogenesis may occur sporadically in other species and may explain the occasional observation of lymphocytic insulitis and the presence of circulating antibodies directed against β-cell components and/or insulin in the absence of prior insulin therapy. However, there is little evidence to suggest that autoimmune islet destruction is a significant mechanism responsible for diabetes in cats or dogs.

Type 2 diabetes in humans and cats

Type 2 diabetes accounts for approximately 90% of cases of diabetes in humans and is a polygenic disease in which there is dysregulation of insulin secretion and insulin resistance. Not all the genes involved are known, but specific HLA haplotypes have been implicated. Insulin resistance is largely genetically determined in humans and is common in indigenous populations in which the incidence of diabetes is high. Chronic malnutrition may contribute to the high prevalence of disease in these populations. Experimental studies in rats have demonstrated that fetal or neonatal protein malnutrition may predispose to impaired glucose tolerance in adulthood and to gestational diabetes in pregnant females; moreover, the offspring of affected females are themselves at risk of developing type 2 diabetes by adulthood. Factors such as obesity, reduced physical activity, high dietary intake of fat and processed carbohydrates, inadequate dietary fiber, and stress greatly influence the expression of the genetic abnormality in humans by promoting insulin resistance.

All humans with type 2 diabetes have both insulin resistance and inadequate insulin secretion, but the relative severity of these two defects is variable. During the preclinical phase of impaired glucose tolerance, patients have a characteristic pattern of insulin secretion in response to glucose: the first-phase secretory response is attenuated, and the second phase is delayed and exaggerated. In later stages of the disease, the second phase of the insulin secretory response is lost.

The major defect in β-cell function in type 2 diabetes appears to be in glucorecognition, such that there is a marked decrease in the capacity of extracellular glucose to stimulate insulin release. This is thought to result from reduced synthesis of the glucose transporter in the β-cell membrane. Insulin release postprandially is normally initiated by GLP-1 acting in synergy with glucose. GLP-1 also inhibits glucagon release from α cells. In type 2 diabetes, augmentation of insulin secretion by GLP-1 is reduced despite increased secretion of this incretin. This is thought to be a consequence of rapid desensitization of the GLP-1 receptor in response to an increased GLP-1 concentration. When persistent hyperglycemia develops, the response of the β cells to glucose stimuli is further diminished by glucose toxicity so that the diabetic state becomes self-perpetuating.

Obesity is an important risk factor for the development of type 2 diabetes as it exacerbates any inherited predisposition to insulin resistance and leads to impaired glucose tolerance. Obesity causes internalization of insulin receptors on target cells, reduced insulin receptor affinity, and postreceptor defects in oxidative and nonoxidative glucose metabolism. However, obesity alone does not explain the occurrence of disease as most obese humans are normoglycemic and diabetes develops in only a small proportion.

Skeletal muscle is the most important site of insulin resistance, although the liver and other tissues are also involved. The major defect responsible for resistance in type 2 diabetes is at the level of postreceptor processing of insulin in muscle and leads to reduced glycogen synthesis within myocytes. IAPP is implicated as it antagonizes insulin-stimulated uptake into myocytes and also directly inhibits glycogen synthetase. IAPP promotes breakdown of muscle glycogen and this leads to release of lactate, which is then utilized in hepatic gluconeogenesis.

Some of the other risk factors for type 2 diabetes, such as *physical inactivity*, also contribute to insulin resistance, as does chronic hyperglycemia.

In the early stages of the disease, basal hyperinsulinemia and an exaggerated response to glucose may be detectable and these are considered to be compensatory responses to the insulin resistance. The combination of peripheral insulin resistance and defective insulin secretion promotes persistence of hyperglycemia. As overt diabetes emerges and progresses, insulin secretion by β cells declines and there is usually also progressive islet amyloidosis. Insulin independence is expected in the earlier stages of the disease, but in later stages insulin dependence may develop.

A small proportion of type 2 human diabetics are monogenic, with inactivating mutations of genes critical for normal β-cell function. Heterozygote carriers of the mutant genes develop early-onset diabetes (*termed mature-onset diabetes of the young, or MODY*). Four MODY genes have been identified. The first encodes glucokinase, the rate-limiting enzyme for glucose metabolism in β cells. The other three genes encode transcription factors required in the regulation of insulin gene transcription: *PDX1* and *hepatocyte nuclear factors 1α (HNF1α)* and *4α (HNF4α)*. The clinical characteristics of **juvenile-onset diabetes mellitus of dogs** closely resemble those of MODY in humans.

Most cases of **diabetes in cats** bear a close clinical and pathologic resemblance to human type 2 diabetes, although there is a more frequent occurrence of ketoacidosis and insulin dependence in cats than in humans. Most diabetic cats are insulin-dependent by the time of diagnosis but, in earlier stages of the disease, have an attenuated first-phase insulin secretory response to glucose and an exaggerated second-phase response. Fasting hyperinsulinemia may be demonstrable in some cats and glucose stimulation may induce an increase in the serum insulin concentration.

In both cats and humans with type 2 diabetes, there is both progressive loss of β-cell function and progressive loss of β cells from islets. Reduced numbers of both β and α cells have been demonstrated in diabetic cats, with the δ-cell fraction remaining normal. This is comparable to findings in many humans with type 2 diabetes, although some patients may have α-cell hyperplasia.

Mechanisms incriminated in the gradual decline in function and number of β cells are glucose toxicity, lipotoxicity, and islet amyloidosis. The marked decrease in insulin secretion that develops as persistent hyperglycemia and overt diabetes emerge is largely referable to glucose toxicity. Islet amyloidosis is detectable in most diabetic humans and cats but is not a prerequisite of type 2 diabetes. The mechanisms by which amyloidosis contributes to altered function and elimination of islet cells have been discussed in Degenerative lesions of the islets, above.

IAPP is deeply incriminated in the pathogenesis of type 2 diabetes in humans and cats, not only because of its amyloidogenic properties but also because of its effect on insulin action in target tissues. Normally, the ratio between the plasma IAPP and insulin concentrations is relatively constant. However, an absolute or relative increase in the IAPP concentration develops in impaired glucose tolerance once fasting hyperglycemia develops and is also present in the early stages of overt type 2 diabetes. As IAPP inhibits glucose-stimulated insulin secretion by β cells and increases hepatic gluconeogenesis, it can contribute to hyperglycemia. In skeletal muscle, IAPP is responsible for insulin resistance by inhibiting glucose uptake and by promoting glycogenolysis. As adipose tissue is insensitive to the action of IAPP, it has been postulated that increased plasma concentration of IAPP could also promote a shift of glucose mobilized from muscle glycogen into adipocyte fat to cause obesity as a secondary event. In later stages of type 2 diabetes, the plasma concentration of IAPP becomes subnormal as a result of β-cell degeneration and loss.

The concept of glucose toxicity is of enormous clinical importance in cats with type 2 diabetes as early therapeutic intervention to reduce the magnitude of hyperglycemia may preserve β-cell function and even allow remission of the diabetic state. With early intervention and adequate glycemic control, remission is possible in 20–40% of cats presented with diabetes. Resolution of these so-called *transient diabetes cases* occurs most commonly within 1–3 months of commencing insulin therapy.

Diabetes mellitus chiefly affects *older cats*, with the highest incidence in those 8 years of age or older. The *Burmese breed* appears to be overrepresented amongst diabetic cats in Australia, but breed predispositions have not been identified elsewhere. Male cats, particularly *castrated males*, are more commonly affected than females.

Obesity significantly increases the risk of developing glucose intolerance and clinical disease in cats. Physical inactivity and consumption of commercial feeds rich in highly digestible carbohydrate may contribute to obesity. Obese cats are insulin-resistant and chronic hypersecretion of insulin to combat this may ultimately exhaust the β cells. Reduction in tissue sensitivity to insulin of as much as 52% has been demonstrated in obese cats. This is probably the major mechanism by which glucose intolerance develops but reduced glucose effectiveness (the ability of glucose itself to promote its own uptake by cells at basal insulin levels) is also a feature of weight gain in cats and may contribute. Cats that are lean because of underlying low tissue sensitivity to insulin are particularly at risk of developing glucose intolerance if they gain weight, especially if they have fasting hyperinsulinemia. The latter observation is consistent with the theory that prolonged secretion of excess insulin ultimately exhausts the β cells. It remains to be seen whether low insulin sensitivity in lean cats is genetically determined, as it is in humans.

Several factors may explain why male cats are at greater risk of diabetes than females. First, males are predisposed to develop obesity and, when obese, tend to have a significantly greater mass of adipose tissue than do affected females. The greater the fat mass, the less effective is insulin in lowering the blood glucose concentration. Second, lean male cats appear to have significantly lower tissue sensitivity to insulin than do lean females and the sensitivity declines further following weight gain. Obese male cats also appear more likely to develop fasting hyperinsulinemia than obese female cats.

Diabetes mellitus in dogs

The typical age range for clinical diabetes in dogs is *4–14 years*, with a peak incidence at 7–9 years of age. *Females* are twice as likely as males to be affected and *obesity* increases the risk because of induction of insulin resistance and impaired glucose tolerance. Breeds that are commonly affected include the Miniature and Toy Poodle, Beagle, Dachshund, Standard and Miniature Schnauzer, Miniature Pinscher, Samoyed, Spitz, Lhasa Apso, Bichon Frise and Australian, Fox, Yorkshire, and Cairn Terriers. A genetic basis for the disease has been demonstrated in Keeshonds and is suspected in Golden Retrievers; in these breeds, clinical onset may be at a few months of age and is referable to islet hypoplasia.

The etiopathogenesis of diabetes is uncertain for a large proportion of canine cases. In many dogs, diabetes is referable to *nonspecific islet destruction* by pancreatic necrosis or to *insulin antagonism* arising from concurrent illnesses such as hyperadrenocorticism. Inherited forms of diabetes are rare. Autoimmune destruction of β cells may be responsible in a minority of dogs.

Almost all diabetic dogs are insulin-dependent by the time of diagnosis. Non-insulin-dependent diabetes is rare and most cases are identified in severely obese dogs. A honeymoon period has been observed in some dogs with insulin-dependent diabetes soon after diagnosis; at this stage, glycemic control can be achieved with small doses of insulin. However, the required dose of insulin usually increases over the following 3–6 months as residual functioning β cells are destroyed.

The clinical course of diabetes mellitus in dogs has many similarities to that of type 1 diabetes in humans in that *most affected animals have an absolute insulin deficiency at the time of diagnosis, the loss of β-cell function is permanent, and lifelong insulin therapy is mandatory.*

Unlike the case in cats, *transient diabetes is uncommon in dogs.* Diabetes may be reversed by ovariohysterectomy of bitches with insulin antagonism by progesterone in pseudopregnancy. Very early therapeutic intervention in other insulin-antagonistic disorders such as hyperadrenocorticism may also be successful in reversing the diabetes.

Diabetes mellitus secondary to pancreatic disease

Diabetes mellitus referable to nonspecific islet destruction is most often seen in dogs. Acute pancreatic necrosis is a common cause of insulin-dependent diabetes mellitus in adult dogs. Diabetes develops in approximately 15% of dogs that have the chronic relapsing pattern of the pancreatic necrosis and there may be concurrent exocrine pancreatic insufficiency. Extensive organ destruction by pancreatic adenocarcinoma may also provoke diabetes mellitus in older cats and dogs. Chronic pancreatitis is occasionally responsible in cats and horses, but in most cases of pancreatitis there is insufficient β-cell destruction to provoke diabetes.

Secondary insulin antagonism, diabetic ketoacidosis, and nonketotic hyperosmolar diabetes

Antagonism of insulin by diabetogenic hormones or drugs is an important mechanism responsible for diabetes mellitus in small animals. *Diabetogenic hormones include glucocorticoids, glucagon, epinephrine, progesterone, thyroxine, and growth hormone (GH).* The antagonism is exerted in peripheral tissues and may lead to sustained hyperglycemia that may ultimately exhaust the β cells. Affected animals are initially non-insulin-dependent, and early clinical intervention to control the underlying disease may allow resolution of the diabetes if an adequate population of functional β cells still remains. However, animals with insulin antagonism are likely to have had some reduction in β-cell number prior to the onset of overt diabetes and are prone to have clinical recurrence of diabetes if insulin antagonism recurs for any reason thereafter. Failure to intervene early in insulin antagonism commonly results in transition from non-insulin-dependent diabetes mellitus to a permanent insulin-dependent diabetes mellitus state.

Endogenous progesterone is diabetogenic in the bitch and persistent corpora luteal action in *pseudopregnancy* may initiate diabetes, with clinical signs usually emerging 3–4 weeks post estrus. Pyometra sometimes coexists with the diabetes. Antagonism of insulin by progesterone and synthetic progestagens in dogs is indirect via stimulation of release of GH from the pituitary; the excess GH inhibits insulin receptor activity and intracellular responses to insulin. Ovariohysterectomy may resolve the diabetes.

Increased progesterone concentration can also result in onset or exacerbation of diabetes during *pregnancy*. Hyperglycemia in pregnant diabetic bitches enhances the secretion of fetal GH so that pups may be large at term. Hyperplasia of β cells and neonatal hypoglycemic seizures have been observed in offspring of bitches in which diabetes was poorly controlled during pregnancy.

Synthetic progestagens such as medroxyprogesterone acetate and megestrol acetate can also induce diabetes in dogs. Synthetic progestagens are directly diabetogenic in cats by virtue of their glucocorticoid-like activity.

Estrogen reduces the sensitivity of insulin receptors. Exacerbation of diabetes at estrus has been observed in dogs.

Insulin antagonism by excess endogenous cortisol or administered corticosteroids is common in dogs with *hyperadrenocorticism*. It is the most consistent expression of that condition in cats, being largely responsible for the major clinical signs of polyuria, polydipsia, and polyphagia.

Functional *pituitary acidophil tumors* secreting excess GH may cause diabetes mellitus via insulin antagonism in cats and dogs. In horses with large *adrenocorticotropic hormone-secreting adenomas of the pars intermedia*, glucose intolerance associated with hyperinsulinemia may develop but it is not referable to hormonal antagonism of insulin. Downregulation of insulin receptors on target cells is thought to develop in response to chronic polyphagia that in turn is referable to hypothalamic compression by the adenoma rather than to diabetes or significant hypercortisolemia.

Thyroxine and triiodothyronine are thought to accelerate insulin degradation and clearance to stimulate gluconeogenesis and glycogenolysis. Concurrent hyperthyroidism may therefore exacerbate diabetes mellitus.

Insulin antagonism may also occur in small animals with glucagon-secreting islet cell tumors and with pheochromocytomas producing excess catecholamines. β-blockers and diuretic drugs such as furosemide and thiazides have been reported to trigger diabetes in dogs. Diuretics may induce hypokalemia that impairs both glucose uptake by peripheral tissues and insulin secretion. Diuretics also promote hyperglycemia by stimulating glycogenolysis in the liver and skeletal muscle.

If diabetic animals develop a concurrent stressful illness, increased circulating levels of diabetogenic stress hormones such as catecholamines, cortisol, glucagon, or GH may induce insulin antagonism and exacerbate the hyperglycemia. This greatly increases the risk of development of **diabetic ketoacidosis** (DKA).

DKA is most commonly observed in dogs and cats in which diabetes mellitus has gone unrecognized and untreated. It may also develop in treated patients that are receiving an inadequate insulin dose, especially if another stressful illness is superimposed. As the discrepancy between available insulin and the metabolic demand for it widens, the stimulus for lipolysis increases so that there is increased entry of free fatty acids into the liver. In the absence of adequate glucose, hepatocellular metabolism shifts from triglyceride synthesis to fatty acid oxidation. β-hydroxybutyric and acetoacetic acids and acetone are generated from excess acetyl-coenzyme A and dissociate to provoke ketoacidosis. Ketone bodies in circulation compound the hyperosmolality attributable to hyperglycemia whilst those in urine contribute to osmotic diuresis.

Once ketogenesis commences, severe illness usually manifests within 7 days. DKA is characterized by severe hyperglycemia, a metabolic titration acidosis, ketonemia, ketonuria, severe hyperosmolality, osmotic fluid shifts from intracellular to extracellular compartments, exacerbated osmotic diuresis with loss of sodium, potassium, magnesium, and glucose, and profound dehydration and hypovolemia. Hypovolemic shock will exacerbate the acidosis by inducing lactic acid release from hypoxic tissues. Clinical signs include lethargy, anorexia, depression, dehydration, vomiting, tachypnea, weakness, and abdominal pain. If ketoacidosis is severe, there may be a strong odor of acetone and dyspnea with slow deep breathing (Kussmaul's respiration). Cats may become recumbent and moribund. Death may result from hypovolemia, hyperviscosity of blood, severe acidosis, hypokalemia, thromboembolism, and/or renal failure.

Nonketotic hyperosmolar diabetes is also a life-threatening complication but occurs much less frequently than DKA in cats and dogs, notwithstanding that many sick diabetic cats are hyperosmolal. The syndrome is characterized by extreme hyperglycemia and hyperosmolality, severe dehydration due to profound osmotic diuresis, and central nervous system depression in the absence of ketoacidosis. Clinical signs reflecting the cerebral effects of progressive hyperosmolality may include restlessness, ataxia, nystagmus, mental confusion, depression, delirium, seizures, hyperthermia, semicoma, or coma. Death may result from respiratory failure. In humans, this form of diabetes is usually seen in aged type 2 diabetics with concurrent illness. Low levels of endogenous insulin in these patients are sufficient to maintain antilipolytic and antiketogenic effects but are insufficient to allow adequate glucose uptake by tissues.

Lesions of diabetes mellitus

The lesions of diabetes mellitus in cats and dogs are comparable. *Apart from emaciation, and possibly dehydration, the principal postmortem finding is diffuse hepatic lipidosis.* The pancreas may appear normal or reveal the lesions of postnecrotic scarring, neoplasia, or chronic pancreatitis. Hypertriglyceridemia may be indicated by lipemia.

Microscopic lesions can usually, but not always, be found in the pancreas. In addition to the insular changes described earlier, there may be *vacuolation of islet cells and of epithelial cells lining the smaller ducts* (Fig. 3.24). Vacuolation reflects accumulation of glycogen and is a specific lesion of diabetes mellitus but is thought to be present only in severe and rapidly developing cases. There is usually severe diffuse macrovesicular hepatic lipidosis and often biliary epithelial vacuolation due to glycogen accumulation (Fig. 3.25). In dogs, glycogen may also accumulate within the nuclei of hepatocytes. *Glycogen nephrosis* is a specific lesion of diabetes. The glycogen is chiefly deposited in tubular epithelium of the loops of Henle and the distal convoluted tubules and mainly in the nephrons of the inner cortex. There is also fatty degeneration of the epithelium of the proximal renal tubules (Fig. 3.26). Lipid emboli are occasionally detectable in glomerular capillaries.

In chronic diabetes, *diffuse or nodular glomerulosclerosis* may develop. Periodic acid–Schiff-positive basement membrane material accumulates to cause hyaline thickening of the capillary basement membranes and sclerosis of lobules in the glomerular tufts. Diffuse thickening of the mesangium also develops and may lead to glomerular obliteration. There may be tubular evidence of proteinuria referable to increased glomerular permeability. Basement membrane thickening may also be apparent in Bowman's capsule and convoluted tubules as well as in capillaries in other organs.

A majority of human diabetics succumb to secondary complications involving the heart, kidneys, vasculature, and nervous system. Some of these complications are a consequence of protracted hyperglycemia and the formation of *advanced glycosylation end-products*. These irreversible products accumulate on long-lived proteins such as those of the lens, renal glomeruli, collagen, and peripheral nerve myelin, and they may lead to significant structural and functional alterations to these proteins. Vascular injury is responsible for many of the complications of diabetes in humans.

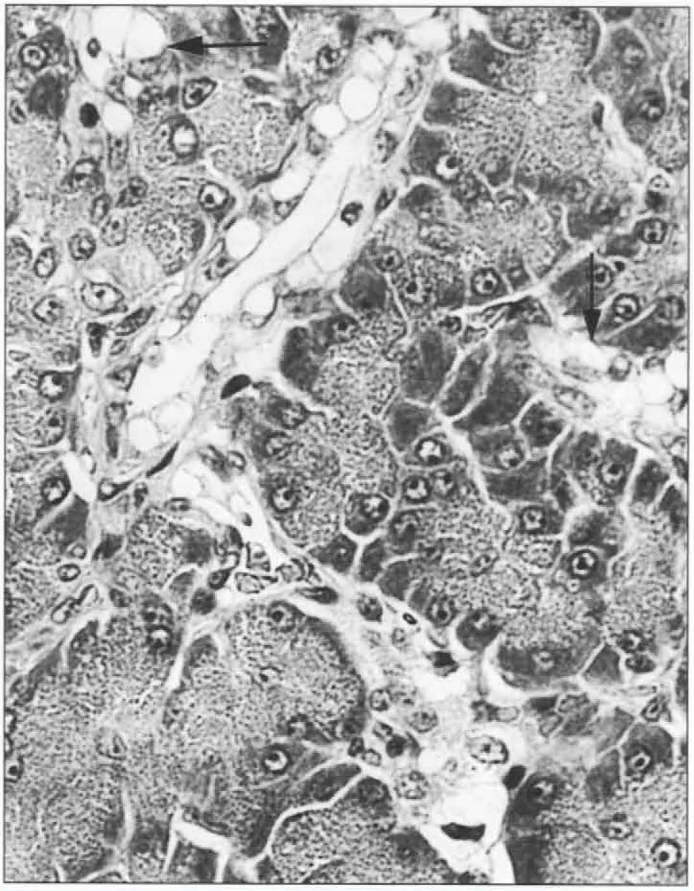

Figure 3.24 Hydropic degeneration of islet cells (arrows) and ductal epithelium due to glycogen accumulation in diabetes mellitus in a dog.

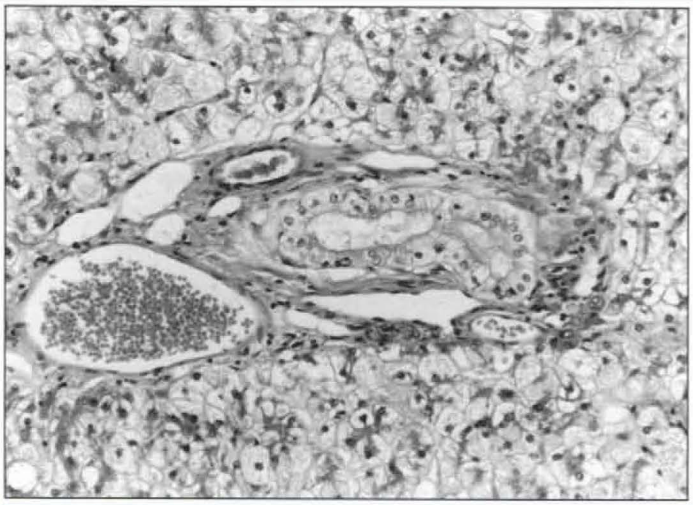

Figure 3.25 Severe hepatic lipidosis with **hydropic degeneration** of bile duct epithelium due to glycogen storage in diabetes mellitus in a dog.

Most of the complications that are so important in human diabetes are rarely seen in domestic animals, probably because of the shorter duration of the disease in animals. *Glomerulosclerosis* is usually only seen in cats and dogs with chronic diabetes of several years' duration. *Diabetic retinopathy* is diagnosed infrequently in dogs and only manifests 5 years or more after onset of diabetes. The retinal vascular changes comprise venous dilation and tortuosity, saccular capillary microaneurysms, and focal hemorrhage, and are most severe at the posterior pole. These nonproliferative lesions in dogs resemble early stages of human diabetic retinopathy. Diabetic retinopathy has been experimentally induced in cats.

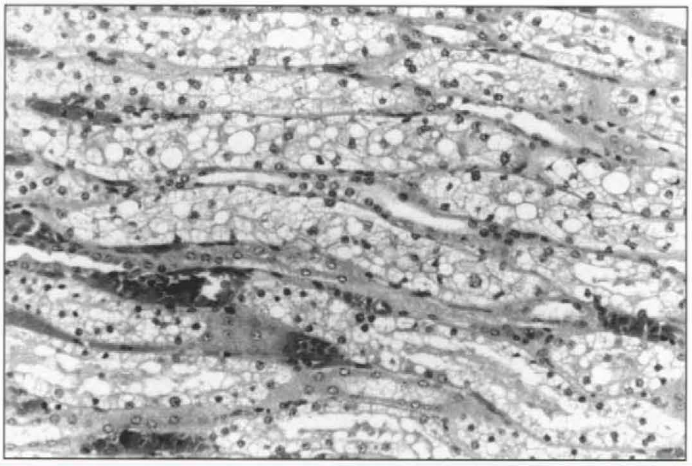

Figure 3.26 Fatty degeneration of proximal renal tubules in diabetes mellitus in a dog.

Cataract formation is an early and common complication of diabetes in the dog and may be the presenting sign. Dogs with poorly controlled diabetes and erratic fluctuations in blood glucose concentration appear to be particularly at risk of developing cataracts. Cataracts can develop rapidly and are irreversible. Cataracts are observed infrequently in diabetic cats, suggesting that their lens metabolism differs from that of dogs or that the lens capsule is less permeable to glucose.

Peripheral demyelinating neuropathy is a well-recognized complication of diabetes in cats but occurs very infrequently in dogs. It usually involves the distal limbs symmetrically and approximately 8% of diabetic cats have a characteristic plantigrade stance. There may be progressive paraparesis, pelvic limb hyporeflexia, proprioceptive deficits, and atrophy of distal hindlimb musculature. Thoracic limb involvement is rare. Autonomic and cranial nerve involvement is common in human diabetes, but is reportedly rare in dogs. The peripheral neuropathy involves axonal degeneration and segmental demyelination and remyelination in distal parts of motor and sensory nerves. The pathogenesis is uncertain but probably multifactorial. Possible mechanisms include depletion of intracellular myoinositol and decreased Na-K ATPase (both of which could impair nerve conduction), nonenzymatic glycosylation of tubulin (which could impair axonal transport), glycosylation of myelin (leading to impaired conduction and macrophage uptake), and altered fatty acid metabolism (with impaired synthesis of cell membranes and myelin). The neuropathy is reversible if glycemic control is achieved soon after it manifests, but not in protracted cases.

As is the case in human diabetes, *secondary infections are common in diabetic cats and dogs.* Most involve the respiratory and urinary tracts and skin. Emphysematous cystitis is occasionally seen in diabetic animals with lower urinary tract infections involving glucose-fermenting bacteria such as *Escherichia coli*, *Proteus* sp., and *Aerobacter aerogenes*. Abnormal neutrophil function has been demonstrated in diabetes, including defective chemotaxis, impaired adhesion, and decreased phagocytic and intracellular killing capacity. Glucose binding to complement C3 may also cause diminished opsonization of microorganisms. In poorly controlled diabetes, lymphocyte proliferative capacity in response to mitogens is also decreased, and there is reduced expression of T and B surface markers.

Diabetes mellitus has also been associated with the development of *superficial necrolytic dermatitis* and, rarely, vitiligo in dogs, a skin fragility syndrome in cats, and cutaneous xanthogranulomas in both species. These disorders are discussed in Vol. 1, Skin and appendages.

Hyperplasia of the islets and nesidioblastosis

The total number of islet cells in health represents the balance between cell division or neogenesis and cell loss via apoptosis or necrosis.

Subtle proliferative responses of the islets may be difficult to detect microscopically due to regional variation in islet density within the pancreas and because of alterations in islet size that may occur with aging. *Diffuse hyperplasia of islets is rarely appreciated in domestic animals but is probably underdiagnosed.* It has been described in humans and other primates, mice, rats, hamsters, and horses. The enlarged islets appear hypercellular and may compress the adjacent exocrine parenchyma. Islets may comprise more than 40% of the affected pancreatic lobules and most of the hyperplastic cells are insulin-secreting.

The cause of islet hyperplasia is uncertain but it may represent a *compensatory phenomenon* following pancreatic injury with partial loss of islets or in conditions of decreased synthetic function of islets or antagonism of their hormone products. In many cases, islet

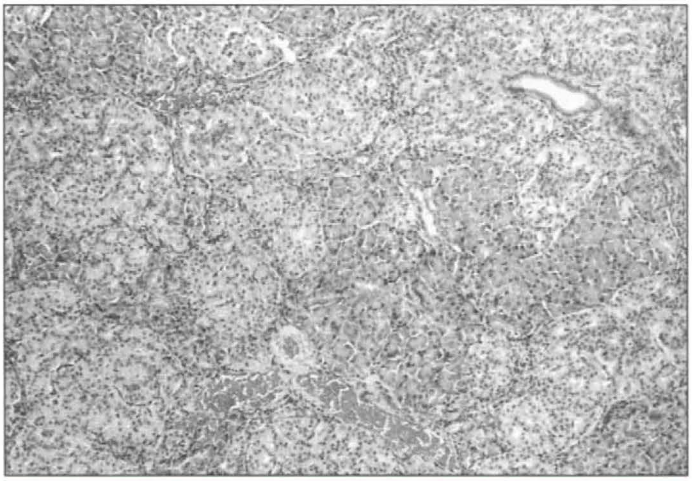

Figure 3.27 Nesidioblastosis (ductular and islet cell proliferation) in a dog.

hyperplasia is accompanied by evidence of β-cell degeneration or islet hyperemia. In humans, islet hyperplasia is seen in hyperinsulinemic hypoglycemia of infants, in infants born of diabetic mothers, in chronic pancreatitis, in Zollinger–Ellison syndrome, and in multiple endocrine neoplasia. In rats and humans, hyperplastic islets have been reported in pancreatic fibrosis. Hyperplasia is also documented in aged rats and horses, in sedentary obese rats, and in hamsters treated with corticosteroids.

Nesidioblastosis *is the term used to describe combined ductular and islet cell proliferation* (Fig. 3.27A, B). Newly formed islet cells appear to bud from proliferating epithelium of small intralobular ductules and thence migrate and organize into discrete islets. Nesidioblastosis may coexist with islet hyperplasia. Nesidioblastosis is typical of *hyperinsulinemic hypoglycemia* in humans. It can be experimentally induced in rodents by pancreatic injury with partial loss of islet cells, partial pancreatectomy, and partial pancreatic duct obstruction. Nitrosamine administration to hamsters induces nesidioblastosis early in pancreatic carcinogenesis, although the islet tissue is eventually replaced by exocrine neoplastic tissue. Nesidioblastosis has also been described in aged rats and horses, in dogs and humans with islet cell neoplasia, and in dogs with type 1 diabetes mellitus.

Neogenesis of islets from ductules is thought to be mediated by growth factors produced within the pancreas and acting locally. As induction of islet neogenesis may be a means to combat absolute or relative insulin deficiency in diabetes mellitus, intensive research is currently focused on delineating the roles of such trophic factors as ilotropin, regeneration protein, insulin-like growth factors (IGFs), and neurotrophins.

Neoplasia of the islets

Pancreatic islet cell tumors are uncommon in domestic animals. Most have been described in dogs and ferrets. They may be benign or malignant and, although usually solitary, may be multiple. In cattle, islet cell tumors may coexist with pheochromocytomas.

Grossly, islet cell tumors are characterized by their firm consistency, sharp demarcation, homogeneity, and distinctive pale gray-purple color. Circumscription and even encapsulation are not reliable indicators of benign behavior as solitary and circumscribed carcinomas may have metastases in adjacent lymph nodes and commonly the liver.

Microscopically, both adenomas and carcinomas form architectural patterns that are highly reminiscent of normal islets. The cells form trabecular, pseudoacinar, or glandular arrays or solid nests separated by a delicate fibrovascular stroma (Fig. 3.28A, B). Ductular structures may be identifiable within both adenomas and carcinomas, and small nests of exocrine acinar cells may be found within adenomas, particularly towards the periphery. Stromal deposits of *amyloid*, derived from IAPP, may be present in insulin-secreting tumors. Most islet cell tumors stain positively with chromogranin A and neuron-specific enolase.

Both adenomas and carcinomas may be associated with syndromes of hormonal hypersecretion, although some tumors are clinically silent. The release of hormones is typically inappropriate and not subject to normal physiological controls, although most tumors are not completely autonomous. Numerous peptide hormones have been identified within islet cell tumors in humans, and more than one hormone can usually be demonstrated by immunohistochemistry within the majority of such tumors in dogs, ferrets, and cattle. The variety of peptide-producing cells present in carcinomas is usually reiterated in metastases. Notwithstanding the presence of multiple hormones, *clinical signs primarily reflect excess or inappropriate secretion of only one hormone.* Clinical syndromes referable to production of insulin, gastrin, glucagon, PP, and somatostatin have been documented in domestic animals; syndromes referable to secretion of VIP, secretin, IAPP, or adrenocorticotropic hormone are yet to be identified.

Insulinoma

Most functional islet cell tumors described in domestic animals have contained a large proportion of β cells and been associated with a *syndrome of hyperinsulinism, episodic hypoglycemia, and neurologic signs.* Most reported cases have involved *middle-aged to older dogs*, with Boxers, Fox Terriers, German Shepherds, Labradors, Golden Retrievers, Irish Setters, Weimaraners, Collies, German Shorthaired Pointers, and Standard Poodles being overrepresented. Insulin-secreting tumors are also common in *ferrets*, especially males, and may coexist with estrogen-secreting tumors of the adrenal cortex. They are very infrequently observed in older cattle, cats, and horses.

Clinical signs reflect both inadequate glucose supply to the central nervous system and increased catecholamine secretion by the adrenal medulla in response to hypoglycemia. *The most common signs are episodic seizures, weakness, and collapse* that, with ataxia, depression,

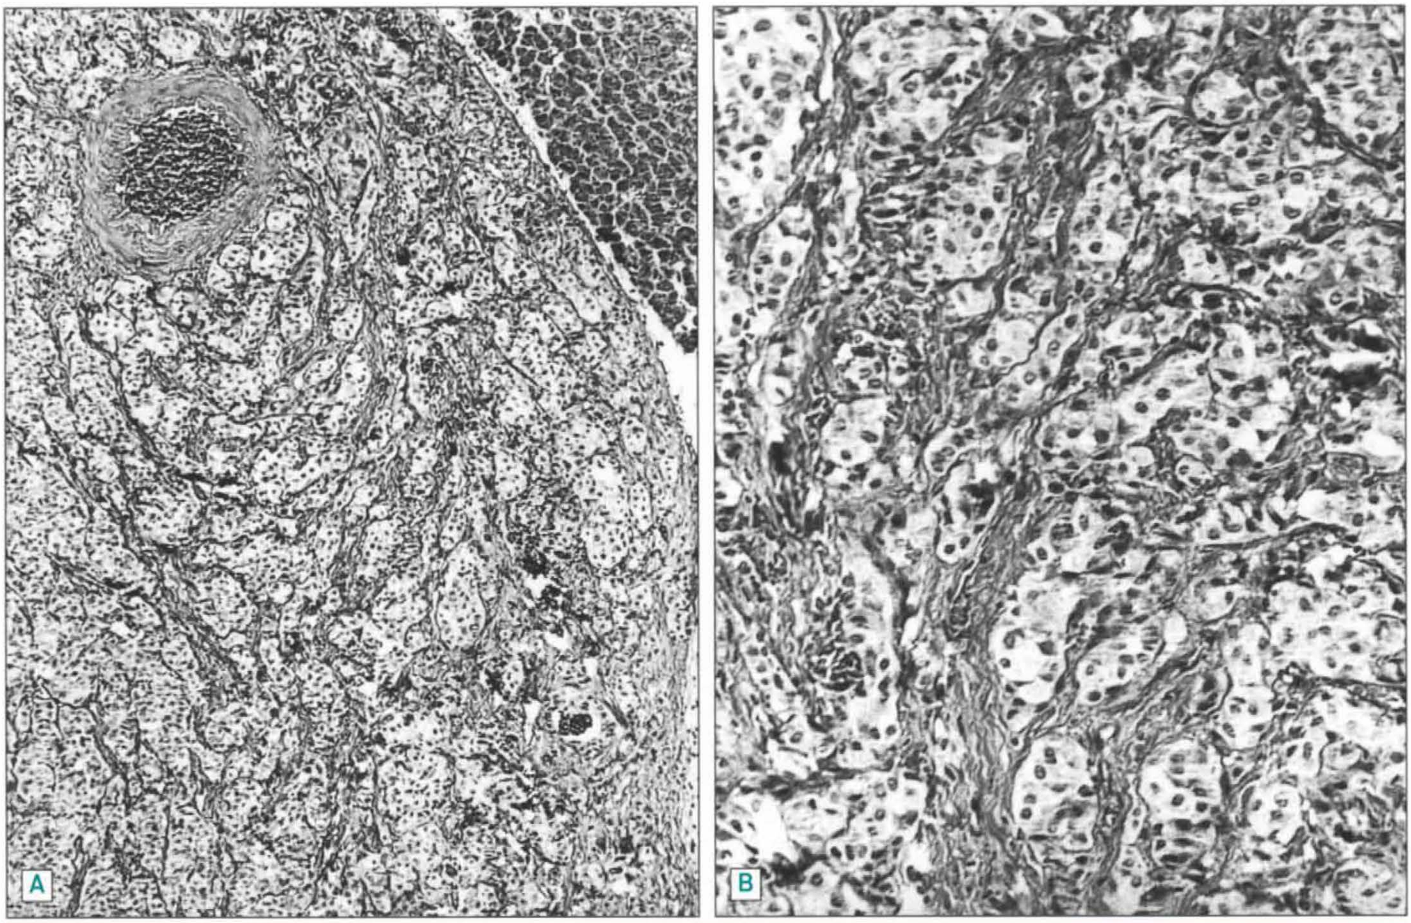

Figure 3.28 Pancreatic islet cell tumor. **A.** Low-power view of the tumor compressing acinar parenchyma. **B.** Detail of (**A**).

and mental confusion, reflect *neuroglycopenia* and are rapidly alleviated by administration of glucose. Signs of sympathetic nervous system stimulation include trembling, muscle fasciculations, restlessness, hunger, and behavioral changes and often precede signs of neuroglycopenia. Ptyalism is a common sign in affected ferrets. The severity of clinical signs depends upon the duration and severity of hypoglycemia and the rate at which the blood glucose concentration falls. When fasting hypoglycemia is recurrent or persistent, adaptation permits tolerance of extremely low blood glucose levels without obvious clinical signs.

Clinical episodes are often triggered by fasting, exercise, excitement, or eating. In fasted animals, insulin secretion by the tumor exacerbates the decline in the blood glucose level. Most dogs with insulinomas will become hypoglycemic after a fast of 8 hours or less. Feeding often stimulates excessive insulin secretion by the tumor to result in hypoglycemia 2–6 hours postprandially. Exercised or excited animals with insulinomas have increased glucose utilization by all tissues because of abnormal availability of insulin and this is exacerbated by impaired hepatic glycogenolysis and reduced capacity for hepatic gluconeogenesis.

The frequency, intensity, and duration of episodes increase progressively over time. However, the episodes are characteristically of brief duration because release of counterregulatory hormones such as catecholamines, glucagon, and cortisol act to restore the blood glucose concentration above the critical threshold. If these compensatory mechanisms are inadequate, syncope, coma, or, more commonly, seizures develop. Seizures may stimulate further counterregulatory hormone release to boost the glucose level so that the seizures usually last only seconds to a few minutes. Rarely, repeated episodes of severe and prolonged hypoglycemia may cause irreversible cerebrocortical necrosis.

Uncommon manifestations of insulinomas in dogs include weight gain, due to the anabolic effects of insulin, and persistent insomnia. In a minority of affected animals, peripheral polyneuropathy develops and is characterized by demyelination, remyelination, and, to a lesser extent, axonal degeneration. Although the neuropathy may have a metabolic pathogenesis, it is considered more likely to result from an immune-mediated process due to common antigens being shared by tumor cells and components of peripheral nerves.

Most insulinomas are small, measuring 1 cm or less in diameter, so that a thorough search for a suspected tumor is necessary. Intraoperative identification may be facilitated by intravenous administration of methylene blue that becomes concentrated in the endocrine pancreas. Unlike the case in humans, *most insulinomas in domestic animals are malignant*, with locally invasive growth and early metastasis to regional lymph nodes and liver. Carcinomas tend to be larger than adenomas and may have a multilobular appearance and contain foci of hemorrhage and necrosis. Their aggressive behavior is belied by their usually well-differentiated histological appearance, although the component cells may be less uniform in size and shape than in adenomas. Demonstration of vascular or lymphatic invasion, the most important criterion of malignancy, may require examination of multiple sections. Adenomas are slow-growing, sharply delineated, and encapsulated, and are amenable to surgical excision.

Gastrinoma

Gastrin-secreting islet cell tumors are rare, but have been described in *dogs* and *cats*. Gastrin is not normally produced in mature pancreatic islets but rather by cells of the pyloric antral and proximal duodenal mucosa. Immunohistochemistry is needed to confirm a diagnosis of a pancreatic islet cell gastrinoma.

The clinical syndrome caused by hypergastrinemia is known as the **Zollinger–Ellison syndrome**. Excess gastrin causes gastric acid hypersecretion, antral mucosal hyperplasia, and gastroduodenal ulceration. There may also be reflux esophagitis and/or jejunal ulceration. Affected dogs and cats are presented with clinical signs of anorexia, vomiting, hematemesis, intermittent diarrhea (particularly with steatorrhea), and severe weight loss. Steatorrhea results from inactivation of pancreatic lipase and precipitation of bile salts at a low duodenal pH. Melena, abdominal pain, and polydipsia may also be observed, and affected animals may be anemic. Hyperplasia of thyroid C cells has been observed in a few dogs with a gastrinoma and may reflect stimulation of calcitonin release by gastrin, but this does not appear to be of clinical significance.

An elevated serum gastrin concentration may support a diagnosis of gastrinoma, especially if measurement of the pH of gastric fluid confirms hyperacidity, but provocative testing with secretagogues such as calcium or secretin may be necessary to demonstrate gastrin hypersecretion.

Gastrin-secreting tumors may be solitary or multiple and are usually of firm consistency, with often a prominent hyalinized stroma microscopically. Even when grossly circumscribed, there is usually infiltrative growth at their periphery. Metastasis to regional lymph nodes and liver is common and in most cases has occurred by the time of diagnosis so that the *prognosis is usually guarded to poor*.

Glucagonoma

A syndrome of *mild nonketoacidotic diabetes mellitus, diffuse vacuolar hepatopathy, hypoaminoacidemia, and superficial necrolytic dermatitis* has been recognized in humans in association with islet cell tumors that secrete excess glucagon. A similar syndrome, accompanied by small intestinal diarrhea, has been described in a few *dogs* with islet cell carcinomas secreting glucagon. Characteristic lesions of erythema, hyperkeratotic crusting, and erosion affect the footpads, mucocutaneous junctions, ears, and frictional and pressure points. *Diabetes mellitus results from the insulin-antagonistic effects of glucagon in stimulating hepatic gluconeogenesis and glycogenolysis*. Diarrhea is thought to be attributable to glucagon causing reduced absorption or stimulating net secretion of water and electrolytes by the small intestinal mucosa. The cutaneous lesions are induced by amino acid deficiency, with protein depletion of the epidermis. Theories as to why such a deficiency develops in an animal with a glucagonoma include amino acid utilization in gluconeogenesis and consumption of amino acids, especially tryptophan, in the synthesis of glucagon itself. The cutaneous lesions are not, however, pathognomonic of a glucagonoma. Indeed, most reported cases of superficial necrolytic dermatitis in dogs have been associated with severe vacuolar hepatopathy of obscure cause, with no pancreatic tumor detected. (Superficial necrolytic dermatitis is discussed in detail in Vol. 1, Skin and appendages).

PPoma

A clinical syndrome resembling Zollinger–Ellison syndrome has been observed in a single *dog* with an islet cell tumor secreting both insulin and pancreatic polypeptide (PP). Clinical signs included chronic vomiting, anorexia, and weight loss and were associated with duodenal ulceration and hypertrophic gastritis. PP secretion may have been responsible as this hormone decreases pancreatic bicarbonate secretion and is also a weak stimulant of gastric acid secretion.

Kidney

GENERAL CONSIDERATIONS

The kidney is the central organ involved in the maintenance of a constant extracellular environment in the body. The vital homeostatic functions performed by the kidney include excretion of waste products, maintenance of normal concentrations of salt and water in the body, regulation of acid–base balance, and production of a variety of hormones (erythropoietin, renin, prostaglandins), including metabolism of vitamin D to its active form, 1,25 dihydroxycholecalciferol ($1{,}25(OH)_2D_3$). *The essential requirements for normal renal function are: adequate perfusion with blood (pressure greater than 60 mmHg), adequate functional renal tissue, and normal elimination of urine from the urinary tract.*

Failure of the urinary mechanism occurs if there is inadequate perfusion (**prerenal failure**), inadequate processing (**renal failure**), or inadequate discharge (**postrenal failure**). The outcome so far as the composition of body fluids is concerned is always approximately the same; there is imbalance of salt and water, and of acids and bases, and there is retention of wastes. *The most commonly used index of failure is the amount of urea that is retained.* Urea itself is rather harmless, but if other urinary functions are sufficiently disturbed, a fairly consistent set of clinical signs emerges and the syndrome is called **uremia.**

Water and salt are, quantitatively and in an evolutionary sense, the most important constituents of body fluids. The assumption during evolution of a terrestrial existence and homeothermy by mammals imposed a need to conserve water and salt and simultaneously excrete large quantities of metabolites. Homeothermy, with sustained high body temperatures, imposed a sustained high metabolic rate, a need for control of the peripheral circulation, and structural modifications to the integument. Carbon dioxide is very soluble in water, and highly diffusible, and responsibility for its excretion has been transferred from the integument of aquatic and amphibian ancestors to the respiratory system of mammals; as the end-product of fat and carbohydrate metabolism, carbon dioxide presents no problem of elimination to the kidneys. However, nitrogenous wastes, and a multitude of other organic compounds and inorganic substances, impose a substantial load on the renal mechanism. Mammals excrete urea, which is highly soluble, diffusible, and osmotically active; excretion of wastes and conservation of water in mammals require concentrating mechanisms capable of raising the osmotic pressure of urine above that of blood. The extracellular fluid and plasma of the body are dialyzed through the kidney many times in a day, producing copious amounts of primary urine, of which almost all is reabsorbed. Although this system effectively rids the body of wastes, it requires a large expenditure of energy and a dependable renal blood supply.

Renal blood flow is normally high, up to 25% of the cardiac output. The kidneys are not given to reactive hyperemia, although blood flow may be increased by the action of pyrogens in febrile states. Pathologists are particularly concerned with the causes and consequences of reduced renal perfusion. Peripheral and splanchnic blood flow may be sacrificed in the event of crisis, but renal blood flow is only diminished in order to preserve circulation to the prime priorities of cardiac output, the heart and brain. Renal oxygen consumption, relatively small in relation to renal blood flow, is high relative to that of other tissues and is equal to about 10% of whole-body consumption. Most of the oxygen consumed by the kidney is expended in the resorption of essential solutes, a predominantly cortical function, and hence the consequences of reduced perfusion are largely borne by the cortex.

A unique feature of renal blood flow is that it varies little over a wide range of arterial pressures, thus ensuring a stable *glomerular filtration rate (GFR).* The kidneys possess intrinsic mechanisms by which they vary their vascular resistance in order to maintain constant glomerular filtration. Renal blood flow, upon which the function of nephrons depends, is normally directed predominantly toward the outer *cortical nephrons* rather than to the inner cortical, or *juxtamedullary nephrons*, but may be redistributed between the two areas. Reduction in perfusion is a common occurrence in the kidney, affects primarily the cortex, and may lead to atrophy of tubular epithelium and tubular dilation, to necrosis of tubular epithelium, or to more or less extensive necrosis of the renal cortex. Blood flow to juxtamedullary nephrons is maintained more effectively than is flow to outer cortical nephrons, and blood may be directed from the outer cortex to the inner cortex under conditions of reduced renal blood flow. Preservation of blood flow to juxtamedullary nephrons serves to maintain function of the nephrons that are able to conserve water, and hence aid in maintaining circulating blood volume, and that are able to concentrate urine, and hence to eliminate waste products economically.

The *glomerulus* produces ultrafiltrate as the net result of the difference between the high systemic blood hydrostatic pressure and the low proximal tubular hydrostatic pressure. Urinary ultrafiltrate is isosmotic with plasma and there is essentially zero colloid osmotic pressure in ultrafiltrate to favor diffusion. The glomerular basement membrane is semipermeable, and dissolved substances and particles in suspension move across the glomerular capillaries at rates determined by size, shape, and electrical charge. Malfunction of the glomerulus may be due to inadequate glomerular blood flow and/or structural alterations that decrease or increase its permeability. The outcome of glomerular injury is influenced by the limited capacity in the glomerulus for disposal of deposits, the capillary obstruction which results from swelling of endothelial and mesangial cells, the production of basement membrane-like material by injured mesangial cells, and permeability changes in basement membranes.

The principal function of the kidney is the regulation of salt and water balance; this requires a system of monitors and feedbacks in order to achieve fine regulation. The *renin–angiotensin system* regulates sodium balance, and the *hypothalamus and antidiuretic hormone* control osmotic and volume regulation. The structural basis of the renin–angiotensin system is provided by the *juxtaglomerular apparatus*; to maintain *glomerulotubular balance*, the GFR is adjusted locally and continually to changes in the chloride concentration of tubular fluid. Generally, and over the longer term, the renin–angiotensin system stimulates the adrenal glands to produce *aldosterone* to assist in the retention of sodium and therefore of water.

The formation of primary urine requires that substances from plasma must pass freely across the glomerular membrane and into the tubules. Once within the tubules the substances are, in a strict sense, outside the body. Many of the filtered substances are retrieved by a system of *selective reabsorption* that requires special machinery and energy. The function may be defective, allowing essential substances to be wasted in the urine. This occurs when enzymes are genetically deficient, or cortical epithelial cells are injured, or, because plasma levels of filterable substances are unusually high or the glomerulus is unusually permeable, the quantity of the material to be reabsorbed exceeds the transport capacity of the epithelial cells. Myriad tubular functions are carried out sequentially, and the structure of the tubule varies along its length corresponding to the function to be performed; at least 12 functionally and anatomically distinct segments are described.

Terrestrial mammals have a need to conserve water while eliminating high loads of waste, and a need therefore to concentrate urine above the tonicity of plasma. This function is provided by the *loop of Henle*; juxtamedullary nephrons have long loops and cortical nephrons have short loops. Some species have predominantly long loops and some predominantly short loops; those animals with a preponderance of long loops have greater concentrating ability. Although the deep or juxtamedullary nephrons are the first to develop and are active while centrifugal development of the rest of the cortex is under way, neonatal nephrons have immature functional capacity and a relative inability to conserve sodium. Neonatal pigs, in particular, are thus very susceptible to dehydration. In calves, in contrast to most other neonates, renal functional capacity approaches that of adult cattle within 2–3 days of birth.

According to the "**intact nephron**" or "adaptive nephron" hypotheses, nephron function is an all-or-none phenomenon. In progressive renal disease, the remaining nephrons respond by hyperplasia and hypertrophy, since new nephrons cannot be formed following renal maturation. Glomerular filtration and tubular function then increase concomitantly, and glomerulotubular balance and homeostasis are maintained. *All of the renal components are interdependent, and if one component is irreversibly damaged, function of the other components is impaired*: glomerular disease can cause decreased peritubular perfusion and tubular atrophy; tubulointerstitial disease can cause glomerular obsolescence. *There is a tendency for all forms of chronic renal disease to destroy all four components of the kidney, resulting in chronic renal failure and shrunken scarred* **end-stage kidneys**; differentiation of the initiating cause may be impossible. Interstitial inflammation and fibrosis may be primary events, but they also commonly accompany primary diseases of the glomeruli and tubules. In the past, chronic generalized renal disease in dogs was frequently ascribed to be the result of interstitial nephritis, and leptospirosis was espoused as the most common cause. Because of vaccination, canine leptospirosis is no longer prominent, and chronic renal disease in dogs, as it now occurs, is the end-result of a wide variety of causes.

Anatomy

The *renal collecting system* is derived from the ureteral bud (metanephric duct), a diverticulum of the mesonephric (Wolffian) duct, and consists of *the ureter, pelvis, calyces, and collecting ducts*. Nephrons develop from the metanephric blastema and attach to the growing ends (ampullae) of the collecting system. The *uriniferous tubule* consists of the nephron and the collecting tubule. The renal calyces are the cup-shaped recesses of the pelvis that enclose conical masses of medullary pyramids. The apex of a pyramid is referred to as a *papilla*, and its tip is fenestrated by collecting ducts (area cribrosa). The fornix is the uppermost blind end of a calyx or pelvis.

The kidneys of domestic animals can be classified as **unipyramidal** (unilobar) or **multipyramidal** (multilobar). *Cats, dogs, small ruminants, and horses have unipyramidal kidneys*. In cats, one lobe is present, and papillary ducts open into a calyx on a single renal papilla. In dogs, small ruminants, and horses, there is complete or partial fusion of several lobes and a single crest-like papilla (*renal crest*). *Pigs have multipyramidal kidneys* in which there are several distinct renal lobes, pyramids, and their respective papillae. Extensions of renal cortex between the pyramids are known as the *renal columns of Bertin*. Simple papillae occur in central pyramids, and compound papillae in pyramids at the renal poles; this is of pathogenetic significance because compound papillae are more susceptible to ascending infection. *The kidneys of cattle are also multipyramidal*, but have distinct external lobation, with each lobe having one pyramid. The renal calyces of cattle join directly to form the ureter without forming a pelvis. Note the difference

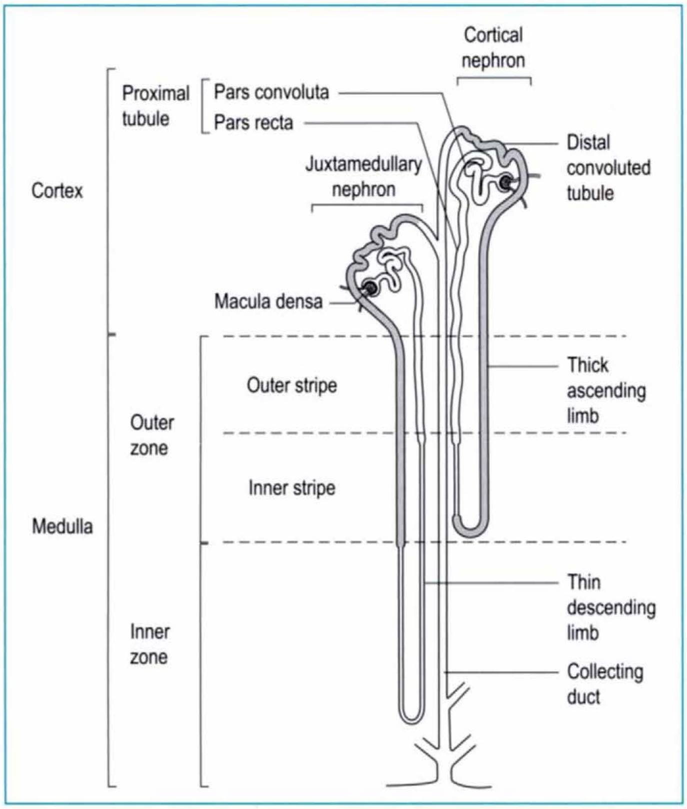

Figure 4.1 Diagram showing components of **cortical and juxtamedullary nephrons** and their location in zones of the kidney.

between a renal lobe and a renal lobule. A *renal lobule* consists of a medullary ray and its associated nephrons. *Medullary rays* are seen histologically as lighter-staining linear areas in the cortex, and consist of collecting tubules, thick ascending limbs, and the terminal straight portions of the proximal tubules. Interlobular arteries course between lobules.

On sagittal section of a kidney, *subdivisions of cortex and medulla* may be distinguished, particularly in dogs and sheep. The *cortex* has a darker outer zone, and a paler inner zone, which in mature dogs often has prominent pale streaks due to the presence of fat in collecting ducts. Outer and inner zones may be seen in the *medulla* of canine kidneys, and the outer zone may be further subdivided into outer and inner bands (stripes), due to the presence of the thick segments of the descending and ascending limbs of the loop of Henle, respectively. The inner zone of the medulla (papilla) contains the thin segments of the loop of Henle (Fig. 4.1). Mucous glands are large and prominent in the medulla of equine kidneys, and mucus and crystals are normally present in the equine renal pelvis.

The functional unit of the kidney is the **nephron**, which consists of the *renal corpuscle, proximal tubule, loop of Henle, and distal tubule.* The glomerulus and Bowman's capsule comprise the renal corpuscle. The following approximate numbers of nephrons are present in each kidney: human: 1 000 000; dog: 400 000; cat: 200 000. The number of nephrons is fixed at birth in most mammals, although nephrogenesis may continue for several weeks after birth in animals with a short gestation period, such as dogs, cats, and pigs.

Renal diseases may primarily affect one of four subdivisions of the kidney: blood vessels, glomeruli, tubules, and interstitium.

Vascular supply

Although the kidneys constitute only about 0.5% of body weight, *they receive 20–25% of cardiac output.* In multilobed kidneys, the *renal artery* divides in the pelvic region to form *interlobar arteries* that run in the renal columns between lobes up to the corticomedullary junction, where they branch to form *arcuate arteries.* These arteries run along the corticomedullary junction parallel to the capsule and terminate by radiating *interlobular arteries* into the cortex. Glomerular *afferent arterioles* are given off by the interlobular arteries, and give rise to several lobules of capillary loops within the glomerulus. The capillaries later rejoin to form the glomerular *efferent arteriole* and then divide again to form a peritubular capillary plexus. The efferent arterioles of the juxtamedullary nephrons branch to form *descending vasa recta* (straight vessels), which enter the medulla. The ascending vasa recta reform from the medullary capillary plexus and form a *countercurrent exchange system* with their closely associated descending vasa recta. The glomerular capillary tufts are perfused at high pressure that favors filtration; the capillary bed rising from the efferent arterioles is low pressure, favoring reabsorption.

Because the renal artery and its branches are *end-arteries,* occlusion of any branch leads to infarction. Interference with glomerular capillary flow markedly alters peritubular blood flow, especially in the medulla. The medulla is particularly sensitive to ischemia because of its relative avascularity and the low hematocrit in medullary capillaries.

Intrarenal blood flow is finely controlled by complex mechanisms, which are still being elucidated. The **juxtaglomerular apparatus** consists of the *afferent and efferent arterioles* adjacent to their respective glomerulus, the *macula densa* of the corresponding distal convoluted tubule, and a collection of cells (*lacis or nongranular cells*) at the glomerular hilus between the arterioles. Myoepithelial cells (juxtaglomerular or granular cells) of the afferent arteriolar wall contain *renin.* When afferent arteriolar blood pressure, and hence GFR, decreases, an intrinsic afferent arteriolar myogenic response and **tubuloglomerular feedback** (a negative-feedback loop) are activated. The tubular fluid chloride concentration is decreased at the macula densa, causing dilation of the afferent arteriole and constriction of the efferent arteriole to increase the GFR, as follows. Renin is released and this proteolytic enzyme cleaves angiotensinogen, an α_2 globulin of plasma, to form angiotensin I. Angiotensin I is subsequently cleaved by angiotensin I-converting enzyme to form *angiotensin II,* one of the most potent pressor agents known, and angiotensin III. Angiotensin III and, to a lesser extent, angiotensin II also initiate adrenocortical synthesis of *aldosterone,* which aids, over the longer term, in increasing afferent arteriolar perfusion by stimulating resorption of sodium from the distal convoluted tubules and collecting ducts, resulting in water retention and expansion of the extracellular fluid volume. Both angiotensin II and III induce prostaglandin synthesis. Angiotensin II also stimulates the secretion of *antidiuretic hormone* (ADH, vasopressin). The above events, in concert with angiotensin-mediated efferent arteriolar constriction, are sensed by the macula densa, and the tubuloglomerular feedback mechanism detailed above is reversed, leading to afferent arteriolar constriction, decreased GFR, and hence restoration of **glomerulotubular balance.**

The above mechanisms of blood pressure sensing and tubuloglomerular feedback result in maintenance of glomerular filtration pressure within fine limits over a broad range of systemic arterial blood pressure. The renin system is intimately interrelated with adenosine, atrial natriuretic peptide, endothelin, vasopressin, the renal kallikrein-kinin system, renal sympathetic nerves, and prostaglandins to *autoregulate intrarenal blood flow and modulate tubular salt and water transport.* The contribution of these factors to control of renal blood flow varies between normal and abnormal states; for example, *prostaglandins* are apparently of little significance in maintaining intrarenal blood flow under normal circumstances, but become important during periods of hypotension. *Endothelin-1*, which is released from endothelium by a range of perturbations, is a potent vasoconstrictor of afferent and efferent arterioles and a constrictor of mesangial cells; its action is countered by the vasodilatory effects of nitric oxide and prostacyclin. *Atrial natriuretic peptide* is released from the cardiac atria in response to volume overload and causes natriuresis and diuresis through vascular and other actions (endocrine effect). *Urodilatin*, another natriuretic peptide, is produced by distal convoluted tubule cells, and causes diuresis by local inhibition of sodium and water resorption (autocrine-paracrine effect).

The *renal venous system* begins with formation of venules from the peritubular vasa recta, and then closely parallels the arterial system. Veins in the outer cortex drain into stellate veins, which in cats are present on the capsular surface and are prominent, and thence into interlobular veins. Veins within the kidney have very thin walls and are susceptible to compression.

Lymphatics occur in the renal cortex and medulla. One set of lymphatics drains the cortical and medullary interstitium and follows the pattern of the vascular system; another set of lymphatics drains the capsular area. Lymphatic flow increases after urinary obstruction and in interstitial disease.

Glomerulus

The glomerulus is a vascular-epithelial structure designed for the ultrafiltration of plasma. It develops embryologically by the invagination of a capillary-rich mesenchymal mass into the Bowman's space, an epithelium-lined sac. The visceral epithelium covers the glomerular capillaries to become an essential part of the filtration membrane, and the parietal epithelium, or Bowman's capsule, lines the urinary space that receives glomerular ultrafiltrate. The arterioles enter and leave the glomerulus at the *vascular pole*, and urine enters the proximal tubule at the *urinary pole* of the glomerulus. The *glomerular filtration membrane* consists of three layers: (1) capillary *endothelium* containing fenestrae of 50–100 nm diameter; (2) *glomerular basement membrane (GBM)*, which is 100–300 nm thick and consists of a central electron-dense lamina densa and peripheral electron-lucent layers, the lamina rara interna and externa; and (3) *visceral epithelial cells (podocytes)*. The podocytes have complex interdigitating trabeculae whose *foot processes (pedicels)* are embedded in the lamina rara externa of the GBM. The pedicels are separated by 25–50 nm wide *filtration slits*, which are bridged by thin *slit diaphragms* with pores of 6–9 nm diameter. GBM is produced continuously by the podocytes, and is continuous below these cells, but does not completely encircle the glomerular capillaries; endothelial cells and mesangium are in direct contact. GBM is a complex porous meshwork composed of collagen (primarily type IV), laminin, polyanionic proteoglycans (mainly heparan sulfate), fibronectin, entactin, and other glycoproteins.

A large volume of glomerular ultrafiltrate is formed as a product of the high hydrostatic pressure of arteriolar blood, and the selective permeability of the filtration membrane. The entire plasma volume is filtered about 100 times per day. The glomerulus is highly permeable to water and small solutes, but virtually excludes albumin (molecular weight ~70 000, radius 3.6 nm) and higher-molecular-weight plasma proteins from the filtrate. The GBM is a *size-dependent barrier* to filtration, prohibiting passage of particles with radius greater than 3.5 nm. The filtration membrane also excludes particles from filtration on the basis of *charge*. Thus, anionic molecules such as albumin are repelled by virtue of the presence of negatively charged sialoglycoproteins in the lamina rara interna and externa and the negatively charged cell coats of the endothelial and epithelial cells. Obviously then, *changes in porosity or charge of the filtration membrane alter glomerular permeability and can lead to proteinuria, a hallmark of glomerular damage.* A small amount of albumin normally passes through the filter but is rapidly resorbed in the proximal tubules. The glomeruli of neonates are permeable to colostral protein for a few days.

The **mesangium** is the central region of the glomerulus that forms a supporting framework about which the glomerular capillaries ramify. *The mesangial matrix is basement-membrane-like periodic acid–Schiff (PAS)-positive glycoprotein, and the mesangial cells are phagocytic, contractile cells, which are derived from vascular smooth-muscle cells.* These cells function in phagocytic removal of deposited macromolecules, removal of GBM, and may modulate intraglomerular blood flow; mesangial cells both respond to and produce a variety of cytokines. Mesangial cell hyperplasia and increased mesangial matrix (mesangial sclerosis) are common changes in glomerular disease.

Tubules

The kidney functions by producing a large volume of protein-free glomerular filtrate from which is resorbed the constituents that the body needs. Thus, about 99% of the sodium chloride and water filtered are resorbed. This system effectively rids the body of wastes that are filtered by the glomeruli and not resorbed by the tubules. *Structure of a tubule segment is correlated with its function.* Thus, cells of the proximal convoluted tubule have a well-developed brush border and numerous mitochondria. Energy for the sodium pump in this actively resorptive area is provided by mitochondrial oxidative phosphorylation; this area is, therefore, especially vulnerable to ischemia. Also, toxins are frequently resorbed by or secreted by the proximal tubule, causing chemical injury.

About 90% of the hydrogen ion excretion by the kidney occurs in the proximal tubule. The proximal tubule actively resorbs large quantities of sodium and chloride, and water passively follows, hence 60–80% of the glomerular ultrafiltrate that enters the proximal tubule is resorbed isotonically. *Tubules and peritubular capillaries are in close apposition to allow rapid removal of resorbed sodium chloride and water.* Sodium is co-transported with glucose and amino acids. Hydrogen ions are accompanied by sodium bicarbonate as counterion. Proximal tubules are not responsive to aldosterone or vasopressin. In addition to salt and water, proximal tubules resorb glucose, amino acids, calcium, phosphate, uric acid, proteins, and potassium. Many substances, e.g., glucose, amino acids, water-soluble vitamins, are "threshold substances" which are almost completely resorbed until a certain concentration is reached in the glomerular filtrate, at which concentration the transport maximum is exceeded and the substance appears in the urine. Overloading of the resorptive capacity of the proximal tubules in conditions such as diabetes mellitus also overwhelms the resorptive capacity of distal tubules and leads to **osmotic diuresis**. Interference with the production, release, or action of ADH on the distal nephron and collecting ducts, as occurs in pituitary or renal diabetes insipidus, results in obligatory **water diuresis** and excretion of hypo-osmotic urine and hence polyuria. Proximal tubules secrete hydrogen ions, organic acids, *p*-aminohippurate, penicillin, and some iodinated radiopaque materials.

The long loops of Henle of the juxtamedullary nephrons penetrate deep into the medulla and assist in making the *renal medulla the only hypertonic tissue in the body*. Urine concentrating ability is directly proportional to the length of the loop of Henle; desert-dwelling rodents have very long loops of Henle, whereas baby pigs have short loops and are thus very susceptible to dehydration. The loops of Henle serve as *countercurrent multipliers* and the capillaries as simple *countercurrent exchangers*, with the flow in each occurring in opposite directions. The source of the solute gradient that becomes greater towards the tip at the papilla is the loop of Henle (active process). The gradient is preserved by the vasa recta countercurrent exchanger (passive process). Sodium chloride is pumped (chloride active, sodium passive) from the ascending limb of the loop of Henle into the interstitium, in turn drawing water from the descending limb, and progressively increasing the solute concentration in the descending limb. The ascending limb is impermeable to water, thus the tubular fluid becomes dilute and may be hypotonic. More salt may be resorbed from the collecting ducts, further diluting the fluid. Water diuresis occurs when a state of water excess exists and ADH is not released from the neurohypophysis. If *antidiuresis* is required, ADH is released and renders the epithelium of the collecting tubule highly permeable to water, reducing the volume of tubular fluid entering the hypertonic medulla. This remaining fluid is then concentrated to 3–4 times the blood osmolality (280 mosmol/L) during passage to the tip of the papilla. The water resorbed in the medulla is passively transported into the ascending vasa recta and removed. The solute concentration of the medulla is about one-half due to sodium, and one-half due to urea. During antidiuresis, ADH renders the cortical portions of the collecting ducts permeable to water but not urea, thus increasing the urea concentration of the luminal fluid. ADH increases the permeability of the medullary portions of the collecting ducts to urea and water; urea then diffuses from collecting tubule to interstitium until luminal urine and interstitial concentrations are equal. Tubules are not functionally mature in the kidneys of most neonates, thus they cannot generate hypotonic urine and hence conserve solute in the medulla; inability to produce a medullary solute gradient limits their capacity to concentrate urine.

There is little, if any, further modification of urine once it leaves the tip of the papilla. However, urea may be conserved by moving across the renal papillary epithelium from the pelvic urine. Either osmotic diuresis or water diuresis may result in **medullary solute washout** due to increased tubular flow rates and hence decreased efficiency of the countercurrent multiplier, the loop of Henle. The quantities of urea and sodium chloride resorbed are decreased due to decreased tubular fluid transit time. Hence, the medullary solute gradient decreases, as does urine concentrating ability. The same mechanism is operative in chronic renal disease in which there are high tubular flow rates in the small number of hypertrophic tubules present.

Although body buffers and pulmonary control of carbon dioxide excretion are the first line of defense in protecting the pH of the extracellular fluids, *it is the action of the kidneys that ultimately corrects acid–base balance*. The kidneys excrete the excess alkali or acid responsible for the disturbance. Thus, the kidneys correct metabolic alkalosis by excreting alkaline urine containing the excess bicarbonate. The kidneys correct metabolic acidosis by increasing resorption of filtered bicarbonate, excreting titratable acids (secrete hydrogen ions), and by producing ammonia.

Interstitium

The interstitium normally contains peritubular capillaries and a few fibroblasts, and interstitial tissue is usually only obvious around interlobar, arcuate, and interlobular arteries. *Expansion of the cortical interstitium is abnormal*, and may occur due to edema, cellular infiltration, or fibrosis. The glycosaminoglycan content of the medullary interstitium increases with age and ischemia. Specialized interstitial cells produce prostaglandins, particularly PGE_2 and $PGF_{2\alpha}$.

Examination of the kidney

Gross examination

The systematic gross inspection of a kidney entails observation of its *size, shape, color, and consistency*. The kidneys are usually equal in size and about three vertebrae long. Renal enlargement may occur due to addition of blood, edema fluid, fat, urine in the pelvis or tubules, or swollen or hypertrophic nephrons. Acute inflammation causes renal enlargement due to addition of fluid and cells, whereas chronic inflammation causes scarring and loss of substance. The kidneys are usually bean- or horseshoe-shaped, although the bovine kidney is lobated externally. Focal lesions, such as those caused by infarction or pyelonephritis, may markedly distort the renal outlines, whereas more generalized diseases such as glomerulonephritis do not. The normal renal color is brown-red, except in mature cats, in which the cortices are yellow due to their high fat content. The fat content in cats is apparently hormonally determined; pregnant females and sexually inactive old males have the most fat, pseudopregnant females and castrated males have somewhat less, estrous females and sexually active males have moderate amounts, and anestrous females have little or no renal fat. Kidneys autolyze fairly rapidly after death, particularly in fat animals in a warm environment. Pulpy kidneys occur due to clostridial enterotoxemia in sheep, and may be difficult to distinguish from advanced autolysis.

The urinary system may be maintained intact during examination, or the kidneys may be removed from the carcass. The kidney should not be severed from the ureter until the absence of hydronephrosis has been established. Each kidney is cut in the sagittal plane and the cut surface is examined. The *normal cortex-to-medulla ratio* in this plane is about 1:2 or 1:3. *The cortex normally accounts for 80% of the renal mass*, a fact which is better appreciated in a coronal, than in a sagittal, section. Diffuse diseases of the kidney usually respect the integrity of the medulla. Pyelonephritis is peripelvic with involvement of the medulla. A pale cut surface suggests the deposition of fat or acute early nephrosis; if the surface is pale and wet, there is edema and diffuse tubular dilation. Focal glomerular lesions do not cause glomerular prominence, but diffuse lesions, such as amyloidosis or diffuse glomerulitis, very often do. *Removal of the renal capsule is essential for examination of the outer surface of the cortex.* The capsule should strip easily and leave a smooth surface underneath. Tearing of the cortex may indicate fibrous adhesions of scarring, except in the horse, which normally has trabeculae attached to the capsule.

Histologic examination

The kidney must be trimmed so that a section from capsule to papilla is available. The section should first be examined subgrossly for evidence of localized lesions, e.g., infarcts, abscesses, granulomas, pyelitis, mineralization, neoplasm, scars, medullary loss. The section is then scanned at low power and lesions are noted. Glomeruli are normally distributed randomly throughout the cortex with approximately 3–4 present per 40× field. Tubules should be tightly packed with little intervening connective tissue. Goat and sheep glomeruli are more cellular than those of most species. Horses have the largest glomeruli of domestic animals (about 200 μm diameter) and the only glomeruli that are visible grossly. Glomeruli in neonatal kidneys are small and hyperchromatic, particularly in the outer cortex. Nephrons may be seen in the "S" stage of development in the outer cortex of fetuses and in neonates with ongoing centrifugal renal development, such as dogs, cats, and pigs.

After scanning the section, the four basic elements of the kidney should be systematically examined, namely glomeruli, tubules, interstitial tissue, and blood vessels, to determine which structure is primarily injured.

Reactions of **glomeruli** to injury consist basically of combinations of cellular proliferation, leukocytic infiltration, thickening of the basement membrane, and hyalinization or sclerosis. Epithelium of the proximal tubule may be present in the glomerular urinary space in acute nephrosis or, more commonly, due to squeezing of the kidney during gross examination, especially if the kidney is autolytic; this change is termed infraglomerular reflux. Hyaline casts in tubules usually indicate increased glomerular permeability.

Tubules, especially proximal convoluted tubules, are the kidney elements most susceptible to ischemia and many toxins; degenerative changes are nonspecific in character and usually not diagnostic of the causative condition. The proximal convoluted tubule is the longest cortical part of the nephron, and hence proximal tubules comprise the bulk of the cortex. Proximal tubules are more eosinophilic than the other tubules and have a brush border that may be seen in rapidly fixed preparations and which is well demonstrated by the PAS stain. Delay in fixation leads to sloughing of apical cytoplasm into tubular lumina (potocytosis). Cells of the distal tubule do not have a brush border, are flatter, and more numerous in cross-section of the tubule than are those of the proximal tubule, and the tubular lumina are larger.

Cortical tubules and capillaries are closely associated in order to facilitate fluid resorption, and **connective tissue** is normally visible in the cortex only near arteries. Hence cortical fibrosis is a significant finding, especially in an animal with renal insufficiency. Fibrosis may cause tubular obstruction and hence create retention cysts proximally.

Blood vessel changes may occur in various systemic states as in other organs, e.g., arteriolosclerosis in diabetes mellitus, arteritis in malignant catarrhal fever.

The **renal medulla** should be closely examined because this is the site of urine concentration and the accumulation of protein casts. Tubules and ducts in the medulla are normally separated by more connective tissue and ground substance than those in the cortex. Tubulointerstitial mineralization is common in renal disease and may be seen along with cortical mineralization in cases of hypercalcemic nephropathy. The papilla should be carefully examined for evidence of papillitis, an early lesion in pyelonephritis, for amyloid, and for papillary necrosis. Inclusion bodies are often prominent in pelvic transitional epithelium in canine distemper; distemper inclusions must be differentiated from nonspecific epithelial inclusions.

Renal biopsy

Percutaneous needle biopsy of kidneys is useful to evaluate renal disease in domestic animals, and *is of particular use in cases of acute glomerulonephritis, nephrotic syndrome, asymptomatic proteinuria, and acute renal failure.* It is usually possible to obtain 10–20 glomeruli using a TruCut or a Franklin–Silverman biopsy needle in an adult dog; a minimum of ~5 glomeruli is necessary to characterize a glomerular lesion. The main hazard of the technique is arterial puncture and hemorrhage, which on rare occasions is fatal.

In addition to the usual hematoxylin and eosin staining of paraffin sections of kidney, several other techniques are useful:

1. The PAS *stain*, which stains glomerular and tubular basement membranes and mesangial matrix. Thin sections (3 μm) must be used. The PAS-methenamine silver technique is an improvement of this stain.
2. *Silver impregnation* of basement membranes and of leptospires.
3. *Other special stains for fibrin, amyloid, and lipids.* Microscopic resolution of glomerular lesions is markedly improved by the use of 1 μm thick methacrylate-embedded sections.
4. *Immunofluorescence* studies for localization of immunoglobulins, complement, fibrin-related compounds, and foreign antigens, especially in glomeruli.
5. *Immunoperoxidase* techniques, for localization of a wide variety of antigens.
6. *Electron microscopy*, particularly for characterization of glomerular basement membrane deposits.

Renal disease, renal failure, and uremia

Renal disease, which encompasses any deviation from normal renal structure or function, is usually subclinical. *Severe renal disease may lead to renal failure*, which is typically divided into acute and chronic forms. **Acute renal** *disease* is characterized by rapid onset of oliguria or anuria and azotemia; it may result from acute glomerular or interstitial injury or from acute tubular necrosis, and is often reversible. **Chronic renal** *failure.* is the end-result of many chronic renal diseases, is usually irreversible, and is characterized by prolonged duration of signs of uremia.

Clarification of terminology is in order:

- **Uremia** literally means urine in the blood. It is a *clinical syndrome of renal failure*, caused by biochemical disturbances, and is often accompanied by extrarenal lesions.
- **Azotemia**, which is sometimes incorrectly used synonymously, is a biochemical abnormality characterized by *elevation of blood urea and creatinine*, but without obligatory clinical manifestations of renal disease. Azotemia may be of renal or of extrarenal origin.
- **Prerenal azotemia** results from renal hypoperfusion, due to conditions such as congestive heart failure, shock, or hemorrhage.
- **Postrenal azotemia** occurs due to urinary obstruction.

The evolution from normal renal function to uremia over the course of progressive renal disease occurs through *four overlapping stages*:

1. In the stage of **diminished renal reserve**, the GFR is about 50% of normal, and the animal is asymptomatic but is susceptible to additional renal insults.
2. At the stage of **renal insufficiency**, GFR is 20–50% of normal; the animal is azotemic and becomes polyuric.
3. In the stage of **renal failure**, GFR is only 20–25% of normal, the kidneys cannot maintain homeostasis, and uremia ensues, with its attendant gastrointestinal, cardiovascular, respiratory, and skeletal complications.
4. In **end-stage renal disease**, GFR is less than 5% of normal and the animal is in the terminal stages of uremia.

The biochemical disturbances of uremia reflect changes in the normal renal functions directed to regulation of fluid volume, regulation of electrolyte and acid–base balance, excretion of waste products, and metabolism of hormones. The clinical signs may be related to the renal disease itself, as with pyuria or renal pain; to the effects of reduced renal function, as with metabolic acidosis or dehydration; or to the compensatory responses to renal dysfunction, as with hyperparathyroidism.

Interference with **fluid volume regulation** may result in either dehydration or anasarca. *Dehydration* due to reduced renal concentrating ability may be related to lesions of the renal medulla and juxtamedullary nephrons. Vomition, and sometimes diarrhea, often exacerbates the dehydration. *Anasarca*, caused by reduction in the volume of glomerular filtrate in diffuse renal disease or by activation of the renin–angiotensin system, occurs infrequently. A more common cause of edema is hypoproteinemia due to loss of protein through injured glomeruli.

Disturbances in **electrolyte balance** include excesses and deficits of plasma sodium, potassium, and calcium. The handling of these substances by the kidney is complex, even in health; in disease it is often paradoxical and involves disordered tubular function, compensatory mechanisms, and endocrine imbalances. Excesses of plasma sodium, potassium, and calcium contribute to anasarca, cardiotoxicity, and hypercalcemic nephropathy respectively, whereas deficits may cause dehydration, muscular weakness, tetany, and osteodystrophy.

Several aspects of the uremic syndrome contribute to **acid–base imbalance** and metabolic acidosis. Compensatory hyperventilation may occur. The main factors leading to acidosis in uremia are a reduced capacity of distal and collecting tubules to produce ammonia, increased retention of hydrogen ions, and increased utilization, with impaired reabsorption, of bicarbonate ions. The term **uremic acidosis** encompasses simultaneous azotemia, anion retention, and acidosis; **renal tubular acidosis** (discussed below in the section on Specific tubular dysfunctions) describes acidosis without retention of urea or anions.

Failure to excrete metabolic wastes is the basis for tests of renal function; *elevated blood levels of urea and creatinine indicate reduced glomerular filtration*. However, azotemia occurs only after the loss of 75% or more of the GFR, and is thus an insensitive indicator of renal disease. Tests of concentrating ability, such as the water deprivation test, are also of limited usefulness because concentrating ability is not affected until at least two-thirds of the renal mass has become nonfunctional.

Disturbances in endocrine function are important causes of signs and lesions in uremic animals. Retention of phosphate, due to reduced glomerular filtration, causes depression of ionized calcium, deficiency of $1,25(OH)_2D_3$, increased synthesis and secretion of parathyroid hormone (PTH), and development of secondary hyperparathyroidism (see section on Fibrous osteodystrophy, Vol. 1, Bones and joints). Reduced renal catabolism of PTH, and end-organ resistance to PTH, may contribute to hyperparathyroidism. Most uremic animals have hyperphosphatemia, and normocalcemia or hypercalcemia. Sometimes hypercalcemia and hypophosphatemia occur in uremic dogs, possibly because of lack of feedback inhibition of PTH release. Similar changes occur in some uremic horses and may be related to decreased renal excretion of calcium.

Nonregenerative **anemia** in uremic animals is of multifactorial pathogenesis and may result from a combination of factors, including decreased renal production of erythropoietin and possibly inhibitory effects of increased serum PTH concentrations (see Vol. 3, Hematopoietic system). A bleeding disorder associated with a platelet factor 3 abnormality may exacerbate the anemia. Renal metabolism of vitamin D is sometimes impaired in animals with diffuse renal disease, and may add an element of osteomalacia to renal osteodystrophy. Abnormal glucose metabolism occasionally occurs in uremic dogs, and may be a result of peripheral resistance to insulin-mediated uptake of glucose or to reduced breakdown of insulin by diseased kidneys.

As well as the metabolic disturbances attributable to particular biochemical derangements, there is in uremic animals a nonspecific effect of "**uremic toxins.**" This is probably due to the combined action of toxic products of protein catabolism and the various chemical and endocrine imbalances described above. These toxins include molecules of low, medium and large molecular weight. Low-molecular-weight molecules (<500 Da) include glomerulopressin, guanidines (e.g., creatine, creatinine), methylamines, myoinositol, oxalate, phenylacetylglutamine, phosphate, polyamines, pseudouridine, purines (e.g., uric acid), pyrimidines (e.g., thymine, uridine), trihalomethanes, and urea. "Middle molecules" range from 500 to 5000 Da, and include α- and β-chains of fibrinogen. Large molecules (>5000 Da) include various peptides and cytokines, such as parathyroid hormone, β_2-microglobulin, granulocyte-inhibitory proteins, degranulation-inhibiting proteins, and chemotaxis-inhibiting protein. These various toxins are thought to be responsible for the profound malaise that characterizes the uremic syndrome.

The *cause of death in uremia* varies from case to case. Metabolic acidosis, hyperkalemia, or hypocalcemia may be severe enough to be fatal.

Gross lesions in uremia may be divided into those that caused uremia and those that resulted from it. The former are usually intrarenal, but may not be in prerenal and postrenal azotemia. Lesions that are the result of uremia are mainly, but not exclusively, extrarenal.

Most forms of prerenal azotemia have a common basis of reduced renal blood flow and glomerular filtration. This occurs in a variety of circumstances, including severe dehydration, massive hemorrhage, especially into the upper intestinal tract, congestive heart failure, and shock of any cause. Reduced renal flow in these conditions is part of an adaptational mechanism that diverts blood to vital organs such as brain and heart. When the diversion is severe or prolonged, intrarenal mechanisms that channel renal flow away from cortical nephrons to juxtamedullary nephrons may produce patchy or diffuse cortical ischemia and necrosis (see section on Renal cortical necrosis and acute tubular necrosis, below). In such cases, if the animal survives, prerenal azotemia may be superseded by uremia of renal origin originating in cortical necrosis.

Postrenal azotemia is always due to obstruction to the outflow of urine, and hence is oliguric or anuric. The causes are those which, if intermittent or incomplete, may lead to hydronephrosis or, if sudden and complete, may lead to rupture or leakage of the lower urinary tract.

A form of extrarenal uremia, distinct from those mentioned, occurs in *newborn animals*, especially pigs, and is characterized by very high levels of blood urea. The kidneys of newborn pigs, dogs, and cats are functionally "immature," and incapable of producing hypertonic urine. Normally this is of no consequence, because milk provides enough fluid to excrete, in hypotonic urine, the small amount of waste produced. However, when these newborn animals are anorectic, they lack both nutrients and fluid, and begin to catabolize tissue proteins and purines. Being unable to excrete the excess solute from protein and purine breakdown, their blood urea and uric acid reach very high levels. Since anorexia is usually associated with fever, vomition, or diarrhea, fluid loss is very rapid. In pigs, the excess solute is deposited in the inner medulla as streaks of light-yellow urate precipitates (Fig. 4.2), which disappear during histologic processing. Pigs are apparently unique among mammals in that they do not reabsorb urates from glomerular filtrate; this accounts for their concentration in the medulla. It is not clear whether baby pigs also have an "immature" liver that fails to convert uric acid to allantoin.

The **nonrenal lesions of uremia** occur inconstantly and unpredictably, though they tend to be seen most often in dogs, especially those with chronic rather than acute renal failure. Many animals dying with uremia are cachectic. This is probably caused by the anorexia, vomition, and diarrhea which often occur, and which necessitate body tissue catabolism to supply energy. Besides this

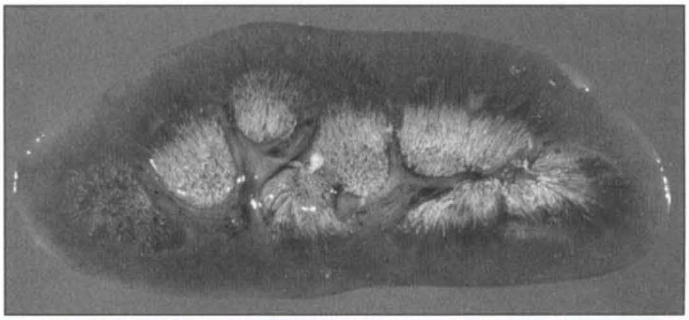

Figure 4.2 Urate calculi in renal medulla of a 3-day-old dehydrated piglet.

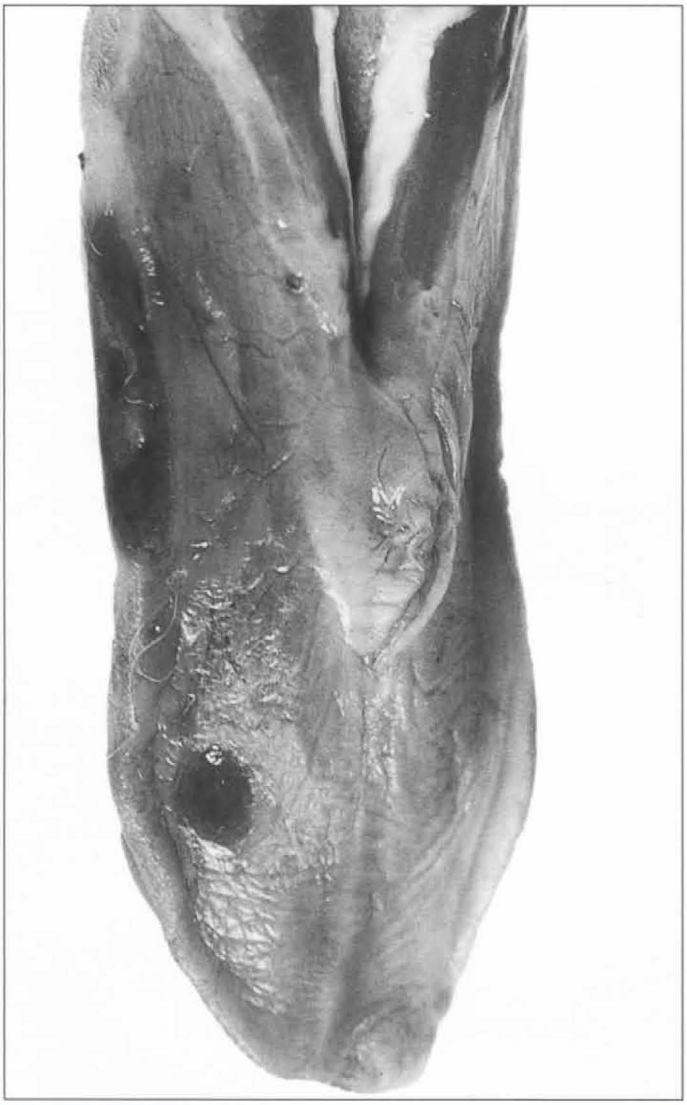

Figure 4.4 Ulcers on lateral margin and ventral surface of tongue in a dog with **uremia**.

general lack of condition, several distinctive lesions may develop in the gastrointestinal, cardiovascular, respiratory, and skeletal systems (see also these systems).

Ulcerative, necrotic stomatitis occurs in dogs and cats, and there is usually a foul-smelling brown film coating the tongue and buccal mucosa (Figs 4.3 and 4.4). Like the gastrointestinal changes, oral lesions are more common in chronic than in acute uremia. The pathogenesis of the ulcers is not always clear, but some are associated with fibrinoid necrosis of arterioles and some are related to bacterial production of ammonia from urea in the saliva. Large areas of the *gastric mucosa* are often swollen, suffused with red-black blood, and partly ulcerated. This lesion, often called "gastritis," is initially noninflammatory, though opportunist bacteria may infect the ulcerated mucosa. Mucosal infarction occurs secondary to arteriolar necrosis. *Mineralization of the middle and deep zones of the gastric mucosa is common* (Fig. 4.5). Necrosis and mineralization of the muscular coats are sometimes present. Intestinal lesions resemble those in the stomach, but they are less frequent, less severe, and without mineralization. Gastrointestinal lesions probably account for much of the vomition, diarrhea, and melena of uremic dogs. Intestinal intussusceptions sometimes develop in dogs with gastrointestinal lesions. Cats may have gastrointestinal lesions similar to dogs but, in uremic cattle, colitis is more common and the stomach and proximal intestine are edematous. The liver shows inconstant degenerative changes, and there may be acinar dilation of the pancreas with inspissation of secretion. The hyperamylasemia and hyperlipasemia that occur in some uremic dogs are apparently the result of concurrent pancreatitis rather than due to reduced renal clearance of the enzymes.

Arterial lesions found in animals with acute renal insufficiency (*arterial hyaline degeneration*) or with chronic renal failure (*hyperplastic arteriolosclerosis*) are discussed elsewhere (Vol. 3, Cardiovascular system). Lesions of various organs, such as uremic gastric infarction, may result from arterial degeneration and thrombosis. Arteriolar lesions in the myocardium sometimes cause ischemia and degeneration. Arterial degeneration is perhaps most frequent in acute uremia due to tubular necrosis. In chronic uremia, the left ventricle is often hypertrophied and dilated. *Hypertension* is common in canine nephritis, and ventricular hypertrophy may be initiated or exaggerated by the hypertension. Lesions in the circulatory system are unusual, except in the dog, but arterial degeneration may occur in the intestines

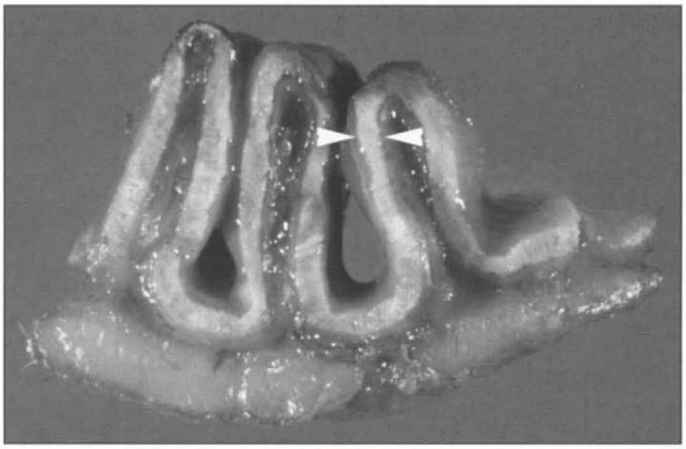

Figure 4.5 Marked **gastric mucosal mineralization** (layer between arrow heads) in a uremic dog.

in cattle with acute nephrosis and contribute to the colonic lesions of acute uremic syndromes in this species. In cattle with urethral calculi, pericardial effusion may be part of the anasarca. In dogs, hydropericardium with dull granulation of the pericardium may occur. Edematous distension of retroperitoneal tissue, expressed particularly as *perirenal edema*, occurs in pigs and cattle; the underlying renal lesion is usually acute tubular necrosis caused by ochratoxin or *Amaranthus retroflexus* in pigs, and oak poisoning in cattle (see section on Nephrotoxic tubular necrosis, below).

Most animals dying in uremia develop *terminal pulmonary edema*. The mechanism is obscure and the edema is not always associated with significant pulmonary congestion; increased permeability of alveolar capillaries is the most likely pathogenesis. In a few animals, acute pneumonia develops terminally. It may be associated with aspiration of gastric content, and its fulminant nature is possibly related to the immunosuppression that develops in uremia. Pulmonary mineralization occurs in chronically uremic dogs. Mineral is deposited in the walls of the alveolar ducts and pulmonary arterioles. Dull granulations of the visceral pleura may be present over the cranial lobes. Occasionally in uremia, spectacular pulmonary lesions develop. They may be visible in radiographs as lines of increased density spreading out from the hilus and these features are those of interstitial edema. At autopsy, the lung is edematous and resilient and the alveolar spaces contain much fibrin in the edema fluid. Leukocytes are present but may be a response to accidental superimposed infection. Mineralization is extensive, with impregnation particularly on reticulin of alveolar walls that are widened (Fig. 4.6). The lesion is referred to as uremic lung or *uremic pneumonitis*; it is not common and when it occurs it may be patchy.

Perhaps the most constant lesion in the dog is *mineralization beneath the parietal pleura* in the cranial intercostal spaces (Fig. 4.7). It is preceded by necrosis of the subpleural connective tissue with extension to intercostal muscle and overlying pleura. Once mineralization has occurred and the pleura is repaired, the lesion appears as gray-yellow thickenings, horizontally wrinkled. The cranial intercostal spaces are involved first; when deposition is extensive many more spaces may be affected.

The pathogenesis of diffuse tissue mineralization in uremia is not clear. There are at least two types of mineral deposit, and serum concentrations of calcium, magnesium, phosphate, and carbonate probably determine the type of calcium phosphate compound that is formed. When calcium is higher than magnesium, apatites are formed, whereas the opposite relationship favors deposition of amorphous calcium phosphate. The regularity with which certain tissues and organs are mineralized is no doubt related to local characteristics such as tissue glycosaminoglycans, local pH, and cellular factors.

The effects of chronic uremia on the *skeleton* are discussed in the section on Fibrous osteodystrophy, Vol. 1, Bones and joints. *Enlarged parathyroids* are common in dogs with chronic renal failure; osseous lesions are less so.

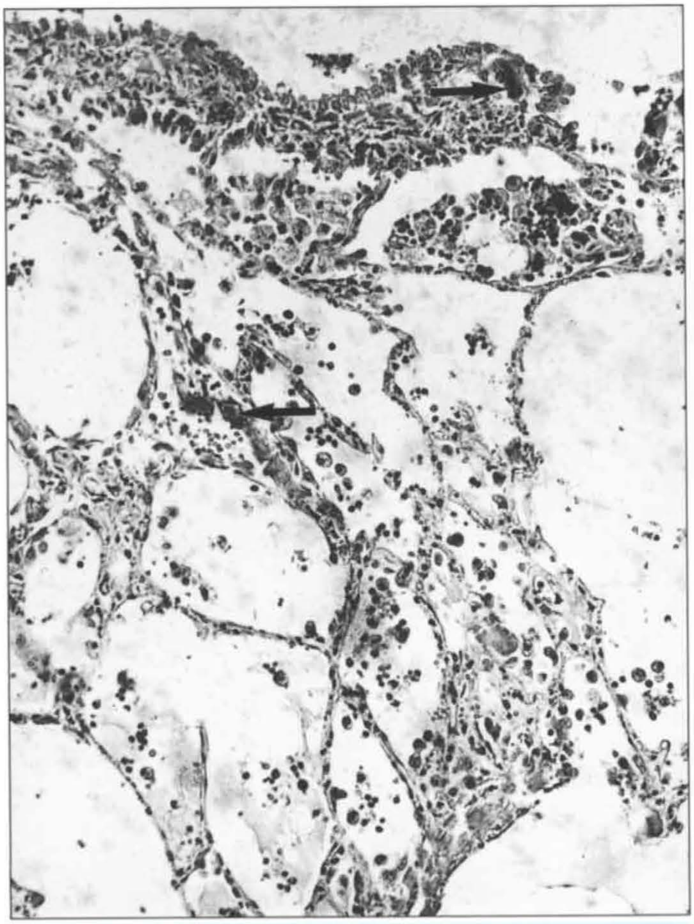

Figure 4.6 Mineralization of alveolar and bronchiolar wall (arrows), mild edema, and intra-alveolar cellular exudate in a dog with uremia.

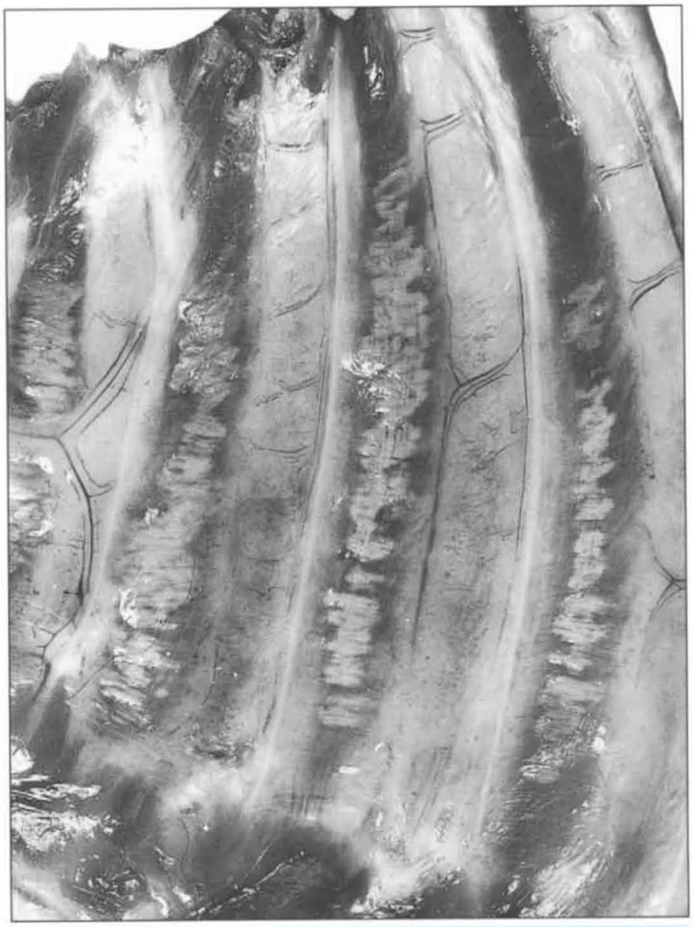

Figure 4.7 Necrosis and mineralization beneath intercostal pleura between cranial ribs in a uremic dog.

Uremic encephalopathy is an uncommon complication of uremia in domestic animals. It has been reported in dogs, ruminants, and horses, and is expressed as white-matter spongiform degeneration that may be accompanied by reactive astrogliosis.

The **renal lesions of uremia** are varied but, if the syndrome is chronic, certain common changes tend to occur. *The end-result is a fibrosed, mineralized kidney with sclerosed glomeruli, and sometimes areas of hyperplastic and hypertrophic tubules.* Often this can only be diagnosed as "**end-stage kidney**." Severe mineralization occurs late in the course of renal failure and may diffusely involve glomerular and tubular basement membranes, or be deposited at the corticomedullary junction. In the latter case, temporary ischemia with reflow involving the straight part of the proximal tubule, which is at the periphery of the postglomerular circulation, may be responsible. According to the "precipitation-calcification hypothesis," phosphorus absorbed from the intestines in excess of the excretory capacity of nephrons will induce precipitation of calcium phosphate microcrystals in tubular lumina, the interstitium, and renal capillaries. Dietary phosphate restriction may inhibit renal mineralization and its attendant inflammation, scarring, and loss of nephrons. Interstitial fibrosis and glomerulosclerosis are slowly progressive lesions that are common in the end-stages of many renal diseases. *Progressive interstitial fibrosis is thought to be the final common pathway to chronic renal failure.* Hyperplasia and hypertrophy of tubules are inconstant changes that probably precede the onset of renal failure. Azotemia develops when glomerular filtration is reduced to 75% of normal. Until this time, adaptive changes in intact nephrons maintain renal function at an adequate level as other nephrons are incapacitated. The glomerulus is probably the limiting factor in this compensatory mechanism, since it has a relatively limited ability to increase its function. It seems unlikely that uremia provides a suitable environment to permit or encourage compensatory hyperplasia, and it is likely that enlargement of nephrons is an early response to a reduction in renal mass rather than an adaptation to uremia.

Regardless of the initiating cause, **chronic renal failure tends to be progressive**. Progression occurs because of persistence of the primary disease problem and/or the addition of other renal insults or complications, such as urinary tract infection, systemic hypertension, and intrarenal deposition of mineral. As well, *endogenous factors* that often develop as compensatory mechanisms may contribute to perpetuation of renal failure. These factors include glomerular capillary hypertension and hyperfiltration, renal hypertrophy, increased renal oxygen consumption, and increased renal ammoniagenesis. Surviving nephrons may also be injured as a result of altered phosphate metabolism, altered lipid composition, and by increased activity of the coagulation system. High dietary protein intake may increase renal blood flow and GFR, possibly through the actions of mediators such as glucagon, growth hormone, prostaglandins, the renin–angiotensin system, biogenic amines, and a hepatic-derived renal vasodilator known as glomerulopressin. Although contentious, restricting protein intake may minimize renal hemodynamic changes and slow the progression of chronic renal failure. Glomerular hyperperfusion can lead to glomerulosclerosis and proteinuria. Compensatory hyperfunction of renal tubules in a failing kidney can lead to increased renal ammoniagenesis, increased renal ammonia concentration, activation of the third component of complement, and complement-mediated inflammation and injury; such tubulointerstitial lesions may be progressive.

Also to be considered when assessing renal disease in a mature or aged animal are **normal aging changes** that occur in the absence of any specific renal insult; these "background" changes may lead to decreased renal reserve, but usually not to renal failure. In aged dogs, for example, *renal weight is reduced* by 20–30% due to decreased size and number of nephrons. In humans, GFR decreases with age because the renal fraction of cardiac output decreases and because of intrarenal vascular changes such as coalescence of glomerular capillaries in juxtamedullary glomeruli and atrophy of arterioles of cortical glomeruli. Glomerular mesangial volume increases, proximal tubule volume and length decrease, and interstitial connective tissue increases. Changes in the ground substance of medullary connective tissue can reduce medullary hyperosmolality and hence renal concentrating ability. Aged animals with purely senescent renal changes have *decreased compensatory abilities*, such as hypertrophy, and are hence very susceptible to renal insults. Proteinuria may be taken as an indicator of increased glomerular permeability, but there is no sensitive and specific test for quantifying renal aging at present.

Renal transplantation is available in a number of centers as a therapeutic option for dogs and cats with end-stage renal disease. Various immunosuppressive protocols are used to prevent postoperative rejection of the transplanted kidney, particularly necessary when the donor is unrelated to the recipient. Surgical complications may be noted at necropsy, e.g., avulsion of the renal vein, torsion of the vascular pedicle. The various stages of rejection of renal allografts have been extensively categorized in human pathology, and can be followed by serial renal biopsy.

- *Antibody-mediated rejection* due to pre-existing antidonor lymphocytotoxic antibody may be hyperacute or acclerated acute.
- *Acute/active rejection* consists of various combinations of interstitial inflammation, tubulitis, intimal arteritis, and transmural arteritis.
- *Chronic/sclerosing allograft nephropathy* consists of various grades of interstitial fibrosis, tubular atrophy, and tubular loss; accompanying transplant glomerulopathy is primarily defined by the presence of "double contours" in affected glomeruli, caused by interposition of mesangium in glomerular basement membranes.

Although a canine or feline renal transplant may enjoy long-term (months to years) success, the pre-existing condition, e.g., systemic hypertension, may of course persist and eventually lead to failure of the transplanted kidney. *Complications* of immunosuppressive therapy in allograft recipients include a spectrum of infectious processes, including a wide range of bacteria and mycoplasmas, yeast/fungi (*Candida, Penicillium*), and protozoa (*Toxoplasma, Encephalitozoon, Pneumocystis, Giardia*). In general, the uninephrectomized kidney donor survives well, and its remaining kidney hypertrophies to meet the body's needs.

Juvenile, familial, and hereditary nephropathies

Juvenile nephropathy is a broad all-encompassing term for noninflammatory, degenerative, or developmental, chronic renal disease of obscure pathogenesis in *young animals*, and is relatively common in inbred lines of animals, particularly dogs and, less so, cats.

Familial nephropathy is a more restrictive term applied to renal disease observed in *families of animals*, particularly dogs. Familial nephropathy occurs in many breeds, including: Alaskan Malamute, Beagle, Chow Chow, Doberman Pinscher, Keeshond, Lhasa Apso, Miniature Schnauzer, Newfoundland, Norwegian Elkhound, Rottweiler, Shar-Pei, Shih Tzu, Soft-Coated Wheaten Terrier, and Standard Poodle.

Hereditary nephropathy *is the definitive term used once the inheritance of the nephropathy has been determined*. Hereditary nephropathies have been investigated and documented in an expanding number of breeds, including Bernese Mountain Dog, Brittany Spaniel, Bull Terrier, Cairn Terrier, English Cocker Spaniel, German Shepherd, Samoyed, West Highland White Terrier, Abyssinian cat. This category will continue to expand as inheritance of disease entities is defined; classifications will also be further refined as the pathogeneses of somewhat obscure familial and juvenile diseases are more fully characterized. For example, the familial renal disease of juvenile Samoyed dogs has now been well characterized as an X-linked hereditary glomerulopathy caused by mutations in the *COL4A5* gene, which encodes the alpha 5(IV) collagen chain. Given greater knowledge of heritability, breed societies are able to undertake control programs.

Examples of specific familial and/or hereditary renal diseases abound, and will be discussed below under their respective sections of developmental defects, glomerular disease, tubular disease, and renal neoplasia. *In general, the canine familial renal diseases are characterized by renal failure, mostly in immature or young adult dogs, which is not associated with primary renal inflammation.* For most breeds, only terminal clinical signs and end-stage lesions are described – inheritance, pathogenesis, and early morphologic changes are not reported. The age of onset of renal failure varies from a few weeks to several years but, in most cases, is 4–18 months. This wide age range and the lack of morphologic specificity hinder the definition of these diseases since there is a danger that any noninflammatory renal lesion in a dog of an appropriate breed will be diagnosed as "familial."

It is probable that some of the chronic interstitial nephritides formerly attributed to leptospirosis were familial renal diseases. The possibility that many of these diseases are examples of renal dysplasia seems unlikely since primitive ducts are not present. Glomeruli with the appearance of immaturity must be interpreted cautiously, particularly when they are found in areas of scarring.

Many of the canine familial renal lesions primarily involve either glomeruli or interstitium around glomeruli. Interstitial lesions are fibrous, and may be radial streaks or generalized. The fibrotic segments often contain apparently immature glomeruli and this pattern is found frequently, but not exclusively, in Lhasa Apso and Shih Tzu dogs; the radial conformation of these scars is suggestive of an ischemic origin. Such "asynchronous differentiation" of nephrons may be the result of acquired scarring and mechanical inhibition of maturation. Whether familial renal diseases are expressions of dysplasia is a moot point. The sine qua non of dysplasia (primitive ducts, cartilage nodules – see section on Renal dysplasia, below) is rarely met in affected kidneys; expanding the definition of dysplasia to include the presence of immature glomeruli greatly, and perhaps illegitimately, expands the number of affected cases of juvenile renal disease characterized as being "dysplastic." Until etiopathogenesis of these syndromes is better defined, they might better be termed "nephropathies."

ANOMALIES OF DEVELOPMENT

The embryology of mammalian kidneys involves the sequential development of three successive but overlapping structures: the *pronephros*, *mesonephros*, and *metanephros*. The first two become vestigial, but act as inducers of the definitive kidney, the metanephros. Pronephric tubules, arising in the intermediate mesoderm of the cervical region, form the pronephric duct by fusion and extension of their caudal ends. This duct opens into the cloaca and, although the pronephric tubules are not functional in mammalian embryos, the utilization of their duct by the mesonephric tubules gives them potential significance in the genesis of renal anomalies. Mesonephric tubules develop from thoracic mesoderm caudad to the pronephros. The mesonephros is functional in mammalian embryos but degenerates before birth. In males, some of the caudal tubules persist as efferent ducts of the epididymis, and the duct itself is utilized as the vas deferens. In females, cystic remnants of mesonephric tubules in the mesovarium may form the epoophoron and paroophoron, and remnants of the duct are known as Gartner's duct.

The formation of **the metanephros**, *the definitive kidney*, begins with the development of a *ureteral bud* from the mesonephric duct immediately cranial to its junction with the cloaca. The bud, accompanied by vessels and nerves, grows into a mass of mesenchymal cells, the *metanephric blastema*, and it is on the interaction of these two structures that normal renal and ureteral development depend. As the bud grows into the blastema it makes a specific number of successive, dichotomous divisions. The tubes formed by early divisions of the ureteral bud dilate and become the pelvis and calyces of the kidney. Tubes formed by later divisions develop into collecting ducts, and the last divisions give rise to collecting tubules. As the blind end of each collecting tubule, the ampulla, grows into the metanephric blastema, it induces compact masses of cells to form about it. These masses soon cavitate, become S-shaped, and unite with the side of the ampulla, which continues to advance and divide.

The cavitated cell masses develop into *nephrons*. Connection of the lumens of the nephron and the collecting tubule occurs very soon after the cell mass cavitates. Glomerular development involves the formation of a lateral invagination in the S-shaped mass by mesenchymal cells that differentiate into endothelial and mesangial cells and become linked with the renal vasculature.

The complicated formation of the kidney provides for many patterns of malformation. The interaction of ureteral bud and metanephric blastema involves mutual inductions, and malformations of renal tissue are often accompanied by ureteral anomalies. Ectopic budding of the ureter from the mesonephric duct appears to be the primary event that precedes many congenital anomalies of the kidney and urinary tract. Ectopia results in hypoplastic kidney, ectopia of the ureterovesical orifice, urinary outflow obstruction, and/or reflux. The genes involved in navigating ureteric budding to the correct site often also regulate later developmental events of the kidney and urinary tract. Candidate genes have been proposed for a wide range of urinary developmental defects in humans and laboratory rodents.

The incidence of urinary tract anomalies is not known for most species. Survey results from large numbers of lambs suggest that anomalies occur much more often than is commonly believed.

Abnormalities in the amount of renal tissue

Lack of renal tissue may be complete (*agenesis*) or partial (*hypoplasia*).

Renal agenesis may be caused by developmental failure of the pronephros, mesonephros, or ureteral bud, by absence or complete unresponsiveness of the metanephric blastema, or by complete degeneration of the metanephric blastema. Partial degeneration, or partial responsiveness of the blastema to the inductive influences of the ureteral bud, probably produces renal dysplasia. The presence of even a fragment of recognizable metanephric tissue necessitates this diagnosis.

Agenesis may be unilateral or bilateral. As is the case with all renal anomalies, agenesis may be associated with other urogenital deformities. Unilateral renal agenesis is compatible with normal life if the other kidney is normal; however, contralateral dysplasia, or even hypoplasia, may be present, in which case renal failure ultimately develops. The ureter may be absent, or malformed with a blind end that terminates in connective tissue at the renal site. Bilateral agenesis is inconsistent with postnatal life. Renal agenesis occurs infrequently in all species, except when there is a *familial incidence*, as in some Beagles, Shetland Sheepdogs, and Doberman Pinschers, and in Large White pigs. Bilateral agenesis may account for some stillbirths, but this can only be assessed by careful examination of fetuses.

Hypoplastic kidneys are small, but most abnormally small kidneys, even in young animals, are not hypoplastic. The limited size of hypoplastic kidneys is associated with *a reduced number of histologically normal nephrons, lobules, and calyces*. Renal hypoplasia is a quantitative defect caused by reduced mass of metanephric blastema or by incomplete induction of nephron formation by the ureteral bud. When the amount of blastema is normal, but there is malfunction of the ureteral bud, renal dysplasia probably develops. Most of the small kidneys diagnosed as hypoplastic are probably dysplastic or scarred. The term "cortical hypoplasia" should be avoided since it is inconsistent with established concepts of renal embryology and anatomy. *Renal hypoplasia is rare*. It may be unilateral or bilateral. When unilateral, contralateral hypertrophy is expected.

Bilateral hypoplasia probably always leads to renal failure, and this often complicates or precludes the diagnosis because of the secondary changes that develop. Several forms of renal hypoplasia occur in humans but, because of the confusion of terminology, the variations and incidence of the condition in animals cannot be assessed. Kidneys suspected of being hypoplastic should be weighed along with their mate and examined for evidence of dysplasia and hypertrophy. In humans, in the absence of acquired disease, a decrease in size of one kidney by more than 50% or reduction of total renal mass by more than one-third is taken as evidence of hypoplasia.

Details regarding **excess renal tissue** are not well documented. *Duplication of ureters and kidneys* occurs in cattle, pigs, and dogs, but it is not clear whether total renal mass is increased.

Anomalies of renal position, form, and orientation

The kidneys develop in the pelvis and migrate to their sublumbar location, meanwhile rotating so that the ureter attains its normal orientation. During this movement, the blood supply shifts from the iliac arteries to the aorta. Various disruptions of this procedure may occur. Vitamin A deficiency in sows may cause anomalies such as those described below.

Malposition of the kidneys (*renal ectopia*), observed more frequently in swine than in dogs or cats, is usually caudal with the kidney in the pelvic or inguinal position. One or both kidneys may be displaced. The kidneys may be normal or abnormally small. The renal arteries arise close to the bifurcation of the aorta or from the iliacs. The ureter is short but may be kinked and thereby predisposed to hydronephrosis and pyelonephritis, or may empty into the genital tract, causing urinary incontinence. *Crossed renal ectopia* refers to malposition of a kidney that has crossed the midline; it may fuse with its contralateral partner.

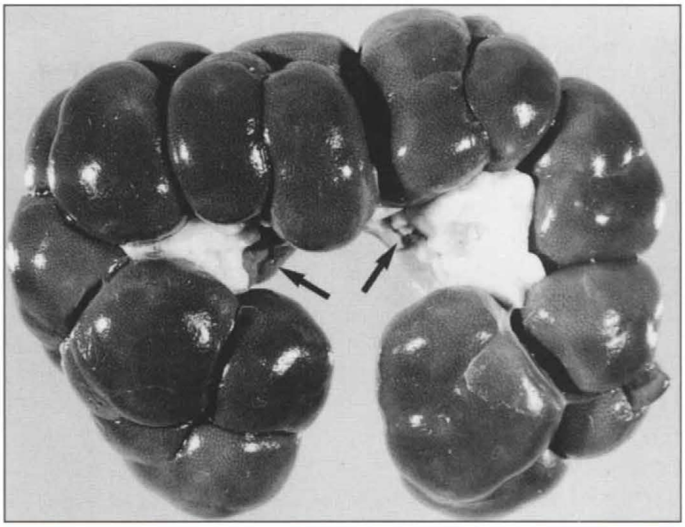

Figure 4.8 Horseshoe kidney in a calf. Ureters have been severed (arrows).

Fusion of the kidneys may occur in utero. *Horseshoe kidney*, seen in all species, results from fusion of the cranial or caudal poles of the kidneys (Fig. 4.8). The fusion may involve only a small portion of the capsule or parenchyma or be sufficient to produce a common pelvis. The ureters are not involved and their disposition depends on whether the cranial or caudal poles are fused. Such kidneys function normally.

Fetal lobulations, normal in embryos and cattle, may persist owing to failure of fusion of individual renal segments. They are not of pathologic significance.

Renal dysplasia

Renal dysplasia is disorganized development of renal parenchyma due to anomalous differentiation. If normal development of the collecting duct system ("renal branching morphogenesis") is disrupted, then renal dysplasia can result. Transcription factors, growth factors, and cell surface signaling peptides are critical in regulation of renal branching morphogenesis. Renal lesions may be gross or microscopic. Renal dysplasia is *usually congenital*, but in cats, dogs, and pigs, which have an active subcapsular nephrogenic zone at birth, dysplasias may be caused by disease in the early neonatal period until differentiation of the nephrogenic tissue is completed. The quantitative changes that continue until maturity are not susceptible to dysplastic influences.

Dysplastic changes may be obscured by secondary compensatory, degenerative, and inflammatory changes.

The **causes** of renal dysplasia are ill defined, but many are likely *hereditary*. Cases of familial renal disease in several *dog* breeds often have dysplastic features. An autosomal dominant form of cystic renal dysplasia has been reported in *Suffolk sheep*. Some of a range of renal lesions reported in *Japanese black (Wagyu) cattle* have a dysplastic component, particularly the condition of multicystic renal dysplasia. Renal tubular dysplasia in this breed is due to deletion of the paracellin-1 gene from chromosome 1, and it may be the antecedent of chronic interstitial nephritis also reported in this breed. Most *human* cases of renal dysplasia are associated with intrauterine *ureteral obstruction,* and some cases in foals, pigs, and calves probably have the same cause; rapid growth and the increased activity of the intrarenal renin–angiotensin system in the fetus may cause greater susceptibility to permanent renal injury. Renal dysplasia in kittens is caused by fetal infection with *Feline panleukopenia virus*, in puppies by neonatal infection by *Canine herpesvirus*, and in calves is associated with fetal infection by *Bovine viral diarrhea virus*. Other teratogenic agents can undoubtedly produce renal dysplasia in these and other species. Renal dysplasia in pigs has been attributed to *hypovitaminosis A*; formation of the trigonal wedge and proper insertion of the ureteral buds into the bladder, and hence proper renal development, are mediated by vitamin A and proto-oncogene Ret signaling pathways.

There is considerable variation in the appearance of those dysplastic kidneys that are grossly abnormal. Most of them are small, which accounts for their frequent misdiagnosis as hypoplastic. They are usually misshapen and fibrosed with thick-walled cysts and dilated tortuous ureters (Fig. 4.9). One or both kidneys may be affected. If the lesion is unilateral, the ipsilateral ureter should be examined for anomalous valves, diverticula, or atresia. If both kidneys are involved, scrutiny of the bladder and lower urinary tract is indicated. Some dysplastic kidneys may be only slightly irregular in contour (Fig. 4.10) or may appear normal, in which case microscopic examination is required for diagnosis. Dysplasias caused by teratogenic viruses are usually included in this group. Considerable emphasis has been placed on the size of renal arteries in dysplasias, but changes should be interpreted with caution since degenerative lesions in the renal parenchyma may be accompanied by vascular atrophy. Extrarenal anomalies, such as imperforate anus, may occur in association with renal dysplasia.

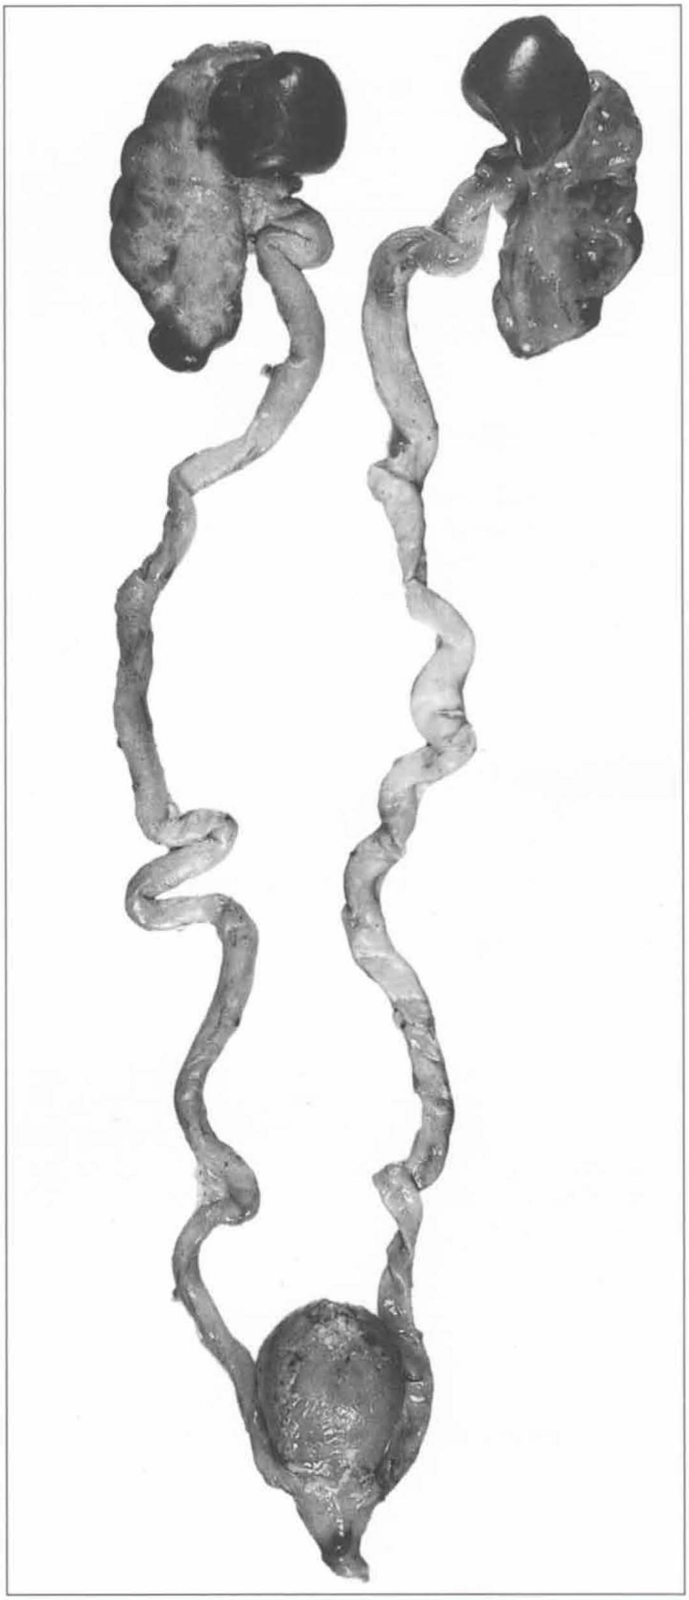

Figure 4.9 Renal dysplasia in a pig. Dilated ureters lead to fibrotic malformed kidneys.

The **microscopic criteria** of renal dysplasia are the presence of structures inappropriate to the stage of development of the animal, or the development of structures that are clearly anomalous. Among the former are *areas of undifferentiated mesenchyme* in cortex or medulla (Fig. 4.11), and *groups of immature glomeruli* (small glomeruli with peripheral nuclei and inapparent capillaries) in the cortex of adolescent or adult animals. Anomalous structures include *collecting tubules ending blindly* in cortical connective tissue, *atypical tubular epithelium*, and *primitive (metanephric) ducts* lined by cuboidal or columnar epithelium and surrounded by concentric layers of mesenchyme (Fig. 4.12). *Dysontogenic (cartilaginous or osseous) metaplasia*, which occurs in some dysplastic human kidneys, is rarely present in dysplastic kidneys in domestic animals. This absence is probably a function of the stage of development at which metanephric injury occurs. Cartilage nodules imply injury to uncommitted mesenchyme, that is, to nephrogenic cord before its interaction with the ureteral bud. Other anomalous structures clearly are nephrogenic, and represent improper interaction of ureteral bud and mesenchyme. There is some support for the opinion that only primitive ducts and cartilage nodules are prima facie evidence of dysplasia, on the grounds that all other lesions may be produced by acquired renal disease. Some of the more prominent

gross lesions of dysplastic kidneys, such as fibrous cysts, dense medullary fibrosis, and fibrous wedges extending from pelvis to cortex, are probably regressive changes due to obstruction or infarction. Because *ureteral anomalies* are often concomitant, dysplastic kidneys are abnormally susceptible to pyelonephritis. Otherwise there is little or no evidence of infection in the renal parenchyma. The dark nuclei of improperly differentiated nephrogenic tissue should not be misinterpreted as lymphocytes.

Renal dysplasia with gross changes usually causes *uremia*. When lesions are bilateral, this is explicable in terms of reduced functional renal mass. With unilateral dysplasia, systemic hypertension induced by constriction of arteries in the affected kidney may be responsible.

Renal cysts

Cystic diseases of the kidney include various conditions characterized by one or more grossly visible cystic cavities in the renal parenchyma. No satisfactory classification of renal cysts exists, but an acceptable compromise would be based on mode of inheritance, or lack thereof, the presence of lesions in other organs, and the clinical course in affected animals.

Cysts can arise during organogenesis, and may be associated with histologic criteria of renal dysplasia. In humans, most dysplastic kidneys are cystic and most cystic diseases of childhood are dysplasias. Cysts can arise in nephrons and collecting tubules after the end of nephrogenesis. Examples are provided by steroid-induced cysts in various species, and atypical cysts in patients undergoing long-term hemodialysis. *Cysts can develop in any part of the nephron, including the glomerular space, or in the collecting system.* In *glomerulocystic disease,* they only develop in Bowman's space, but this exclusivity is exceptional. There is no evidence that cysts are caused by failure of nephrons to unite with the collecting system. Analyses of their content indicate that *they are part of functional nephrons,* and that their activity is consistent with their location in the nephron.

Three **mechanisms**, which are not mutually exclusive, may lead to the formation of renal cysts:

1. Renal cysts may be caused by *obstructive lesions* – examples are the acquired retention cysts of chronic renal disease, some dysplastic cysts, and possibly those of glomerulocystic disease.
2. A fundamental change, of unknown origin, may occur in the *tubular basement membrane* and result in formation of saccular or fusiform dilations of the tubules.
3. Disordered growth of tubular epithelial cells may lead to *focal hyperplastic lesions* and cyst formation.

Mutation of polycystic kidney disease (PKD) genes in humans may alter production of *polycystin* proteins, which are important in cell–cell and cell–matrix interactions; altered tubular epithelial growth and differentiation may lead to cyst formation. Enhanced renal cystogenesis occurs in humans with primary aldosteronism or primary renal potassium wasting, perhaps as a consequence of chronic hypokalemia and tubular obstruction by proliferating tubular epithelial cells. Renal cysts are dynamic structures and their growth may be modified by pharmacologic means.

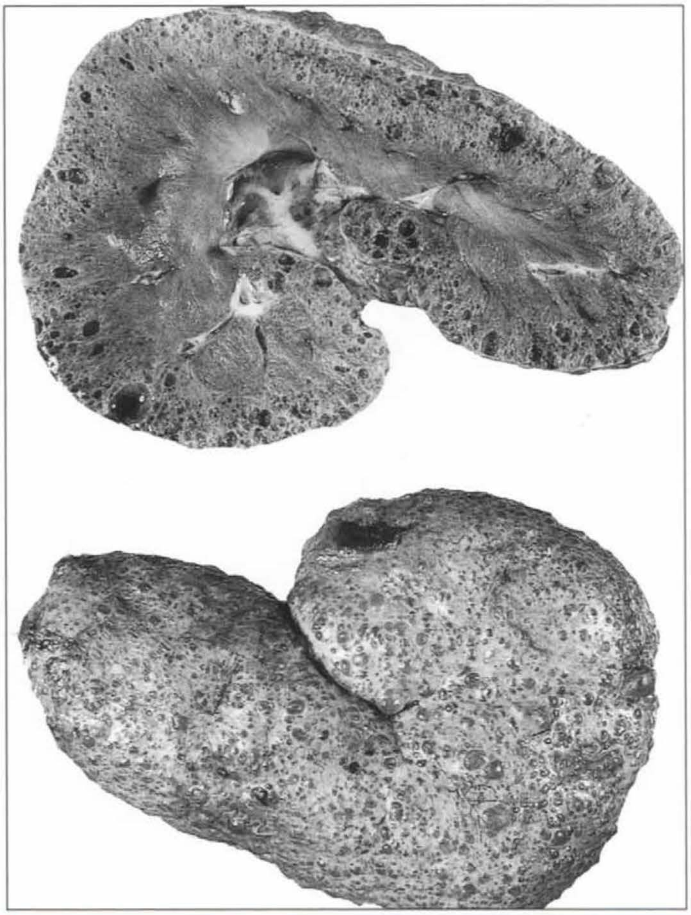

Figure 4.13 Polycystic kidney from an 8-year-old horse.

Many *chemicals,* such as long-acting corticosteroids, diphenylamine, polychlorinated biphenyls, 5,6,7,8-tetrahydrocarbazole-3-acetic acid, alloxan, diphenylthiazole, and nordihydroguaiaretic acid, cause renal cysts in experimental animals. Corticosteroids induce hypokalemia, and cyst formation is prevented by injections of some potassium salts, but in general the mechanisms of cyst development are not known. It seems possible that some of the therapeutic, prophylactic, and pollutant chemicals to which animals are exposed could be responsible for sporadic cases of renal cysts.

Renal cysts vary in size from the barely visible (Fig. 4.13) to structures that exceed that of the organ itself (Fig. 4.14). Most lie within these limits, and although they are more numerous in the cortex than medulla, this may simply reflect the relative volumes of the two regions. The cyst wall is clear or opaque depending on the amount of surrounding connective tissue. The content is watery. Cysts are lined by flattened or cuboidal epithelium that grossly is smooth and shiny. A few cysts are more or less divided by thin trabeculae but most are unilocular and roughly spherical, ovoid, or fusiform.

Simple renal cysts occur in all species but are most common in pigs and calves. There are different patterns of occurrence in pigs, but it is not clear whether similar patterns exist in other animals. The usual

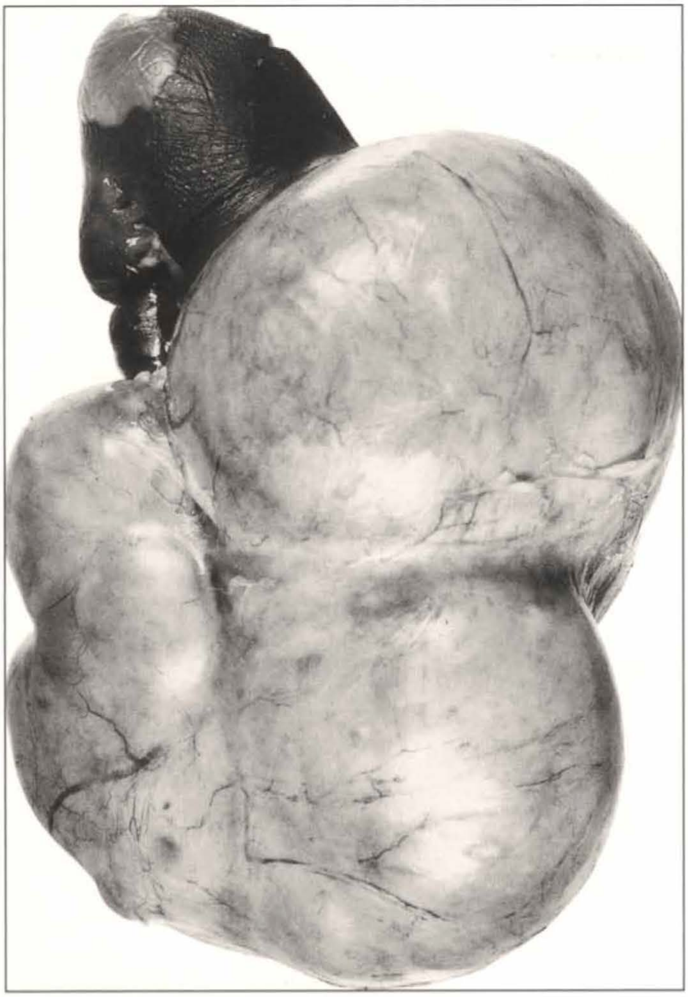

Figure 4.14 Renal cysts involving both poles of the kidney of a pig.

finding in pigs is one or a few unilocular cortical cysts, about 1–2 cm across, that bulge from the renal surface or are exposed when the kidney is sliced. They are usually bilateral, and are incidental findings in young pigs. Affected kidneys are discarded in abattoirs. Although usually regarded as sporadic occurrences, these lesions may be examples of a cystic renal disease that is inherited as an autosomal dominant trait. Polygenic inheritance may determine the number of cysts in animals with the dominant gene. In this condition, few cysts are present at birth but they gradually increase in number, and there may be 80–90 by 1 year of age. Cysts occur in different parts of the kidney and nephron. Signs of renal failure are not seen, but the condition has similarities to a human cystic disease in which renal failure develops in adults – a similar course in mature swine is not inconceivable.

Occasionally areas containing many small cysts occur in one lobe of a bovine kidney or one pole of an equine kidney. They are not significant clinically.

Polycystic kidney disease (PKD) occurs in two major forms:

1. *Autosomal dominant* polycystic kidney disease (ADPKD), in Bull Terriers and Persian cats, is similar to the *adult-onset* form of PKD in humans, which is linked to defects in genes *PKD1* and *PKD2*. Renal cysts develop bilaterally, are of proximal or distal tubular origin, grow progressively over time, and lead to chronic tubulointerstitial nephritis and renal failure in adult life. ADPKD in Persian cats, also linked to a *PKD1* gene defect, is commonly accompanied by hepatic cysts and/or hepatic fibrosis, and pancreatic cysts.
2. *Autosomal recessive* PKD (ARPKD), described in West Highland White and Cairn Terriers, Persian cats, and sheep, is similar to the *childhood* form of PKD in humans. ARPKD in West Highland White Terriers may be accompanied by hepatic biliary cysts.

Congenital PKD, of unknown inheritance, occurs in pigs, lambs, calves, goat kids, puppies, kittens, and foals and can also be associated with cystic bile ducts, bile duct proliferation, and sometimes pancreatic cysts. This form of PKD in domestic animals is manifest by stillbirths or death in renal failure during the first few weeks of life. Grossly the kidneys are large and pale, and contain numerous 1–5 mm cysts that involve both cortex and medulla. Bile duct cysts range from barely visible up to 3 cm across, and the gallbladder and biliary system are often distended with bile that discolors the liver. PKD has also been reported as a sporadic event in adult horses.

Uremic medullary cystic disease complex is a group of progressive renal disorders of children that leads to chronic renal failure as a result of formation of corticomedullary cysts, cortical tubular atrophy, and interstitial fibrosis. A similar syndrome has been identified in a Shetland Sheepdog.

Glomerulocystic disease is occasionally seen in stillborn foals and Collie dogs. Cysts, barely visible, are only present in Bowman's spaces, perhaps as a consequence of periglomerular fibrosis and hence stenosis of the glomerulotubular junction. Their significance in foals is not known. In affected dogs, uremia develops.

Acquired cysts of the kidney do develop when tubules are obstructed by scar tissue. They are multiple and small, rarely exceeding 1.0 cm in diameter. Most are located in convoluted tubules and Bowman's spaces. Hyperplastic collecting tubules are sometimes grossly visible as elongated cysts in the medulla of dogs with renal failure. These acquired cysts are distinguishable from primary cysts in that they occur in kidneys with extensive scarring.

Perinephric pseudocysts occasionally develop uni- or bilaterally as a collection of fluid, which may be urine, blood, lymph, or transudate, in the space between the renal capsule and the renal reflection of the peritoneum; *the space is not lined by epithelium* and is thus a pseudocyst rather than a true cyst. Potential causes include trauma, ureteral or lymphatic obstruction, venous congestion, and hypertension. Affected cats are usually old and have concomitant chronic renal disease.

CIRCULATORY DISTURBANCES AND DISEASES OF THE BLOOD VESSELS

Renal hyperemia

Active hyperemia is seen in acute nephritis but especially in the acute septicemias and bacterial intoxications. The kidney is swollen and uniformly dark, although in some cases the hyperemia may be largely restricted to the medulla. Microscopically, all vessels, especially capillaries, are filled with blood. Very acute congestion with intertubular hemorrhages occurs in clostridial enterotoxemia of lambs and calves.

Passive hyperemia (congestion) follows the usual principles. Affected kidneys are enlarged and dark and the capsular vessels are injected. On section, the corticomedullary junctional zone is dark and prominent and there is engorgement of visible tributaries.

Renal hemorrhages

Hemorrhages are especially common in the renal cortex in a variety of bacteremias and viremias and sometimes in healthy slaughtered animals. Petechiae are very common in piglets dead of any cause. Many or few pinpoint hemorrhages occur beneath the capsule in classical swine fever (hog cholera). African swine fever, and porcine salmonellosis (Fig. 4.15). In porcine erysipelas, the hemorrhages tend to be larger and more irregular in size and shape. Severe hemorrhage in the wall of the renal pelvis and the medulla sometimes occurs in classical swine fever, in other acute infections of swine, and in the hemorrhagic diatheses; the hemorrhage occurs from the congested medullary vessels. Extensive subcapsular hemorrhage is not uncommon in clostridial enterotoxemia of calves; it produces a black cast molded to the shape of the cortex.

Renal infarction

Infarcts of the kidney are common lesions of localized coagulative necrosis produced by embolic or thrombotic occlusion of the renal artery or of one of its branches. The sequelae depend on whether the obstructing material is septic or bland and on the size and number of the vessels obstructed (Fig. 4.16). Bland thrombi produce typical infarcts; septic thrombi produce abscesses that may heal, sequestrate, or discharge into the pelvis. Thrombosis of a trunk of a renal artery will produce total or subtotal necrosis of the kidney, the extent of the

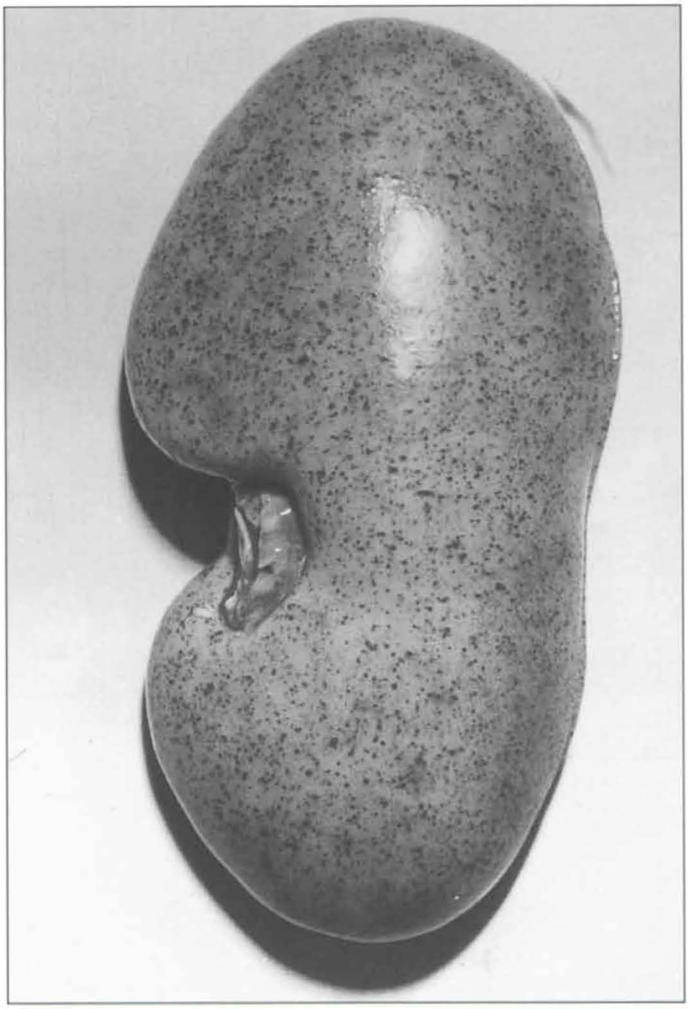

Figure 4.15 Renal cortical petechiae in **African swine fever**. (Courtesy of C Brown.)

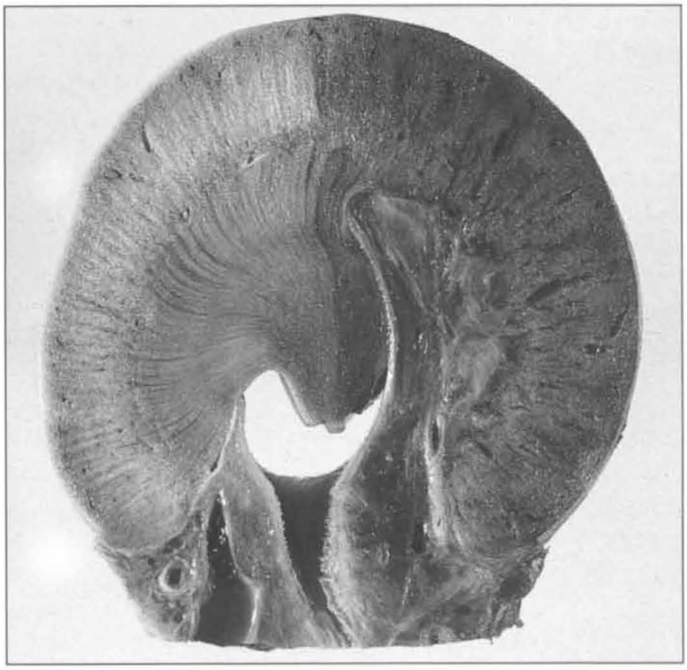

Figure 4.16 **Infarction** of half kidney following ligation of one of two renal arteries in a dog. (Courtesy of BP Wilcock.)

latter depending on the presence and efficiency of parahilar and capsular collaterals. If an arcuate artery is obstructed, there is necrosis of a wedge of both cortex and medulla; if an interlobular vessel is involved, infarction is limited to the cortex. The ease and the frequency with which the kidneys are infarcted result from their vascular architecture being of the "end-artery" type and the large volume of blood that continually traverses them.

Soon after total obstruction of a vessel, the related wedge of tissue is swollen and intensely cyanotic and it is congested by the blood that oozes into the vessels from collaterals. There is no sharp line between the infarcted zone and the adjacent normal tissue because in the narrow boundary zone there is an outer part in which blood continues to ooze slowly and an inner part that is more or less well served by diffusion from the viable tissue. In the outer part of the marginal zone, the red cells survive and circulation may be re-established, but this zone persists for the first 2–3 days; it is usually referred to, apparently erroneously, as the zone of reactive hyperemia. The limit of useful diffusion determines the actual limit of the infarct, and it is here that dehemoglobinization begins, neutrophils accumulate, and the area of total necrosis begins. The dehemoglobinization begins from the periphery at about 24 hours and may be complete in 2–3 days, the infarcted area then being white (Fig. 4.17A). Before decoloration begins, the area that will be affected is outlined by a thin but distinct white line of leukocytes.

The sequence of degenerative changes in the infarcted tissue reflects the specialization and sensitivity of the various structures. At the outer margins, only a few proximal tubules show epithelial necrosis. More centrally, every proximal tubule is dead and inside the zone of diffusion everything is dead (Fig. 4.17B). In the peripheral dead zone there may in a week or so be some revascularization along preformed channels. The necrotic zone is progressively replaced by fibrous tissue, and healed infarcts persist as pale gray-white scars, wedge-shaped and much depressed below the surface. The scars may be difficult or impossible to distinguish grossly from focal healed pyelonephritis.

Minute emboli that lodge in the glomerular or intertubular capillaries may produce small infarcts that are not detectable macroscopically. Because of the small size of such infarcts, there may be adequate diffusion across the infarcted zone so that leukocytes do not accumulate, epithelial necrosis is minimal and soon repaired, and circulation is re-established. Commonly, infarcts of various ages in a kidney indicate recurrent embolic episodes.

Primary vascular disease of the kidneys in animals is of little significance. Renal arteriosclerosis is not rare as an incidental finding in cattle, and arteritis is occasionally observed as "polyarteritis nodosa" or in systemic disease such as malignant catarrhal fever. A variety of degenerative proliferative arterial changes occur in chronic diffuse inflammatory disease, but they are probably secondary, although

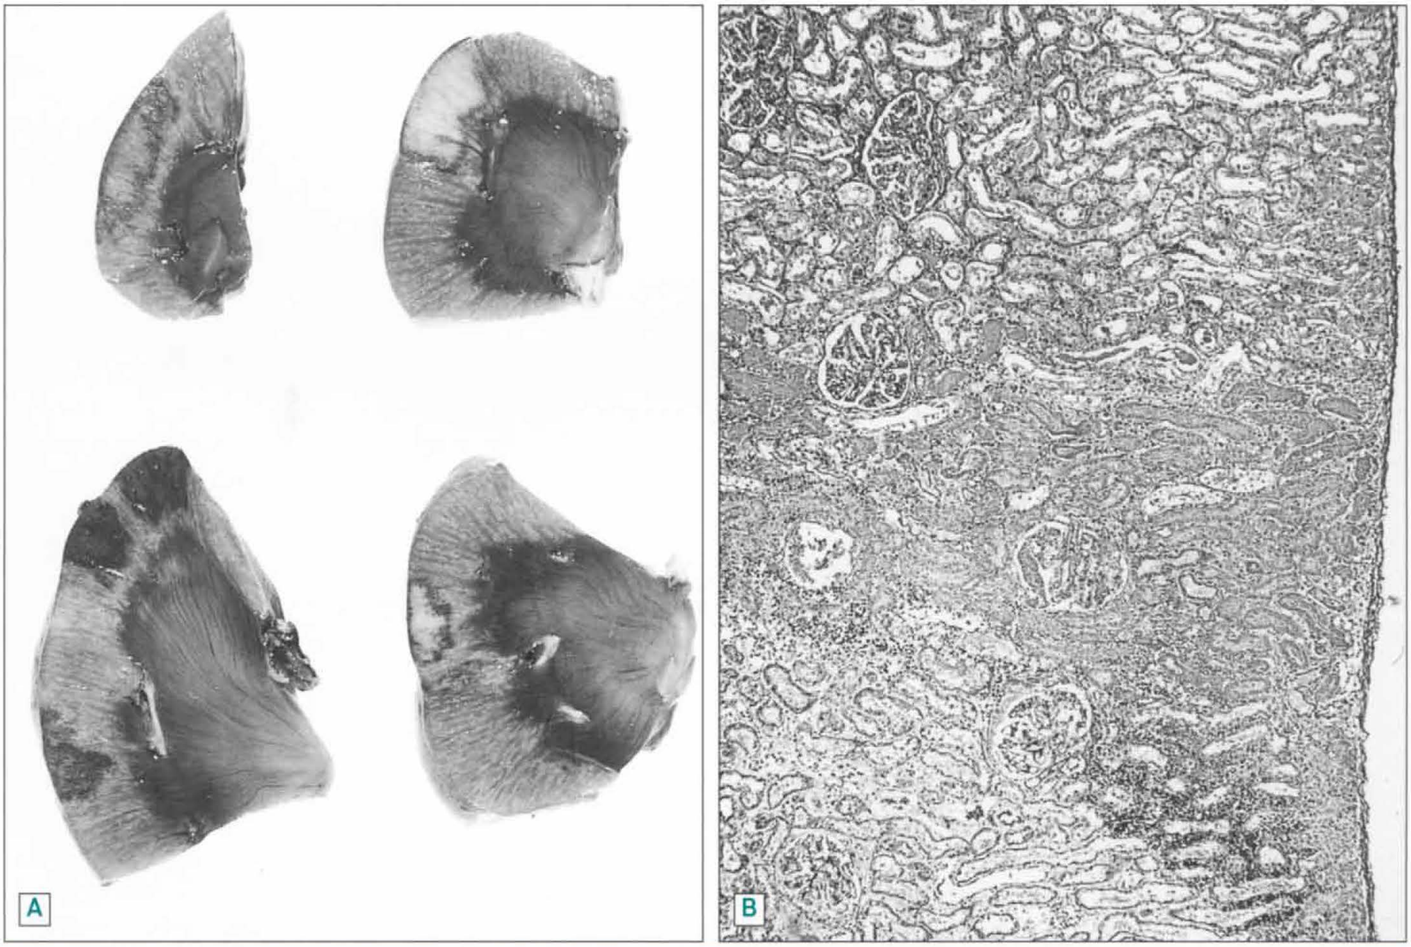

Figure 4.17 A. Renal infarcts in a cow. The dark (hemorrhagic) infarcts are about 1 day old; those with dehemoglobinized centers are 2-3 days old. **B. Renal infarct** in a sheep.

exaggerated by the *hypertension* that is expected to develop. Hypertension is common in canine and feline renal failure, and can lead to further deterioration in renal function by causing additional glomerular and tubular damage. Familial *renal telangiectasia* is an oddity that occurs in Pembroke Welsh Corgis and results in hematuria.

Renal cortical necrosis and acute tubular necrosis

Acute tubular necrosis and renal cortical necrosis are grouped together here for purposes of discussion; acute tubular necrosis is also discussed later in the section on Diseases of tubules. These lesions occur infrequently in animals, but may, if severe, cause acute renal failure and death. *Either variety of renal necrosis is usually a manifestation of hypoperfusion, or "shock,"* which may be classified as cardiogenic, hypovolemic, septic, or neurogenic. Outbreaks of renal cortical necrosis of unknown cause have occurred in kennels of dogs. Renal cortical necrosis and acute tubular necrosis occur in cattle in a variety of endotoxemic conditions, such as mastitis or metritis, and in gastrointestinal diseases, such as severe enteritis and grain overload. In horses, this often provides the fatal outcome to "azoturia." Bilateral cortical necrosis is a rare complication of esophagogastric ulceration in swine, and apparently results from hemorrhagic shock.

In **acute tubular necrosis**, there is patchy necrosis of segments of both proximal and distal tubules with involvement also of the basement membranes; necrotic tubular epithelial cells become casts, which cause tubular blockage and oliguria. Other contributors to oliguria are tubular backleak through disrupted tubular basement membranes, compression of medullary tubules by blood vessels dilated with trapped red cells, reflex constriction of afferent arterioles, and decreased glomerular membrane permeability. In **renal cortical necrosis**, the whole or part of both cortices is involved and there is destruction of both tubules and glomeruli. It appears probable that these lesions represent differences in degree and that they result from patchy or complete renal ischemia.

The usual balance between the renin–angiotensin and the eicosanoid systems that maintains fine regulation of intrarenal blood flow is disrupted during ischemia. During hypotension, perfusion of outer cortical nephrons is reduced while perfusion of inner cortical nephrons is maintained, that is, *intrarenal blood flow is redistributed toward the inner cortex and medulla.* This reaction occurs because the vasoconstrictive effects of angiotensin II and adrenergic stimulation are unopposed in the outer cortex, while in the inner cortex, prostaglandins modulate vasoconstriction; PGE_2 is produced in the medulla in response to ischemia, travels in tubular fluid to the area of the juxtaglomerular apparatus, and has a local vasodilatory effect on afferent arterioles of juxtamedullary nephrons.

The duration of ischemia is of obvious importance for the pathogenesis of necrosis. Complete ischemia of less than 2 hours' duration can be expected to be followed by *good reflow* if cardiac output and blood pressure are restored to normal, whereas total ischemia of longer duration may be followed by patchy reflow or complete failure of reflow in the cortex, medulla, or both. Reflow is inhibited primarily because of vascular congestion by red cells swollen by plasma water uptake, and perhaps also by ischemia-induced swelling of endothelial cells of glomeruli, vasa recta, and peritubular capillaries, and by swelling of parenchymal cells. This *"no-reflow" phenomenon* may make an important contribution to renal ischemia and acute renal failure. Severe ischemic injury may permanently alter renal capillary density, resulting in decreased urinary concentrating ability and predisposing to interstitial fibrosis. This progression may be mediated through local synthesis of *angiostatin*, a proteolytic cleavage product of plasminogen that inhibits angiogenesis, promotes endothelial cell apoptosis, and disrupts the integrity of capillaries.

Another mechanism by which renal cortical necrosis occurs is via the generalized Shwartzman reaction, an example of *disseminated intravascular coagulation*, which is often due to gram-negative endotoxemia. Endothelial injury in glomerular and peritubular capillaries leads to microthrombosis and hemorrhagic renal cortical necrosis. This severe degree of renal damage is usually rapidly fatal but minimal lesions of this pathogenesis are common in a number of bacteremic diseases and visible as petechial or larger hemorrhages in the cortex.

The cellular destruction that occurs in ischemic renal injury begins with a decreased ability to produce adenosine triphosphate and hence an increase in membrane permeability that allows influx of calcium into the cell. Excess free cytosolic calcium activates phospholipases that further increase membrane permeability and lead to membrane disruption and generation of toxic lipid byproducts. Increased intracellular calcium also interferes with mitochondrial respiration and causes increased production of free radicals that further injure cell membranes and mitochondria. Unfortunately, reperfusion can be deleterious because reoxygenation increases the production of free radicals.

The **gross appearance** of the kidneys, other than those with hemorrhagic renal necrosis, varies considerably from case to case; it is probably determined by the severity, distribution, and duration of the ischemia and the quality of the reflow. In acute tubular necrosis, the cortices are finely mottled or flecked by small yellow foci of necrosis. In renal cortical necrosis, the cortices may be totally affected (Fig. 4.18) or the injury may be patchy (Fig. 4.19); pigs tend to develop a "turkey egg" pattern marked by hemorrhagic glomeruli, but die before marked necrosis is evident, whereas cattle sometimes develop a distinctive patchy cortical necrosis (Fig. 4.20). The reaction is the same as for infarction given above. A narrow subcapsular rim of viable tissue may remain. The affected areas of cortex are pale, almost white, slightly swollen, and stop sharply at the corticomedullary junction. The irregular areas of cortical infarction may be outlined by hemorrhage. The medulla may be normal, but in some cases there is severe congestion of the inner stripe of the outer medulla or of the whole of the medulla so that it is swollen and resembles a blood clot.

The **histologic appearance** of a kidney with acute tubular necrosis includes irregular necrosis of the proximal tubules, often with disruption of the tubular basement membranes. Hyaline and granular casts may be present, particularly in distal tubules and collecting ducts. There may be interstitial edema as a result of tubular leakage. Preferential damage occurs to the pars recta and thick ascending limb, primarily because of their location in the poorly perfused outer medulla. If the animal survives the ischemic episode, evidence of regeneration may be seen in ~1 week, namely tubules lined by flattened epithelial cells with hyperchromatic nuclei and occasional mitoses. In cases of severe ischemia and renal cortical necrosis, various patterns of infarction may be seen, with glomeruli and vessels, as well as tubules, being necrotic. Microthrombi may be

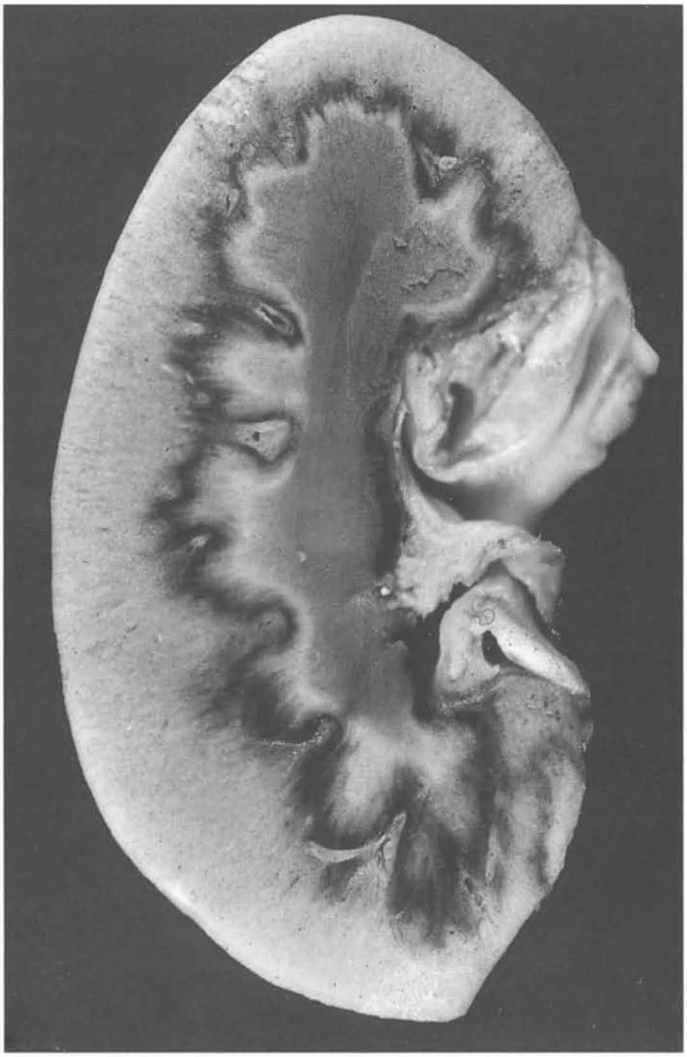

Figure 4.18 Renal cortical necrosis in a pig. The pale cortex is delineated by a hemorrhagic zone, which emphasizes the vascular supply.

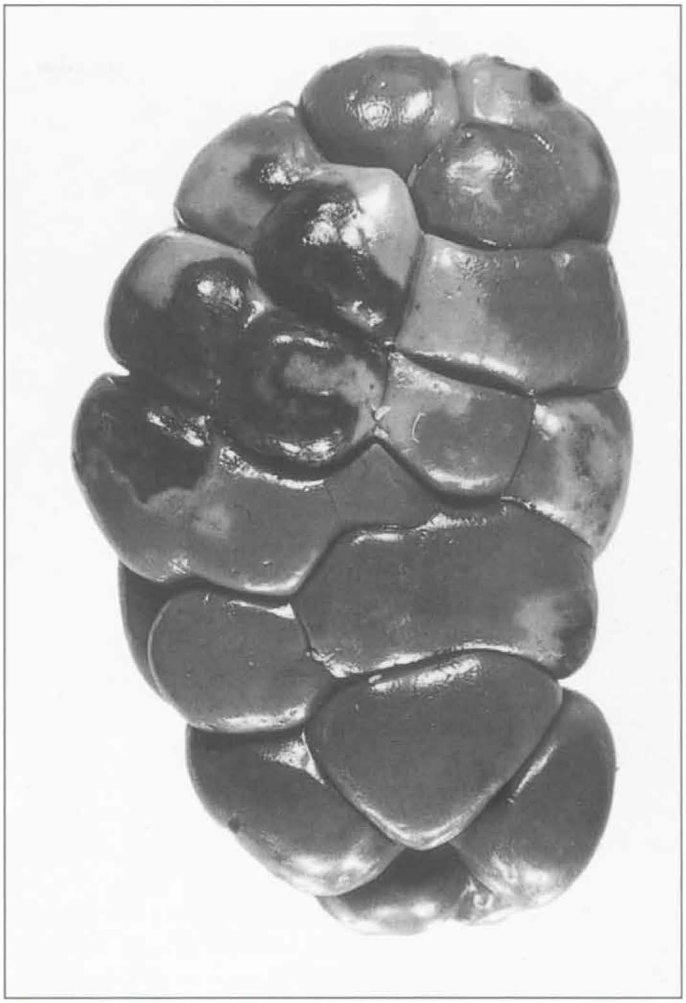

Figure 4.19 Renal cortical necrosis in a cow. Note recent hemorrhagic and older dehemoglobinized areas of infarction.

seen in capillaries, and hemorrhage may be present in glomeruli. The medulla is usually preserved.

Renal medullary necrosis

Under certain circumstances, medullary necrosis is the primary manifestation of renal injury. As noted above, when renal hypotension occurs, cortical necrosis usually predominates due to redistribution of arterial flow to juxtamedullary nephrons. However, medullary vessels are damaged by greater than 2 hours of ischemia and there may hence be failure of both medullary and cortical reflow after temporary ischemia, and both medullary and cortical necrosis result. In the case of venous occlusion, the elevated intrarenal blood pressure maintains the patency of lower-resistance cortical vessels but not of

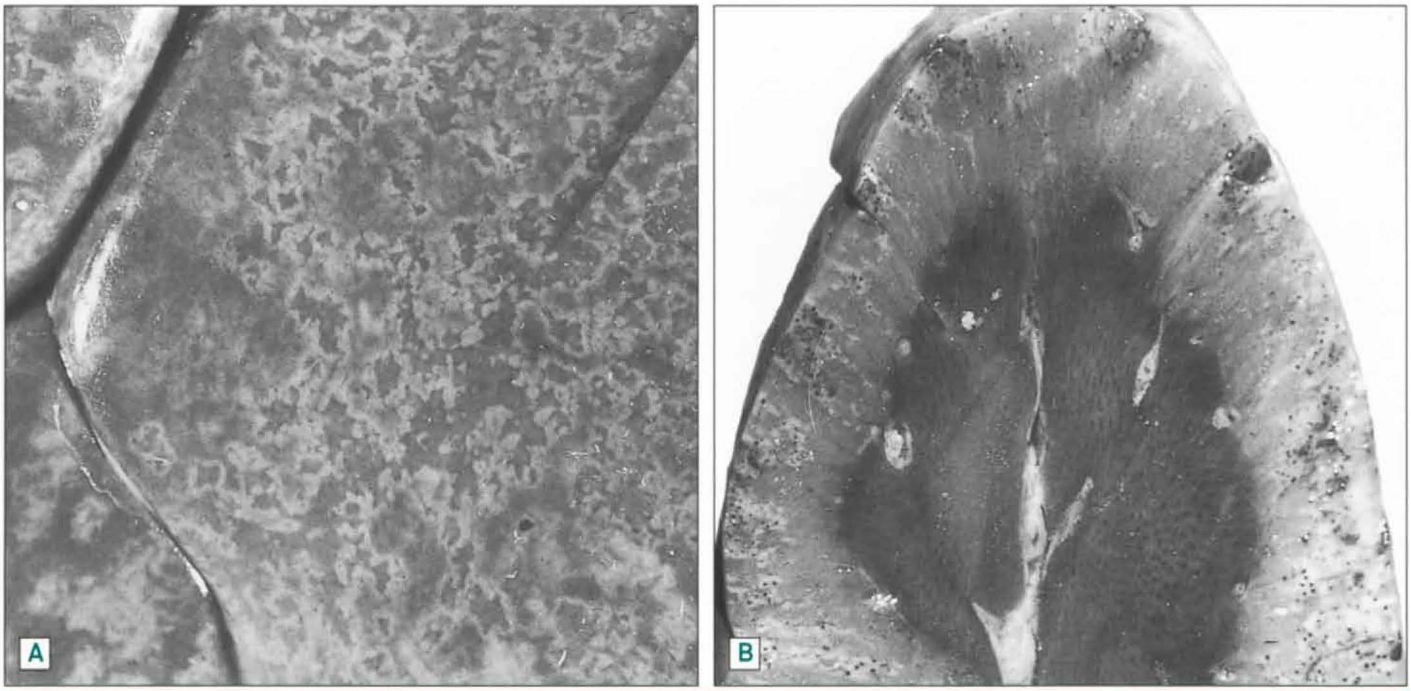

Figure 4.20 A. Capsular surface of kidney demonstrating **renal cortical necrosis** associated with metritis and mastitis in a cow. **B.** Cut surface of kidney shown in (**A**). Note predominance of lesions in the outer cortex.

higher-resistance medullary vessels, and hence medullary infarction predominates.

Toxic and hypoxic insults to the kidney are synergistic, and several protective mechanisms must be incapacitated to produce medullary injury. Prostaglandins are important autoregulators of renal perfusion. *Nonsteroidal anti-inflammatory drugs* (NSAIDs), such as aspirin, phenacetin, phenylbutazone, flunixin meglumine, and ibuprofen, inhibit cyclooxygenase, resulting in decreased production of PGE_2 and loss of its vasodilatory effect on arterioles of juxtamedullary nephrons. As well, NSAIDs may be directly toxic to renal medullary interstitial cells. Papillary necrosis is characteristic of "**analgesic nephropathy**" in humans, and also occurs in animals, especially seen as renal crest necrosis in dehydrated horses treated with phenylbutazone (Fig. 4.21). Chronic interstitial fibrosis is an associated lesion in affected humans; cortical atrophy follows obstruction of collecting ducts.

Dehydration is involved in the pathogenesis of papillary necrosis in racing Greyhounds. Papillary necrosis occurs in lambs and calves that are dehydrated when treated with phenothiazine, and the necrosis is again apparently due to *ischemia*. Accidental ingestion of a combination of monensin and roxarsone has caused renal medullary necrosis in normally hydrated dogs and pups. Diabetes mellitus is not the important pathogenetic factor in animals that it appears to be in humans.

Urinary obstruction and *pyelonephritis* are common causes of papillary necrosis in animals. Fulminating pyelonephritic infections may produce necrosis of the papilla with scant inflammatory reaction in the early stages. The long thin-walled vessels supplying the medulla are easily occluded by compression, which could be caused by edema of the papillary interstitium alone. Compression of vessels is probably the mechanism by which *amyloidosis* causes papillary necrosis in cats. Deposition of amyloid mainly in the renal medulla, with or without

little concomitant glomerular deposition, occurs often in cats and occasionally in cattle (see section on Amyloidosis, below).

The *gross lesions* of medullary necrosis vary greatly in their extent and stage of development (Figs 4.21 and 4.22). Acute papillary infarction may be an incidental finding in an animal dead of other causes, such as dehydration and electrolyte imbalances in neonatal diarrhea. Massive medullary infarction would no doubt be part of acute renal failure leading to death. In an animal that survives an episode of medullary necrosis, medullary scarring occurs, the papilla may slough, and secondary cortical scarring is seen. The sloughed papilla may remain in the pelvis and may become mineralized. *Microscopic lesions* cover the usual range of necrosis and scarring. *Sequelae* to medullary necrosis are based on the loss of the ability to concentrate urine, and include chronic renal failure and uremia.

Hydronephrosis

Hydronephrosis is dilation of the renal pelvis and calyces associated with progressive atrophy and cystic enlargement of the kidney. The cause is some form of *urinary obstruction*, which may be complete or incomplete, existing at any level from the urethra to the renal pelvis. The obstruction may be caused by anomalous development of the lower urinary passages or it may be acquired. *Acquired causes* include urinary calculi in any location, prostatic enlargement in the dog, cystitis especially if it is hemorrhagic, compression of the ureters by surrounding inflammatory or neoplastic tissue, displacement of the bladder in perineal hernias, and acquired urethral strictures. Depending upon the site of obstruction, hydronephrosis may be unilateral or bilateral, and there may be some degree of hydroureter and dilation of the bladder.

The pathogenesis of hydronephrosis is based on the persistence of glomerular filtration in the presence of urinary obstruction, plus the development of ischemic lesions. Even with sudden complete obstruction, glomerular filtration continues since filtrate diffuses into the renal interstitium and perirenal spaces, where it is drained by lymphatics and veins. However, continued filtration creates increased pressure throughout the nephrons, collecting ducts, calyces, and pelvis, and shearing forces develop between the compressible parenchyma and the resistant connective tissues of the trabeculae. Pressure atrophy and apoptosis of tubular epithelium occur, and hence tubular function and concentrating ability diminish. As well, blood vessels are compressed, particularly hilar veins and inner medullary vessels, leading to *papillary ischemia and necrosis*. An interstitial inflammatory response, triggered by activated tubular epithelial cells and leukocytes, releases a range of vasoactive factors, growth factors, and cytokines, leading to progressive interstitial fibrosis. Glomerular filtration progressively decreases due to intrarenal vasoconstriction, and nephrons atrophy and are replaced by scar tissue.

The degree of development of hydronephrosis depends on whether or not it is bilateral, the completeness of the obstruction, and on other complications of obstruction. The development of an extensive degree of hydronephrosis requires that it be unilateral (Fig. 4.23). Bilateral obstruction, which includes obstruction localized to the bladder or urethra, results in early death from uremia. Unilateral obstruction will produce the greatest degree of hydronephrosis, especially if the obstruction is incomplete or intermittent, because glomerular filtration will be little suppressed, and such kidneys may be massively enlarged. If an obstruction is removed within about 1 week, renal function returns. After about 3 weeks of complete obstruction, or several months of incomplete obstruction, irreversible renal damage occurs. If hydronephrosis is unilateral, the remaining

kidney, if normal, compensates adequately. Urinary stasis predisposes to infection, and hence pyelonephritis may be superimposed upon hydronephrosis or vice versa.

Early *gross changes* consist of progressive dilation of the pelvis and calyces with blunting of the apices of the pyramids (Figs 4.24 and 4.25). Eventually these may become excavated to form multilocular cysts communicating with the pelvis and separated by an intricate series of ridges that represent original septa (Fig. 4.23). In advanced cases, the kidney may be transformed into a thin-walled sac with only a thin shell of atrophic cortical parenchyma.

The *microscopic changes* begin with dilation of the proximal convoluted tubules and shortly there is also dilation of the distal and straight segments. The latter persists, with atrophy of the epithelium, but the dilation of the proximal tubules subsides; these portions then atrophy, become separated, and are replaced by light diffuse cortical fibrosis (Fig. 4.26). Much of the tubular atrophy may be through apoptosis. The glomeruli persist for a long time, flattened and spread apart. Various degrees of ischemia up to infarction may develop patchily in the cortex if the obstruction is sudden and complete; the infarcts are venous in origin. There is progressive destruction of the pyramids by liquefaction necrosis that spares the pelvic epithelium and tissue in a narrow zone immediately beneath. The necrotic tissue, to which there is no reaction, is liquefied and removed, and the pyramids are gradually destroyed.

GLOMERULAR DISEASE

Glomerular disease is of importance because, first, interference with glomerular blood flow, as well as decreasing the formation of ultrafiltrate, *impairs peritubular perfusion* and hence may cause loss of the entire nephron, and second, glomerular permeability may be altered, leading particularly to *proteinuria*.

- The terms *glomerulonephritis* and *glomerulonephropathy* are used interchangeably, and imply that secondary tubulointerstitial and vascular changes accompany the primary glomerular disease.
- The term *glomerulitis* is used when inflammation is restricted to glomeruli, as may occur in acute septicemias.
- *Glomerulopathy* refers to glomerular disease without cellular inflammatory components.

Glomerulonephritis, which is usually of immune origin, is a common form of renal disease in domestic animals, and is a common antecedent of end-stage kidneys and renal failure, particularly in dogs and cats.

Glomeruli may also be significantly affected in a variety of *systemic diseases*, such as **amyloidosis**, which is discussed below, systemic lupus erythematosus, diabetes mellitus, bacterial endocarditis, and in various forms of vasculitis.

The *clinical presentations* of any renal disease are of limited variety, and clinicopathologic findings in animals with glomerular disease usually have no specificity. Thus, hematuria, proteinuria, oliguria, hyposthenuria, and azotemia occur in glomerular and other renal diseases; *only proteinuria, occurring in the absence of urinary tract inflammation, is particularly indicative of glomerular damage*, namely increased glomerular permeability. Marked proteinuria, as occurs in chronic glomerulonephritis and in amyloidosis, can lead to development of the **nephrotic syndrome**, which is a clinical syndrome characterized by hypoalbuminemia, generalized edema, and hypercholesterolemia; edema is less common in dogs than in humans with the nephrotic syndrome. The edema is the result of decreased plasma colloid osmotic pressure, stimulation of the renin–angiotensin–aldosterone system, and release of antidiuretic hormone in response to hypovolemia. The hepatic response to hypoproteinemia is apparently a generalized increase in production of proteins, including lipoproteins, leading to hyperlipoproteinemia and hypercholesterolemia. Proteinuria due to glomerular disease may be *highly selective* or *poorly selective*, that is, albumin or albumin plus globulins respectively appear in the urine. In summary, *glomerulonephritis can be expressed clinically as acute or chronic renal failure, or as the nephrotic syndrome.*

The following terms are generally accepted for the description of glomerular disease, and are often appended to the histologic diagnosis:

generalized – involves all glomeruli to some extent
focal – involves only some glomeruli
diffuse (global) – involves the whole glomerulus
segmental (local) – involves only part of the glomerulus
mesangial – affects primarily the mesangial area

Classification of glomerulonephritis in humans is relatively advanced and complex, based on extensive clinicopathologic correlations, clinical outcomes and responses to therapy. The following simple classification system is currently in use for glomerulonephritis in domestic animals:

membranous – basement membrane thickening predominates
proliferative (mesangioproliferative) – cellular proliferation predominates (Fig. 4.27)
membranoproliferative (mesangiocapillary) – both changes are present (Fig. 4.28)
glomerulosclerosis – a combination of increased mesangial matrix and obliteration of capillary lumina; progressive hyalinization sometimes results in *glomerular obsolescence*, in which the glomerulus is a shrunken, eosinophilic, hypocellular mass (Fig. 4.29).

Lesion development may be at different stages in glomeruli of the same kidney, and the type of glomerular reaction may not be uniform among glomeruli.

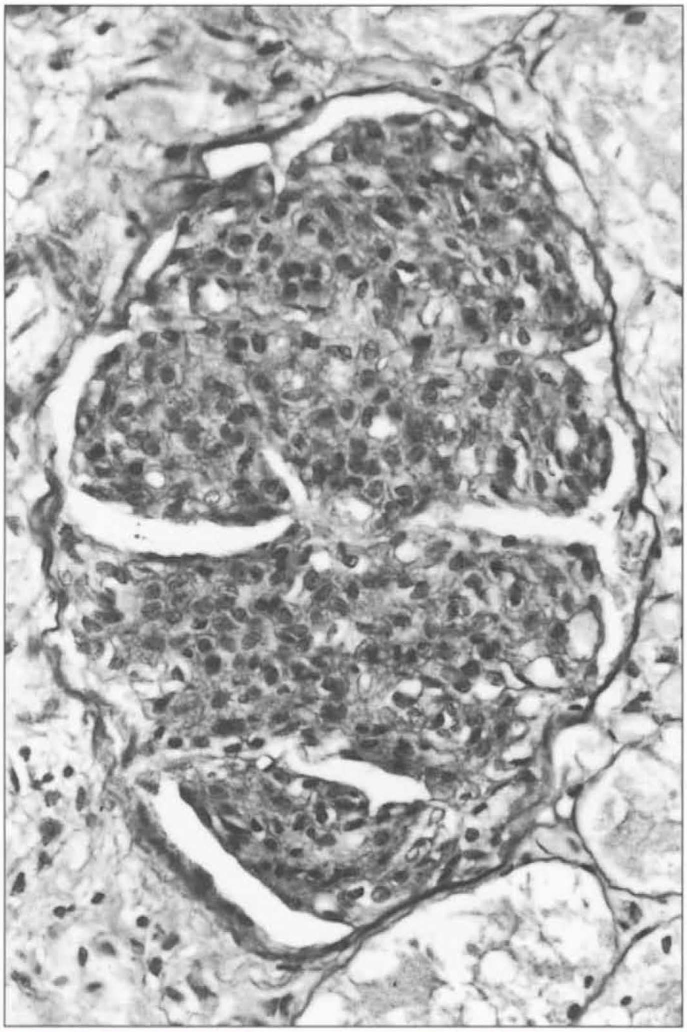

Figure 4.27 Proliferative glomerulonephritis in a 12-week-old Doberman Pinscher.

Histologic changes in glomerulonephritis

Glomeruli commonly exhibit a spectrum of histologic changes. In view of the large renal reserve, it is important to correlate clinical and histologic findings in order to determine the clinical importance of glomerular changes. For example, in sheep and goats, glomerulonephritis is often generalized and well developed histologically, but is usually of little functional significance. Conversely, histologic glomerular changes may be slight but clinical disease may be marked, as occurs in **minimal-change disease**, wherein a mild ultrastructural lesion (fusion of foot processes) is accompanied by marked proteinuria; this lesion has been produced experimentally in dogs by infection with *Ehrlichia canis*.

Glomeruli may be nonspecifically involved in renal reactions such as renal cortical necrosis, discussed above, and may be secondarily involved in tubulointerstitial diseases such as pyelonephritis. Septic emboli frequently lodge in the glomerular and peritubular capillary beds and cause focal glomerulitis and focal interstitial nephritis in diseases such as porcine erysipelas and in actinobacillosis of foals (Fig. 4.30A). Generalized glomerulitis, not necessarily associated with other renal change, is seen in acute septic disease and is characterized by increased glomerular cellularity involving either or both epithelial and endothelial cells. Inclusions are common in glomerular endothelium in infectious canine hepatitis (Fig. 4.30B).

Basic inflammatory reactions of exudation, necrosis, and thrombosis occur in glomeruli as elsewhere but some changes are typically glomerular.

Cellularity of the glomerular tuft may be increased by proliferation of endothelial, epithelial, or mesangial cells. This assessment is usually subjective. Proliferation of endothelial versus mesangial cells may be difficult to distinguish, and the term *endocapillary glomerulonephritis* is then applied. Mesangial cells in glomeruli of dogs usually occur singly or in pairs, hence at least three mesangial cells must be in close proximity before the term *mesangial hyperplasia* is applied. In response to fibrin exudation into the urinary space in severe glomerular damage, monocytes invade, parietal epithelial cells proliferate, and *glomerular crescents* are formed. Some of the cells, possibly monocytes, undergo metaplasia to fibroblasts and produce collagen. In humans, crescents are most commonly seen in cases of rapidly progressive extracapillary glomerulonephritis, but they are only indicative of severe glomerular damage, and not pathognomonic of any one disease.

Neutrophils and monocytes may accumulate within glomerular capillaries and infiltrate the glomeruli, and may accompany cellular proliferation in glomerulonephritis.

The **swelling of foot processes** and their subsequent retraction is a reversible reaction of the visceral epithelial cells, and apparently occurs in response to basement membrane damage and protein leakage. Podocytes do not replicate postnatally. Severe injury can cause loss of podocytes and exposure of "bare" GBM, which can adhere to parietal epithelial cells leading to fusion of part of the tuft with the interstitium and passage of filtrate inside the *adhesion* ("synechia") towards the interstitium.

Glomerular capillary walls may be thickened in routine hematoxylin and eosin-stained sections due to endothelial or epithelial swelling and/or **thickening of the GBM**. The GBM itself is not visible unless special stains, such as PAS or PAS-methenamine silver, are employed on thin (1–3 μm) sections. Electron microscopy is required to characterize properly the morphology of the thickening, which may be regular, as occurs in diabetic glomerulosclerosis, or irregular, as with deposition of electron-dense material in *subendothelial, intramembranous, or subepithelial* (epimembranous) locations. *These electron-dense deposits are usually immune complexes.* Thickened peripheral capillary walls are particularly prominent in cases of membranous glomerulonephritis, and are referred to as "*wire loops*;" subepithelial immune complexes (*humps*) may become separated by projections (*spikes*) of basement membrane, and eventually surrounded by and incorporated within the membrane (Fig. 4.31). This marked thickening of the GBM is somewhat paradoxically associated with marked proteinuria, probably as a result of changes in the charge and pore size of the GBM. In membranoproliferative glomerulonephritis, thickening of the GBM may be due to infiltration and splitting by mesangial processes and matrix, and is seen with silver stains as a characteristic *double-contoured glomerular basement membrane* or "*tram-tracks,*" a change that is also termed "*reduplication.*" According to the World Health Organization classification of human glomerular diseases, membranoproliferative glomerulonephritis can be subdivided into *type I* (subendothelial deposits), *type II* ("dense deposit disease," intramembranous deposits), and *type III* (both subendothelial and subepithelial deposits, with spike formation).

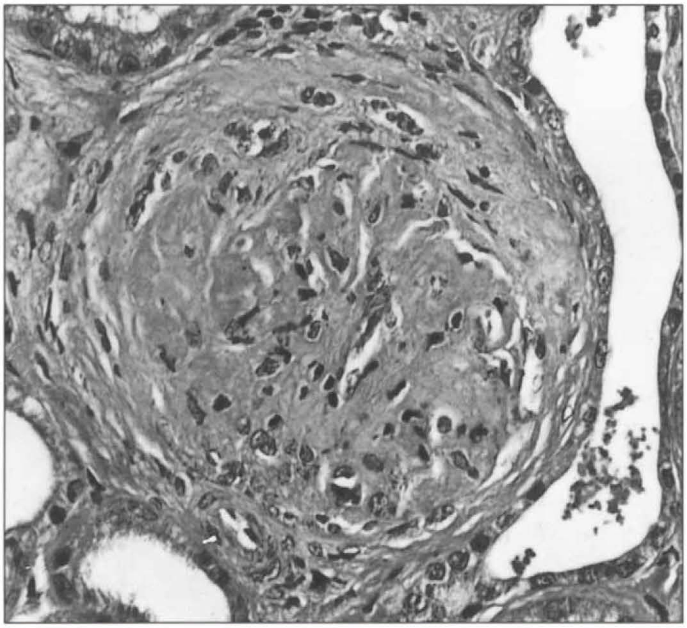

Figure 4.29 Obsolescent glomerulus in chronic glomerulonephritis in a dog.

As seen by light microscopy, **hyalinization**, or accumulation of homogeneous, eosinophilic, PAS-positive, basement membrane-like material, is common in the mesangial areas in glomerulonephritis, especially in chronic cases. This mesangial sclerosis may be reversible but, if irreversible and progressive, may lead to obsolescence of the glomerulus. Hyaline material is commonly deposited in the mesangium in *diabetes mellitus* and *amyloidosis*; in diabetes mellitus, diffuse (Fig. 4.32) or occasionally nodular hyaline deposits (Kimmelstiel–Wilson nodules) may be seen in glomeruli.

Renal glomerular fibrosis, characterized by the primary deposition of collagen type III in glomeruli, has been reported in dogs, pigs, and a cat (only collagen type IV is normally present in glomeruli). Proteinuria and renal failure result from mesangial sclerosis and capillary collapse. This variant of glomerulosclerosis resembles the human condition collagenofibrotic glomerulonephropathy.

Thickening of Bowman's capsule may occur due to various combinations of hyperplasia of parietal epithelial cells in crescents, invasion by monocytes, thickening of the basement membrane, and periglomerular fibrosis. These changes may be particularly marked in glomerular ischemia due to vascular occlusion.

Glomerular tuft atrophy may occur subsequent to scarring, which causes tubular constriction, inhibits or stops tubular fluid flow, and causes dilation of Bowman's capsule and secondary atrophy of the glomerular tuft (*"glomerulocystic" change*).

Nonglomerular histologic changes in glomerulonephritis include *tubular proteinuria*, which is prominent in membranous glomerulonephritis but is most marked in glomerular amyloidosis. Proteinuria can damage and activate tubular epithelial cells, causing release of proinflammatory cytokines and growth factors that induce *interstitial fibrosis*. Indeed, the amount of tubulointerstitial fibrosis often correlates closely with the degree of chronic renal dysfunction in glomerulopathies. Histologic changes may also be of *ischemic origin* due to decreased glomerular, and hence efferent arteriolar and peritubular, blood flow, and may result from acute and chronic interstitial *inflammation*. Hence, *tubular atrophy, interstitial fibrosis, and scarring occur in advanced lesions*, eventually producing the nonspecific histologic picture of *end-stage kidney*. Tubulointerstitial and glomerular damage may be coincident and due to the same mechanism rather than either one being primary.

Pathogenesis of generalized glomerulonephritis

Glomerulonephritis may result from the deposition in glomeruli of circulating immune complexes unrelated to glomerular components, from formation in situ of antibodies against GBM, or from activation of the alternative pathway of complement. Some types of glomerulonephritis are of unknown pathogenesis. By far the most commonly identified pathogenesis of glomerulonephritis in domestic animals is immune-complex deposition.

In **immune-complex glomerulonephritis**, circulating nonglomerular antigen–antibody complexes localize in glomeruli and are visible by immunofluorescence or electron microscopy as granules within, or on either side of, the GBM. Causative antigens may be exogenous, e.g., serum sickness, or endogenous, e.g., nucleic acid in systemic lupus erythematosus. Immune-complex deposition may cause *acute or chronic, membranous or proliferative lesions*. The classical example of immune-complex glomerulonephritis is acute, or "single-shot," serum sickness. When a large quantity of foreign protein is injected intravenously into an experimental animal, immune complexes occur in glomeruli in a *characteristic "lumpy-bumpy" pattern, as seen by immunofluorescence* (Fig. 4.33). By electron microscopy, the complexes are seen as irregular electron-dense deposits in a subendothelial or subepithelial location or within the mesangium. The immune complexes usually contain complement as well as antigen and antibody. In general, it has been believed that immune-complex deposition, and hence glomerular damage, occurs during the period of equivalence of antigen and antibody concentrations or during slight antigen excess. An alternative view is that antigens capable of penetrating the basement membrane localize, or are "planted," in a subepithelial position, and then bind antibody of low avidity. This antigen localization may be charge-dependent. As well as taking part in the usual immune-complex glomerulonephritis, dirofilarial antigens, for example, can apparently be deposited directly in basement membrane, inducing formation in situ of immune complexes, and producing linear fluorescence, which is usually a characteristic of anti-GBM disease (Fig. 4.34). Candidates for "planted" antigens that may localize in glomeruli and result in the formation in situ of immune complexes include viral, bacterial, and parasitic products, drugs, DNA, and large aggregated proteins, e.g., aggregated immunoglobulin G (IgG). The relative importance of circulating soluble immune complexes versus in situ formation of complexes in causing

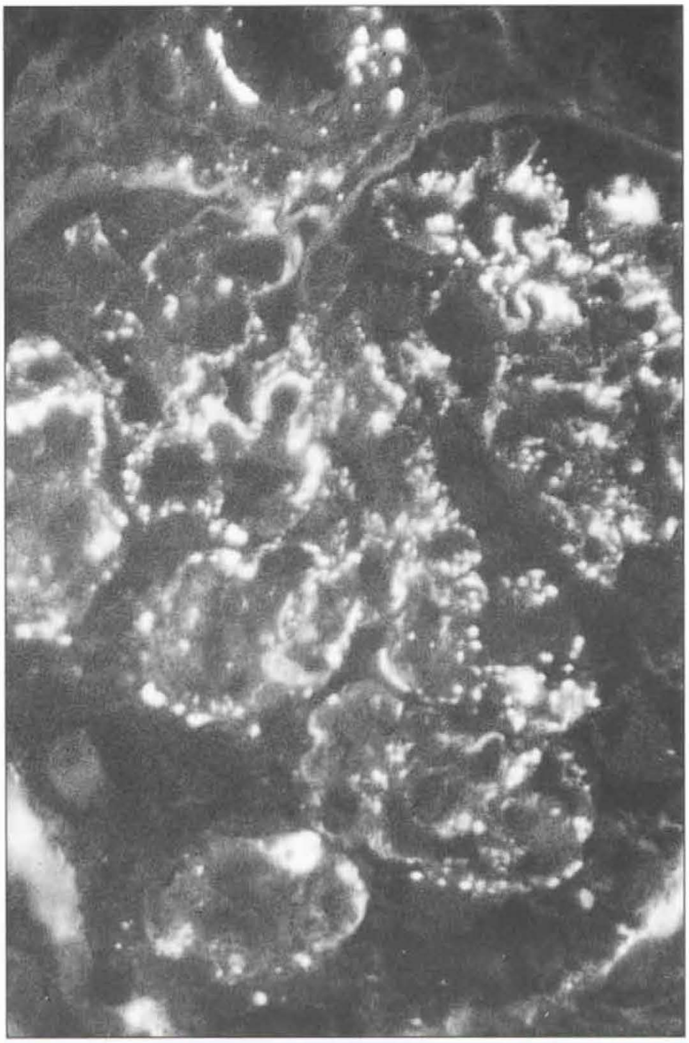

Figure 4.33 C3 granular ("lumpy-bumpy") immunofluorescence in postinfectious glomerulonephritis. (Courtesy of BN Wilkie.)

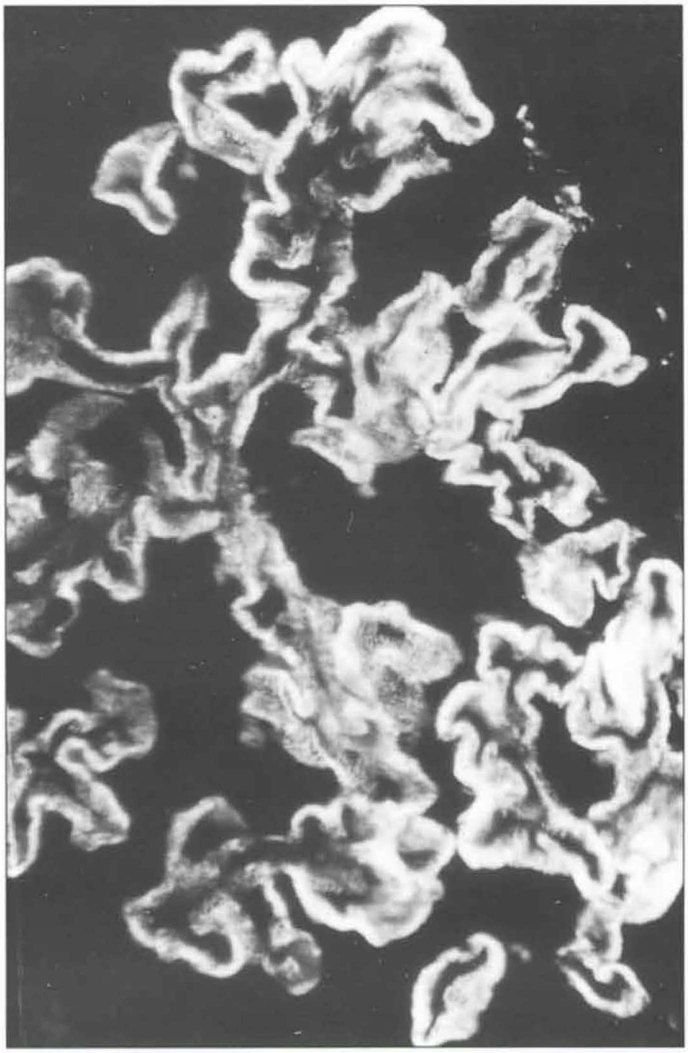

Figure 4.34 Immunoglobulin G linear immunofluorescence in membranous glomerulonephritis. (Courtesy of BN Wilkie.)

immune-complex glomerulonephritis is not resolved. Another modification of the classical soluble immune-complex disease model is that insoluble or poorly soluble complexes play a major role in subendothelial and mesangial deposit diseases.

Chronic serum sickness occurs when repeated small doses of foreign protein are given to an animal, and circulating immune complexes are continually present. This condition of continued antigenemia occurs during various microbial and parasitic infections, such as *Feline leukemia virus* infection and canine dirofilariasis, as well as during continued release of endogenous antigens, such as nucleoprotein in systemic lupus erythematosus or tumor-specific or tumor-associated antigens.

It is not completely straightforward to ascribe the cause of glomerulonephritis to immune complexes since the presence of immunoglobulins and complement in a lesion does not necessarily indicate that they are responsible for the lesion; C3, C1q, and IgM are sticky molecules that may adhere to previously injured tissue. As well, the significance of circulating soluble immune complexes is controversial, since they may be present in the absence of glomerulonephritis and, even if present, they may be more markers for the disease than actual causative agents, since *glomerular damage may be caused by various combinations of insoluble, soluble, and in situ-formed immune complexes.* To go one step further, some investigators dispute the primary role of immune complexes in the pathogenesis of glomerulonephritis and suggest that glomeruli that have suffered primary damage by other agents, such as hydrocarbons, are then susceptible to secondary immunologic damage.

The reasons for *localization of immune complexes* in various glomerular sites, namely subendothelial, intramembranous, subepithelial, or mesangial, are complex. Localization may be affected by the size, shape, charge, and chemical composition of the complexes. Thus, large complexes tend to localize in the mesangium and cause mesangiopathic glomerulonephritis, whereas small complexes (or antigens) penetrate the glomerular loop to produce the membranous or proliferative form. Antibody avidity may affect localization; complexes containing high-avidity antibody localize in the mesangium, while those with low-avidity antibody may localize subepithelially. Penetration of the basement membrane by complexes may be aided by products of inflammation, such as IgE-mediated release of histamine and serotonin from platelets and basophils, which is induced by antigen. The location of deposits may change with time; subepithelial deposits (humps) separated by spikes of GBM may become surrounded by GBM and hence become intramembranous deposits.

Modification of glomerular immune complexes occurs; they may be eliminated or may enlarge. Complexes may be eliminated by solubilization by excess antigen, phagocytosis by neutrophils, macrophages, or mesangial cells, passage through mesangial channels and egress at the vascular pole, excretion by mesangial cells through epithelial cells into the urinary space, degradation within the mesangial matrix, extracellular degradation by proteases, or by solubilization by complement. Thus, for example, removal of the source of persistent antigenemia in pyometra of dogs by ovariohysterectomy results in resolution of glomerulonephritis and cessation of proteinuria. Conversely, complexes may enlarge due to combination with various bloodborne reactants, such as small amounts of antigen, free antibody, immune complexes of the same or different specificity, complement components, or antibodies against immunoglobulins or complement components (immunoconglutinin or C3 nephritic factor).

In **anti-GBM glomerulonephritis**, *antibodies are formed against intrinsic GBM antigens*, resulting in a *linear pattern of immunofluorescence* reflecting the uniform distribution of immunoglobulins and complement along the GBM. There is a notable lack of dense or other deposits on electron microscopic examination. This lesion was the first recognized immune-mediated nephritis, and was induced in rats by injection of antirat-kidney antibodies obtained from rabbits or ducks immunized with rat kidney tissue; this experimental model is also referred to as *Masugi or nephrotoxic nephritis.* Although arbitrarily separated, *anti-GBM glomerulonephritis and immune-complex glomerulonephritis are not separate conditions but actually two poles of a spectrum of immune-mediated glomerular disease.* In fact, the typical linear immunofluorescence pattern of anti-GBM glomerulonephritis is gradually converted to the granular pattern typical of immune-complex glomerulonephritis with time, as linearly arrayed immune complexes become reorganized into dense aggregates in subepithelial and subendothelial locations.

Anti-GBM glomerulonephritis occurs as a component of Goodpasture's syndrome in humans, but occurs much less frequently than does immune-complex glomerulonephritis. In domestic animals, anti-GBM disease is apparently rare, having been reported in a horse and suspected, but not proved, in several dogs.

While the above descriptions of immune-complex glomerulonephritis and anti-GBM disease are conceptually useful, the mechanisms operative in clinical cases are often less well defined and more complex. Thus, in the well-recognized acute poststreptococcal disease in humans, factors implicated in glomerular injury include immune-complex deposition, damage by antibodies that cross-react with streptococci and GBM, activation of the alternative complement pathway, and cell-mediated reactivity to altered GBM.

Mechanisms of glomerular injury

Several mechanisms result in glomerular injury once immune complexes are formed or deposited in glomeruli in either immune-complex glomerulonephritis or in anti-GBM disease. The best-established mechanism is that of *complement fixation with resultant chemotaxis of neutrophils.* Complement components C3a, C5a, and C567 attract neutrophils, which, in the process of ingesting complexes, release lysosomal enzymes, arachidonic acid metabolites and oxygen-derived free radicals, and hence cause GBM damage. This is the *complement-leukocyte-dependent mechanism.* The terminal membrane attack complex of complement, C5b-9, can damage glomeruli independent of neutrophils through damage of epithelial, endothelial, and mesangial cells, with release of oxidants, cytokines, and other mediators. Complement fragments cause release of histamine from mast cells, and hence cause increased capillary permeability, which may be important in allowing deposition of further immune complexes in the capillary wall.

Chemokines (*chemo*tactic cyto*kines*) play an important role in transmigration of leukocytes into sites of inflammation. Produced by glomerular, mesangial, tubular, and interstitial cells, these locally active molecules are produced in response to simulation by agents such as proinflammatory cytokines, immune complexes, complement activation, and hypoxia, perhaps through the production of free radicals. Once chemokines reach the endothelial surface, they activate circulating leukocytes bearing the respective surface receptors. Local attachment of leukocytes occurs through interaction of leukocyte integrin with adhesion molecules, such as intercellular adhesion molecule-1 and vascular cell adhesion molecule-1, on endothelial, mesangial, and interstitial cells. *Leukocytes migrate along the chemokine gradient to the site of injury.* Activated leukocytes will initiate their effector functions, such as respiratory burst, immune complex phagocytosis, release of hydrolases, removal of matrix, cell debris, and apoptotic cells. Activated leukocytes will also release additional mediators, chemokines, and cytokines, in an amplification loop that will recruit more leukocytes. A late influx of T cells can then be generated by production of T-cell-specific chemokines.

It is paradoxical that, while complement participates in glomerular injury, it also is capable of solubilizing immune complexes and accelerating their removal. Hence, hereditary hypocomplementemia, as occurs in Finnish Landrace lambs, may contribute to persistence of immune complexes and facilitate damage.

Interaction of complement fragments with platelets can initiate coagulation, thrombosis, and fibrinolysis; Hageman factor links the complement, coagulation, and kinin-forming systems. Fibrin and its degradation products are often present in glomeruli in glomerulonephritis, and fibrinogen that leaks into the urinary space is a stimulus to monocyte infiltration, proliferation of parietal epithelial cells, and crescent formation.

Monocytes play a role in glomerular damage also, especially through their interaction with mesangial cells. Monocytes may be beneficial in removing immune complexes, but may cause enzymatic damage, as do neutrophils. There is evidence that they transform to cells of fibroblastic type in glomerular crescents.

The central role of *mesangial cells* in production of the cellular lesions of glomerulonephritis is increasingly being recognized. Mesangial cells can be stimulated to produce inflammatory mediators, including oxygen free radicals, interleukin-1, arachidonic acid metabolites, and a variety of growth factors, and may initiate glomerulonephritis in the absence of inflammatory cells. Macrophages and other immune cells can also release a variety of mediators, such as interleukin-1, beta-endorphin, tumor necrosis factor, and platelet-derived growth factor (PDGF), which promote growth of mesangial cells and hence increased production of mesangial matrix. Proliferating mesangial cells release autocoids, such as interleukin-1 and PDGF, producing an amplifying loop of inflammation. The growth-promoting factors are antagonized by suppressive factors such as transforming growth factor-β. Immunomodulatory peptides released by proliferating mesangial cells stimulate replication and activation of macrophages. These activated macrophages amplify the inflammatory lesion and also phagocytize immune complexes.

Cell-mediated hypersensitivity reactions occur in some humans with progressive glomerulonephritis, and may help cause glomerular damage.

Cytotoxic antibodies directed against glomerular antigens may cause direct cell injury without formation of deposits. These antibodies may be directed against mesangial cell antigens, endothelial cell surface proteins, or visceral epithelial cell glycoproteins.

In addition to the immunologic causes of glomerulonephritis discussed above, a number of *nonimmunologic causes of glomerular injury* have been invoked. These include increased glomerular capillary pressure, coagulation in response to endothelial injury, serum lipid abnormalities, and glomerular hypertrophy.

Morphology of glomerulonephritis

Acute glomerulonephritis may not significantly alter the gross appearance of the kidney, which may be slightly or markedly enlarged, pale, soft, and edematous. The glomeruli may be visible as fine red dots. Petechial hemorrhages may be visible if bleeding has occurred from the inflamed glomeruli. In **subacute glomerulonephritis**, the kidney is enlarged, perhaps greatly, and pale with a smooth surface and nonadherent capsule (there may be numerous cortical petechiae indicating recurrent acute episodes). The capsule is tense and the cut surface bulges, and the cortex is wide and yellow-gray, which demarcates it from a normal-colored medulla. This subacute phase is anatomically and developmentally arbitrary and grades into the **chronic** phase in which the kidney is shrunken and contracted with generalized fine granularity of the capsular surface (Fig. 4.35). The capsule may be adherent. On cut surface, the cortex is rather uniformly narrowed and corticomedullary markings are obscured. Fine cysts may be present, developed from obstructed tubules. This stage when contraction is severe is grossly indistinguishable from chronic interstitial nephritis. It can usually be distinguished from the end-result of pyelonephritis, which tends to produce more irregular contraction and scarring, often with intervening areas of normal parenchyma.

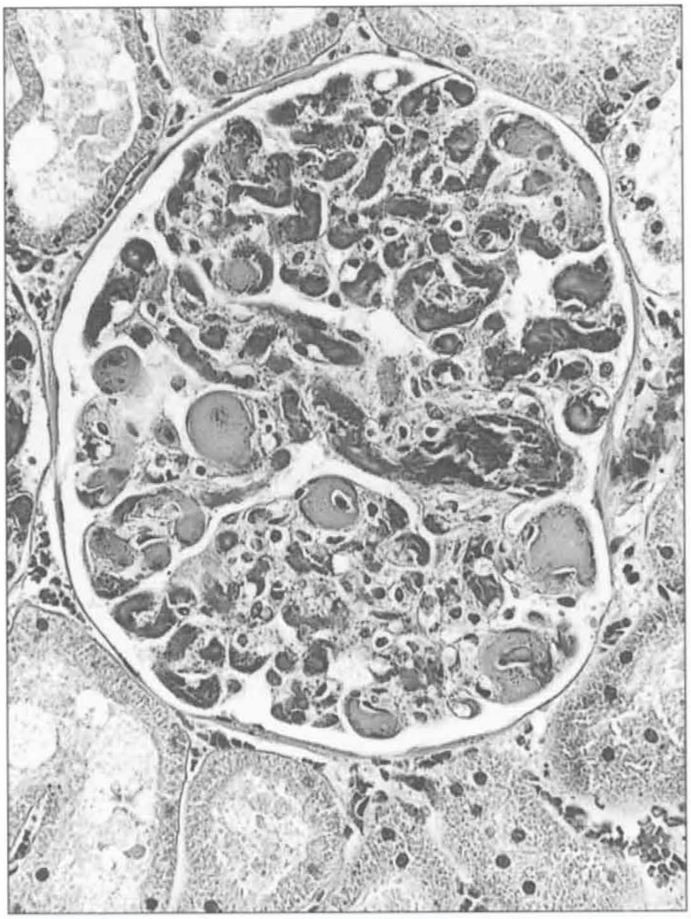

Figure 4.37 Pale-staining glomerular **hyaline thrombi** in an adult male fallow deer, as part of disseminated intravascular coagulation that occurred in epizootic hemorrhagic disease. (Courtesy of F Leighton.)

The **histologic features of the acute phase** are those of exudative inflammation. Initially hyperemic, the glomeruli soon become ischemic as a result of edematous thickening of the capillary walls and swelling of endothelial and epithelial cells. Neutrophils marginate in the capillaries and with the swollen and proliferated native cells of the glomerulus give a distinct impression of hypercellularity. The tuft swells and occupies most of the capsular space; any remaining space may contain migrated leukocytes, precipitated protein, or extravasated erythrocytes. Occasionally, fibrin thrombi form in the capillaries and cause focal necrosis and hemorrhage into the capsular space (Figs 4.36 and 4.37). This form of hemorrhagic glomerulonephritis with the formation of fibrin thrombi is the usual picture seen in swine with petechial hemorrhages as a gross manifestation. Concomitantly, interstitial edema develops. The tubular epithelium may contain hyaline droplets; casts of protein, erythrocytes, and leukocytes form in the urine.

Although functional changes vary greatly, some can be anticipated. The swelling and resultant ischemia of the glomeruli reduce filtration so that there is oliguria. The concentrating capacity of the tubules is unimpaired, as yet, so the urine is of high specific gravity. It also contains protein, and hyaline, granular and red-cell casts.

In the **subacute** phase, either mesangial hyperplasia or glomerular crescent formation may predominate. Fatty degeneration of the tubular epithelium may occur in this stage, as may hyaline droplet formation or necrosis. Casts of protein, leukocytes, and necrotic epithelial cells are present in the tubules.

In the **chronic** phase, fibrous scarring of glomeruli occurs. There may be a reduction in the apparent number of glomeruli as sclerotic glomeruli blend with surrounding scar tissue. If the original proliferative phase was mesangial, scarification may obliterate the tufts, transforming them to large or small masses of collagen and preserving the capsular space. If the proliferation was initially epithelial, fibrosis may completely obliterate the capsular space but, since the two forms usually coexist, obliteration of both glomerulus and capsule is usual. Although all glomeruli are usually involved, the degree varies somewhat so that many retain some function. The interstitial reaction initiated during the edematous exudative phase develops prominently with fibrosis and lymphocytic infiltration. Large numbers of tubules undergo disuse, ischemic or pressure atrophy, and are replaced by scar tissue, and the fibrosis becomes slowly self-perpetuating. Tubules that remain connected to functioning glomeruli may become dilated and develop epithelial hypertrophy and hyperplasia; these are in part responsible for the fine granularity of the surface and streakiness of the cut surface.

In chronic glomerulonephritis at the stage of decompensated renal failure, there is an increased volume of urine with a fixed, low specific gravity. Albuminuria may be only slight and casts may be absent. Death occurs in uremia. Acute glomerulonephritis does not inevitably lead to fatal chronic glomerulonephritis. In fact, healed mild glomerular lesions with full renal function are much more common than debilitating or fatal chronic generalized glomerulonephritis. The only evidence of previous injury may be mild mesangial sclerosis and the presence of occasional small adhesions between peripheral capillary loops and the parietal epithelium.

Once the glomerular filtration rate has decreased to 30–50% of normal, progression to end-stage renal failure tends to be inexorable. This sequence is thought to occur partly because of continuation of the primary glomerular condition, partly because of the addition of complicating factors such as hypertension, and perhaps partly because of adaptive changes in glomeruli in a failing kidney. These adaptive changes include hypertrophy and glomerular capillary hypertension, with resulting epithelial and endothelial injury and proteinuria. Mesangial cells respond by hyperplasia and by production of extracellular matrix; combined with intraglomerular coagulation; this response leads to glomerulosclerosis. A proposed common determinant of glomerulosclerosis is a sustained increase in glomerular permeability to macromolecules. In any case, these further reductions of renal mass contribute to a vicious cycle of continuing glomerulosclerosis.

Prevalence of glomerulonephritis

The frequency of diagnosis of glomerulonephritis in domestic animals has increased dramatically, mostly due to increased awareness and understanding of glomerulonephritis by clinicians and pathologists. There may also be a real increase in prevalence caused by poorly understood factors such as the increased use of modified live virus vaccines that may result in persistent antigenemia and predispose to immune-complex disease. Immune complexes commonly circulate throughout life, but few individuals develop significant lesions, so various factors such as genetic susceptibility or defective immune or other mechanisms may be operative in affected animals. Many associations of infectious and other diseases with glomerulonephritis have been identified (Table 4.1). In essence, *any infection of low pathogenicity that is able to produce persistent antigenemia has the potential to cause immune-complex disease.* Most of the animal glomerulonephritides characterized to date are of immune-complex origin and of the *membranoproliferative type.* The morphology of the glomerular lesion is of little assistance in identifying its cause however, since many agents cause the same type of lesion, and conversely one agent can produce a spectrum of glomerular changes. Most cases in animals are idiopathic, and hence may be referred to as *primary;* those occurring in association with other diseases or in which glomerular lesions contain known antigens are referred to as *secondary.*

Associations of particular types of glomerulonephritis with specific clinical presentations, clinical course, and outcome are rare in veterinary medicine but common in human medicine. An exception is *membranous glomerulonephritis, which is often associated with the nephrotic syndrome. Most other forms of glomerulonephritis are associated with chronic renal failure.*

The prevalence and importance of glomerulonephritis vary with species. In general, mild glomerular lesions (hypercellularity and occasional glomerular adhesions) are common, chronic lesions leading to renal failure are less common, and the acute disease is rare.

Table 4.1 Causes of immune-mediated glomerulonephritis in domestic animals

Viral	*African swine fever virus* *Aleutian mink disease virus* *Bovine viral diarrhea virus* *Canine adenovirus 1* (infectious canine hepatitis) *Classical swine fever virus* *Equine infectious anemia virus* *Feline immunodeficiency virus* *Feline infectious peritonitis virus* *Feline leukemia virus*
Bacterial	*Borrelia burgdorferi* Canine pyometra *Campylobacter fetus* Chronic pancreatitis Subacute valvular endocarditis
Protozoal	African trypanosomiasis Canine leishmaniasis Coccidiosis *Encephalitozoon cuniculi*
Helminths	*Dirofilaria immitis*
Neoplasms	Various
Autoimmune	Antiglomerular basement membrane disease Immune-mediated hemolytic anemia Polyarteritis Systemic lupus erythematosus
Hereditary	Canine familial renal disease Hypocomplementemia in Finnish Landrace lambs

Dogs

Glomerulonephritis is a common finding in dogs and is a leading cause of renal failure; it is usually membranoproliferative. In canine *pyometra,* tubulointerstitial lesions appear to be of more significance than glomerulonephritis, which may be present as an age-related change rather than as a product of pyometra. Focal segmental glomerulosclerosis is reported in a colony of Maltese Beagle dogs with *glucose-6-phosphatase deficiency* (glycogen storage disease Ia); hepatomegaly and renomegaly occur because of vacuolation of hepatocytes and proximal tubular epithelial cells respectively. A unique form of rapidly progressive and fatal renal disease putatively associated with infection with *Borrelia burgdorferi* is characterized by membranoproliferative glomerulonephritis, diffuse tubular necrosis with regeneration, interstitial nephritis, and has been noted in young adult Labrador and Golden Retriever dogs.

Some of the *familial glomerular diseases* of dogs have been well characterized and will be discussed now.

Samoyed hereditary glomerulopathy

Samoyed hereditary glomerulopathy occurs in both sexes but is much more common and severe, and has an earlier onset and more rapid course, in males than in females. Affected males develop proteinuria and wasting at 2–3 months of age, azotemia after 5 months, renal failure after 7 months, and die by 15 months of age. The disease is inherited as *an X-linked dominant trait*; severe disease occurs in about 50% of male offspring of carrier dams. A mutation in exon 35 of the *COL4A5* gene, the gene encoding the α5 chain of type IV collagen, results in a 90% reduction in the amount of α5 chain in GBMs, and probably leads to inadequate cross-linking of collagen type IV in the GBM. Normal glomerular development is arrested in affected dogs; there is failure of the switch from the α1/α2 to α3/α4/α5 network of type IV collagen, which is essential for normal glomerular structure and function. Glomerular lesions consist of *membranoproliferative glomerulonephropathy, progressing to glomerulosclerosis*; fibrin may be present in the urinary space. As well, there may be thickening of basement membranes of Bowman's capsules and tubules, periglomerular and interstitial fibrosis, and mild interstitial infiltration by mononuclear inflammatory cells. The pathognomonic transmission electron microscopic change, which precedes light microscopic changes, is *multilaminar splitting of the lamina densa of the GBM* (Fig. 4.38); electron-dense particles are occasionally present between the split layers. Scanning electron microscopy reveals effacement of foot processes and the presence of microvilli and globular projections on podocytes. Proteinuria is initially selective (primarily albumin) but becomes nonselective as the GBM lesion becomes more severe.

Samoyed hereditary glomerulopathy closely resembles *X-linked human hereditary nephritis* in its clinical, genetic, ultrastructural, and immunohistological features. The nerve deafness and ocular abnormalities that occur in *Alport syndrome*, a form of human hereditary nephritis, are not features of the disease in Samoyeds.

An X-linked dominant hereditary nephritis has also been characterized and reported in a family of *mixed-breed dogs*; labeling of α3-α6(IV) collagen chains was absent from GBMs in affected dogs.

Bull Terrier hereditary nephritis

A model for autosomal dominant human Alport syndrome, Bull Terrier hereditary nephritis is an *autosomal dominant* syndrome with either juvenile or adult onset seen with proteinuria and progressive azotemia. Kidneys have marked loss of nephrons, thickened glomerular and tubular basement membranes, thickened Bowman's capsules with glomerular adhesions, marked interstitial fibrosis at the corticomedullary junction, tubular dilation, and focal interstitial nephritis. Glomeruli become sclerotic and Bowman's spaces are commonly dilated. Ultrastructurally, GBM's are lamellated and often have intramembranous dense deposits. Foot processes are commonly effaced and mesangial matrix is expanded. Collagen chains α3(IV), α4(IV), and α5(IV) are expressed in the GBMs of affected dogs.

English Cocker Spaniel hereditary nephritis

A naturally occurring model for autosomal recessive human Alport syndrome, English Cocker Spaniel hereditary nephritis is a progressive *autosomal recessive* disorder of basement membrane (type IV) collagen. Affected dogs develop proteinuria and juvenile-onset chronic renal failure. Histologic lesions begin in a radial pattern that eventually becomes diffuse throughout the cortex. Lesions begin as segmental thickening of GBMs and mesangial expansion, and progress through segmental glomerular fibrosis to complete glomerulosclerosis. Periglomerular fibrosis and tubulointerstitial nephritis also develop. Ultrastructurally, typical GBM thickening and multilamellation occur. Type IV collagen chains are expressed in GBMs as follows: α1–α2(IV) are increased, α3(IV) and α4(IV) chains are absent, α5(IV) chains are markedly decreased, whereas α6(IV) chains are present.

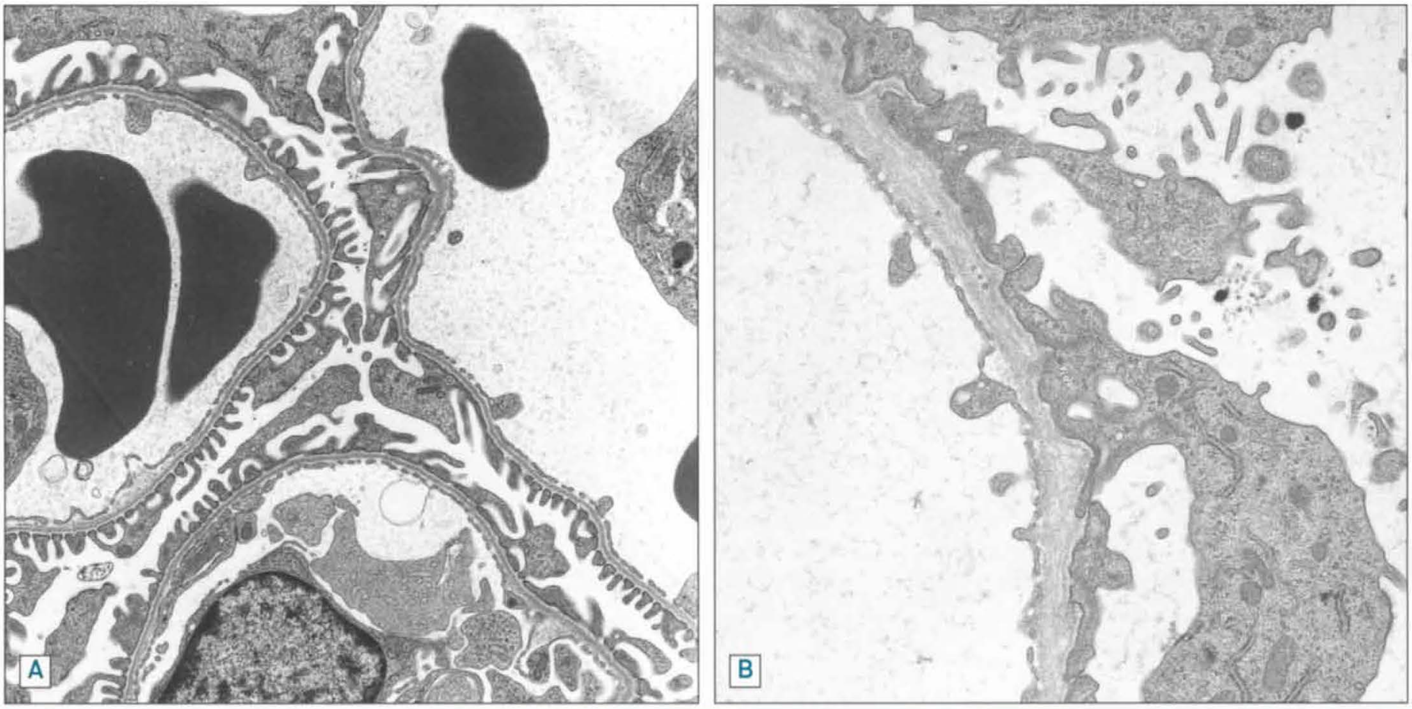

Figure 4.38 A. Normal glomerulus showing epithelial (podocyte) foot processes, fenestrated endothelium and trilaminar basement membrane. **B. Samoyed hereditary glomerulopathy**, 4-month-old male. Note multilaminar, irregular splitting of basement membrane. (Courtesy of B Horney.)

Familial glomerulonephropathy in Bernese Mountain Dogs

This condition is inherited as an *autosomal recessive*, and is expressed as proteinuria and renal insufficiency in young adults. It is characterized as a membranoproliferative glomerulonephritis with concomitant tubulointerstitial nephritis; GBMs are reduplicated, there is mesangial interposition in GBMs, and immune-complex-type subendothelial deposits are detectable. IgM and complement component C3 are deposited in glomeruli.

Familial glomerulonephropathies in other dog breeds

Familial glomerulonephropathies have been reported in other dog breeds but are less well characterized. There is a familial tendency in **Doberman Pinschers** to develop proteinuria and renal failure; the precise mode of inheritance is unknown. Grossly, the kidneys are light brown, slightly small, and have diffuse, fine, subcapsular pits that appear as radial streaks on cut surface. There may be fine white stippling of the subcapsular surface due to the protein-filled tubules and lipid in epithelial cells in the subacute stage of the disease (Fig. 4.39). The histologic renal lesion is membranoproliferative glomerulonephritis with various degrees of tubulointerstitial disease; the glomerular lesion begins as focal segmental mesangial thickening and accentuation of glomerular lobulation (Fig. 4.27). Ultrastructurally, GBMs display two distinct lesions: the lamina densa may be lamellated and contain intramembranous electron-dense deposits, or there may be diffuse attenuation of the lamina densa with thickening of the GBM by collagen fibers. These ultrastructural lesions resemble those in Samoyeds and humans with hereditary nephropathy.

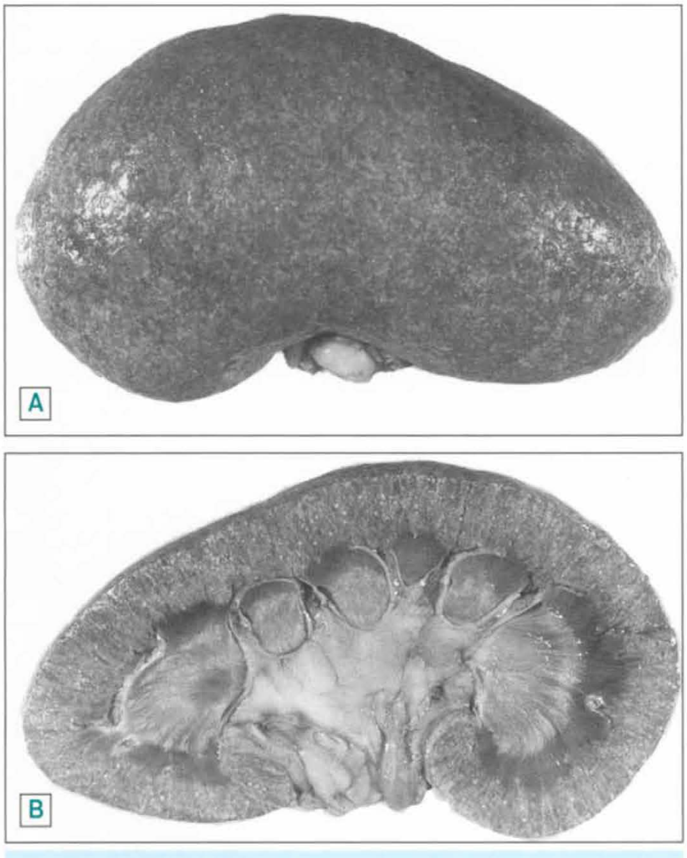

Figure 4.39 Familial renal disease in a **Doberman Pinscher**. **A.** White stippling due to protein-filled tubules and lipid in tubular epithelium. **B.** Cut surface of kidney shown in (**A**).

Familial glomerulonephropathy is reported in a litter of **Beagles**; the multilamellated GBM lesion resembles that seen in Samoyeds and Cocker Spaniels.

Inherited deficiency of the third component of complement in **Brittany Spaniel** dogs leads to the development of membranoproliferative glomerulonephritis.

Glomerulosclerosis in juvenile **Newfoundland** dogs appears to be familial, but of unknown inheritance; proteinuria and renal failure ensue. *Glomerulofibrosis* results from subendothelial and mesangial deposition of collagen fibrils and an increase of mesangial matrix.

The protein-losing nephropathy in **Soft-Coated Wheaten Terriers** is familial but of unknown, but possibly autosomal recessive, inheritance. Affected dogs have chronic glomerulonephritis/glomerulosclerosis and may have features of renal dysplasia.

Familial renal diseases of uncertain inheritance occur in **Lhasa Apsos** and **Shih Tzus, Standard Poodles, Shar-Peis, Old English Sheepdogs, Miniature Schnauzers, Rottweilers**, and **Chow Chows**. They share nonspecific lesions in their end-stage kidneys – radial scarring of cortex and medulla, cystic glomerular atrophy, presence of immature glomeruli, and loss of nephrons. Glomerular lesions may be secondary to primary interstitial lesions.

Familial renal disease in **Norwegian Elkhound** dogs is seen as rapidly progressive renal failure in juvenile dogs; the mode of inheritance is unknown. Histologic changes begin as *periglomerular fibrosis* with hypertrophy and hyperplasia of parietal epithelium and progress to more or less diffuse fibrosis of cortex and medulla and progressive loss of glomeruli. In contrast to the hereditary glomerulopathies discussed above, the lesion in Norwegian Elkhounds involves glomeruli, but is *primarily a noninflammatory tubulointerstitial nephropathy*.

Cats

Glomerulonephritis is common in cats, is predominantly *membranous*, and is a major cause of the nephrotic syndrome and/or renal failure. Type III membranoproliferative glomerulonephritis has been reported in a cat.

Horses

Glomerulonephritis is fairly common in horses, but renal failure is rare. Membranoproliferative glomerulonephritis often occurs in horses with equine infectious anemia (Fig. 4.28A), and the renal lesions may be important. *Streptococcus equi* and herpesviral infections are suggested as causes of glomerulonephritis in horses.

Swine

Acute fatal glomerulonephritis occurs sporadically in swine, but is of little economic importance. Deposition of immune complexes containing IgG and C3 is common in the mesangium of normal slaughter swine, but the mesangioproliferative glomerulonephritis is not of clinical significance. The *porcine dermatitis and nephropathy syndrome* (PDNS) in feeder pigs is associated with *Porcine circovirus-2* (PCV-2) infection and/or the antibody response to PCV-2. The systemic necrotizing vasculitis in PDNS appears to be immune-mediated, and is accompanied in the kidney by exudative glomerulonephritis and interstitial nephritis. *Hyaline droplets*, of unknown pathogenesis and significance, form in the glomerular mesangium of some pigs. An autosomal recessive *hereditary deficiency of factor H*, a complement inhibitory protein, caused lethal membranoproliferative glomerulonephritis type II (dense deposit disease) in Norwegian Yorkshire pigs; factor H deficiency led to massive glomerular deposition of complement, intramembranous dense deposits, and mesangial hypercellularity.

Ruminants

Immunologic evidence of glomerulonephritis is common in ruminants, but clinical disease is not. Glomeruli of sheep and goats are often hypercellular and have membranous changes, but the changes appear to have little clinical significance. An interesting exception is the *membranoproliferative glomerulonephritis of* **Finnish Landrace sheep**, which is present at birth, and is characterized by recessive inheritance of a deficiency of the complement component C3; in affected lambs, blood levels of C3 are about 5% of normal. This congenital deficiency contributes to the development of membranoproliferative (mesangiocapillary) glomerulonephritis, probably due to impaired complement-mediated solubilization of immune complexes in glomeruli. Affected lambs are clinically normal at birth, but die at 1–3 months of age due to renal failure. At autopsy, the kidneys are enlarged, and have pale cortices and glomeruli that are grossly visible as red spots. The glomerular lesion is characterized by mesangial proliferation, capillary wall thickening, and often by the formation of glomerular crescents. Subendothelial electron-dense deposits are present and consist of C3, smaller amounts of IgM and IgA and, with prolonged survival, progressively larger amounts of IgG; this pattern resembles type I membranoproliferative glomerulonephritis of humans. Glomerular changes begin in the lambs in utero and develop progressively after birth. Choroid plexus lesions also occur due to immune-complex deposition, and lead to encephalopathy.

Amyloidosis

Amyloidosis is a group of disorders in which *amyloid, an eosinophilic, homogeneous, hyaline, proteinaceous material,* is deposited in the walls of small blood vessels and extracellularly in a variety of sites, particularly in renal glomeruli. Because all amyloid fibrils have a β-pleated sheet structure, the term *β-fibrilloses* is an alternative descriptor of amyloid deposits and amyloidosis. Deposition of amyloid causes pressure atrophy of adjacent cells, and, depending on the organs involved, can lead to chronic renal failure, nephrotic syndrome, thrombosis, hepatic failure, spontaneous hepatic hemorrhage and rupture, arthritis, or diabetes mellitus. Amyloidosis is seen in a number of presentations:

- **Reactive systemic amyloidosis** (secondary, or AA) is the most common form of amyloidosis in domestic animals (dogs, cattle, horses, cats; rare in swine and goats). **AA amyloid** is derived from *serum protein AA* (apoSAA; serum amyloid-associated), an acute-phase reactant apoprotein product of hepatocytes predominantly. ApoSAA is produced in excess as a result of chronic antigenic stimulation, such as occurs in persistent infectious, inflammatory or neoplastic conditions.
- **Immunoglobulin-derived amyloidosis** (primary, or AL) is the most common form in humans, but it is uncommon in domestic animals (dog, horse, cat). **AL amyloid** is produced from *immunoglobulin light chains* in plasma cell dyscrasias as a product of monoclonal B-cell proliferation; either λ or κ light chains may predominate in this dysproteinemia.
- **Familial** amyloidosis occurs in a number of species and breeds. Systemic AA amyloidosis occurs in Beagles, Shar-Peis (likely autosomal recessive), gray Collies, English Foxhounds, Abyssinian cats (likely autosomal dominant with incomplete penetrance), and Siamese and Oriental cats. Systemic κAL amyloidosis has been described in a Holstein cow with bovine leukocyte adhesion deficiency.
- **Apolipoprotein AI** (apoAI)-derived amyloidosis affects the pulmonary vessels of old dogs.
- **Islet amyloid polypeptide** (IAPP)-derived amyloidosis is common in the pancreatic islets of cats with non-insulin-dependent diabetes mellitus.

Both AA and AL amyloidosis can occur in either systemic or localized forms. The *cause* of amyloid fibril formation and deposition is obscure, but the *nidus theory* postulates that amyloid fibrils serve as templates for fibril growth and as scaffolding for fibril polymerization; amyloid-enhancing factor may be involved. Macrophages appear to be important in the conversion of precursor proteins to amyloid fibrils. Always associated with amyloid are extracellular matrix components, including amyloid P component (a glycoprotein of the pentraxin family), glycosaminoglycans, and proteoglycans.

Most cases of amyloidosis in domestic animals are of the reactive systemic type. Deposits of AA amyloid may be found in many organs and may be concentrated in one or other of them, such as the liver or spleen, but *the kidney is the organ most commonly involved in amyloidosis*. Localization of amyloid is usually *glomerular* in most breeds of dogs, but *medullary* localization predominates often in Shar-Pei dogs, in cats, and occasionally in cattle. Systemic amyloidosis involving the liver can lead to fatal spontaneous liver hemorrhage.

Amyloidosis is most common in older **dogs** and is usually idiopathic, although some cases do occur in association with chronic suppurative and granulomatous lesions in other tissues. Glomerulopathy and amyloidosis occur in dogs with *Hepatozoon americanum* infection in the southern USA, and in dogs with *Ehrlichia canis* infections. Dogs with glomerular amyloidosis develop progressive renal insufficiency and proteinuria that may be sufficiently severe to cause the *nephrotic syndrome*. Dogs with medullary amyloidosis without glomerular involvement, e.g., the Shar-Pei, may have little or no proteinuria. Amyloidosis is less common in **cats** than dogs and is primarily medullary; hence marked proteinuria is an uncommon finding. In **cattle**, glomerular amyloidosis can cause severe proteinuria; medullary amyloidosis is reported as a common subclinical disease. A chronic suppurative or tissue-destructive process is occasionally demonstrable in affected cattle. Amyloidosis occurs systemically (AA amyloid) in **horses** used for antiserum production, as well as in localized nodules (AL amyloid) in the skin and the upper respiratory system. **Sheep and goats** can develop glomerular and medullary amyloidosis in the course of chronic inflammatory processes. **Pigs** rarely develop amyloidosis.

With small deposits of amyloid, the **gross** appearance of the kidney may be normal except for a slight increase in size and a peculiar translucence of the glomeruli. The characteristic renal change is one of paleness, enlargement, and increase in consistency. In cattle, the kidneys may be very large. The capsule strips smoothly to reveal a cortical surface with a finely stippled appearance due to numerous fine yellow spots that are glomeruli, and gray points of translucence that are dilated tubules. On cut surface, the cortex is widened and presents the same appearance as the capsular surface, rather like pumice stone. *Affected glomeruli stain brown-red when exposed to an iodine solution; subsequent exposure to dilute sulfuric acid changes the color to purple* (Fig. 4.40).

Histologically, amyloid is first deposited in the mesangial area and in the subendothelium of glomerular capillaries. Nodules of amyloid gradually develop until the glomeruli, when uniformly involved, are enlarged and converted to homogeneous spheres with loss of endothelial and epithelial nuclei (Fig. 4.41). Similarly, amyloid is deposited in tubular basement membranes in cortex and medulla, and eventually broad cuffs of amyloid appear around the tubules. The physical presence of amyloid causes ischemia and pressure atrophy of nephrons, and resultant scarring. The tubules contain a striking number of pink hyaline casts of protein and are dilated, sometimes to such an extent that normal renal structure is not recognized ("thyroidization") (Fig. 4.42). Urinalysis reveals a high level of protein, and the loss of protein from this source may cause hypoproteinemic edema. The amyloidotic kidney, especially when medullary amyloidosis predominates, may have various of the features of end-stage renal disease, including interstitial fibrosis and lymphoplasmacytic infiltration, tubular atrophy, tubular dilation, mineralization, intratubular deposition of oxalate crystals, glomerular atrophy, and glomerulosclerosis.

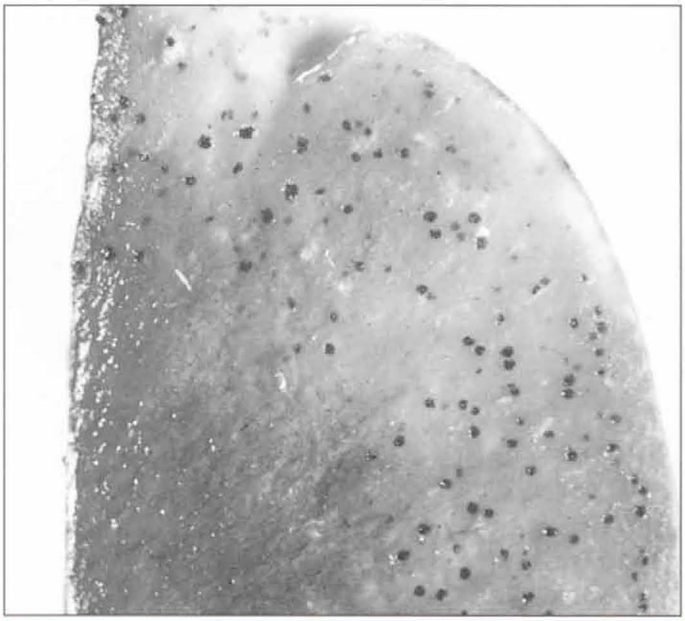

Figure 4.40 Amyloidosis in a cow. Glomeruli are prominent after exposure to iodine, followed by dilute sulfuric acid.

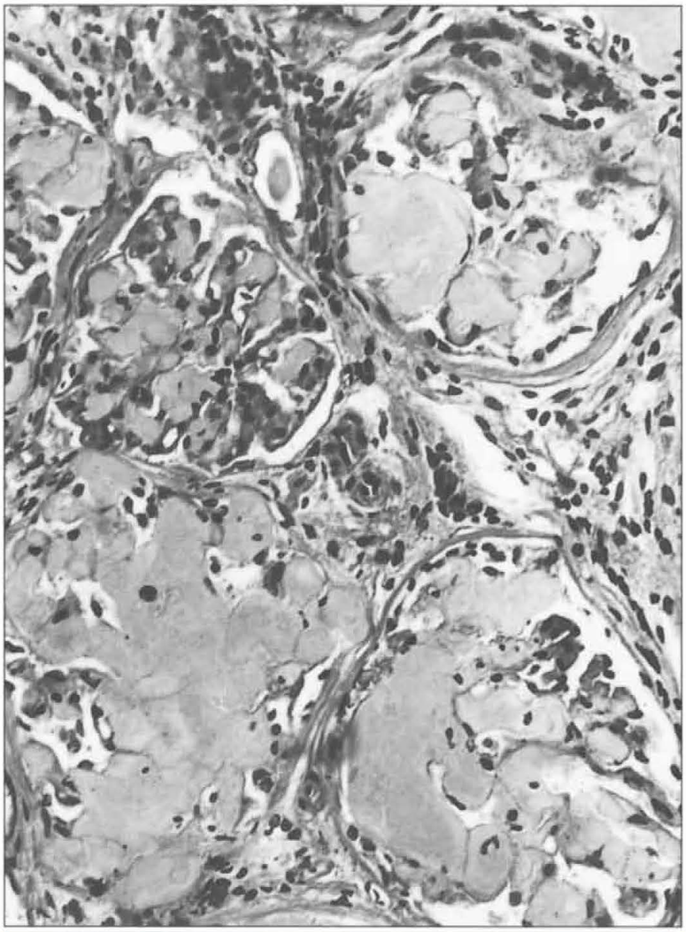

Figure 4.41 Amyloidosis in a dog. Severe lesions in glomeruli have caused atrophy of tubules and aggregation of tufts.

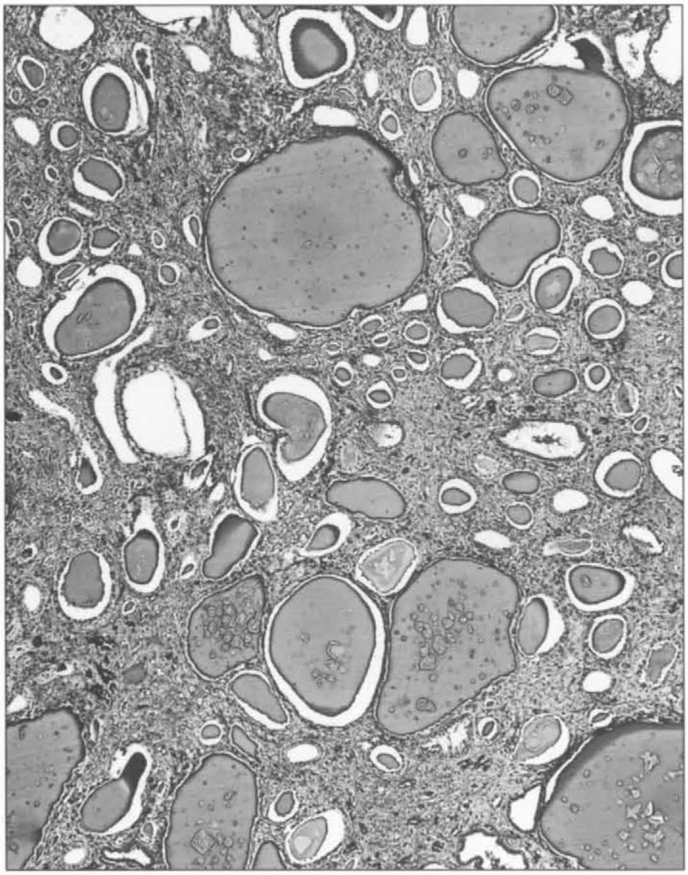

Figure 4.42 Marked proteinuric **"thyroidization"** in medulla of a sow with glomerulosclerosis. (Courtesy of D Johnson.)

Thrombosis of the pulmonary arteries or renal veins is occasionally a prominent finding in dogs with the nephrotic syndrome due to amyloidosis; they are in a *hypercoagulable state* due to stimulation of production of acute-phase proteins, such as fibrinogen, while simultaneously losing low-molecular-weight anticoagulants, such as antithrombin III, due to increased glomerular permeability.

The **cat** (including Abyssinians, Siamese, domestic shorthairs, and captive tigers and cheetahs) differs somewhat from other species, in that amyloid is deposited mainly in the papilla and outer medulla with relative sparing of the glomeruli. The kidneys are very firm, shrunken, and coarsely nodular. The papilla, in cats dying in renal failure, is necrotic, or excavated in some that survive. The nodularity is due to scarring extending from medulla to capsular surface; medullary interstitial fibrosis may also be diffuse. The capillary and tubular basement membranes in the medulla are thick and hyaline, and this is presumed to produce capillary occlusion with papillary necrosis on the one hand, and occlusion of collecting ducts with obstructive atrophy and fibrosis in the medullary rays on the other. The prevalence of amyloidosis in cats is much increased on diets providing excess vitamin A (see Vol. 1, Bones and joints).

Amyloid is nonspecifically eosinophilic in routine sections and weakly birefringent in polarized light. *The histologic diagnosis is thus usually confirmed with special stains.* Amyloid is stained a light orange-red with *Congo red*, and then exhibits green birefringence in polarized light; elimination of the Congo red staining affinity of amyloid by oxidation of tissue sections in potassium permanganate indicates that the amyloid is of the AA type. Retention of congophilia after pretreatment with potassium permanganate indicates the presence of AL amyloid; the potassium permanganate reaction may be unreliable in cats. Amyloid exhibits a bright yellow fluorescence after staining with *thioflavine-T*, which may be required in cats due to poor staining of amyloid with Congo red in this species. The above staining patterns of amyloid are due to its characteristic beta-pleated pattern, which also confers on it resistance to proteolysis and insolubility, and hence its resistance to removal from tissues. Specific immunohistochemistry can be useful in identifying amyloid and in distinguishing amyloid types. The characteristic nonbranching 7–10 nm diameter fibrils of amyloid may be seen by electron microscopy. The β-fibrils have a distinctive X-ray diffraction pattern. Definitive characterization of amyloid rests on isolation of the amyloid and amino acid sequencing; the amino acid sequences of feline SAA and AA amyloid vary slightly between Abyssinian and Siamese cats.

Glomerular lipidosis

Large *foam cells*, which by appropriate techniques are seen to contain sudanophilic droplets, may be found in one or more lobules of glomerular tufts in many dogs (Fig. 4.43). In paraffin preparations, the cells are closely packed and finely vacuolated and the cell boundaries are distinct. These large cells appear to arise from mesangial cells. This lesion is not associated with glomerulonephritis and has no functional significance.

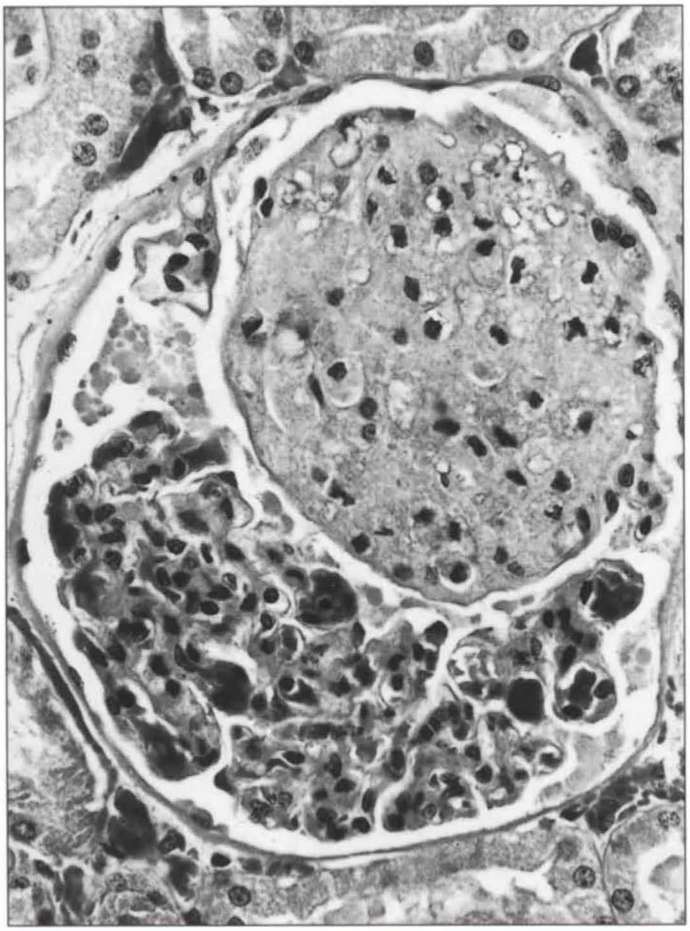

Figure 4.43 Glomerular lipidosis in a dog.

Lipid embolization of renal arterioles and glomerular capillaries occurs occasionally in dogs with diabetes mellitus or following trauma. The lipid in these cases is intravascular rather than within foam cells.

DISEASES OF TUBULES

Diseases of tubules are primarily reflected in morphologic changes in lining epithelial cells, although specific defects of function due to enzyme deletions may not be visible histologically. Degenerations are best regarded as homeostatic disturbances of intracellular functions that may become balanced at new levels or be sufficiently severe that the cell or part of it dies. As noted above, *the tubules and interstitium are intimately associated, and damage to one affects the other*, thus, many disorders are termed *tubulointerstitial diseases* and are discussed later. Regeneration of tubular epithelium can occur (Fig. 4.44) but postnatal development of new nephrons is limited to a short period of time, depending upon species. The response of the kidney to destruction of tubules is limited to compensatory hypertrophy of remaining nephrons. Thus, the tubules remaining in damaged kidneys are often large and dilated.

Degeneration and swelling of tubular cells cause the kidney to enlarge and bulge on cut surface. *Hydropic degeneration* occurs due to damage to mitochondrial membranes and formation of vacuoles, and is potentially reversible. *Necrotic tubular cells* are eosinophilic, have pyknotic nuclei, and slough into the tubular lumen where they form cellular or coarsely granular casts (Figs 4.44–4.46). Tubules filled with *proteinaceous fluid* usually indicate that there is increased glomerular permeability in that nephron; extreme proteinuria may indicate the presence of the nephrotic syndrome clinically. *Tamm–Horsfall mucoprotein*, which is produced in the ascending limb of the loop of Henle and the distal tubules, and/or autolytic tubular epithelial cytoplasm may appear as a granular pink substance in many cortical tubules, but this is not a lesion. *Hyaline droplets*, which are pink homogeneous globules of protein, appear in the cytoplasm of proximal tubular cells in nephrons with increased glomerular permeability. The hyaline droplets are lysosomes swollen with protein that is undergoing proteolysis and will be returned to the circulation as amino acids. Protein reabsorption by proximal tubules is a physiological process; hyaline droplets indicate that this mechanism is saturated.

Fatty degeneration is difficult to evaluate in swine, dogs, and cats, which normally have considerable quantities of fat in the renal epithelium; infiltration fat accumulates in the loop of Henle in the outer medulla in starved animals. In fatty degeneration, the fat is usually found in the cells of the convoluted tubules.

Thickening of the basement membrane is seen in a variety of situations involving chronic tubular damage and is usually associated with atrophic tubular epithelium. In renal *amyloidosis*, amyloid is deposited on the tubular basement membrane, as well as in glomeruli. Disruption of the tubular basement membrane occurs in ischemic necrosis and frequently in focal renal lesions, and may allow herniation of tubular epithelial cells, with some of these cells persisting as interstitial foam cells.

Acute tubular necrosis

Acute tubular necrosis, or *nephrosis*, is a reversible condition in which tubular degeneration is the primary process, and it is an important cause of **acute renal failure.** "Nephrosis" is an imprecise term applied to noninflammatory renal disease, particularly tubular degeneration; *acute tubular necrosis* is a more accurate descriptor of the changes to be discussed here. Affected animals are *oliguric or anuric* and die within a few days unless given appropriate therapy. *The principal causes of acute tubular necrosis are ischemia and nephrotoxins.* Another major cause of acute renal failure is postrenal, namely complete urinary outflow obstruction. Severe acute glomerulonephritis can also cause acute renal failure, but is uncommon in domestic animals. The renal tubules, and particularly the proximal straight tubule and the medullary thick ascending limb, are metabolically very active and are hence the renal components that are most susceptible to ischemia or nephrotoxins. "Lower nephron nephrosis" was a term applied in the past to acute tubular necrosis, but is inaccurate and no longer in use.

Ischemic or **tubulorrhectic acute tubular necrosis** follows a period of hypotension (shock) that causes marked renal ischemia. *Prolonged renal ischemia causes renal cortical necrosis*, that is, all cortical

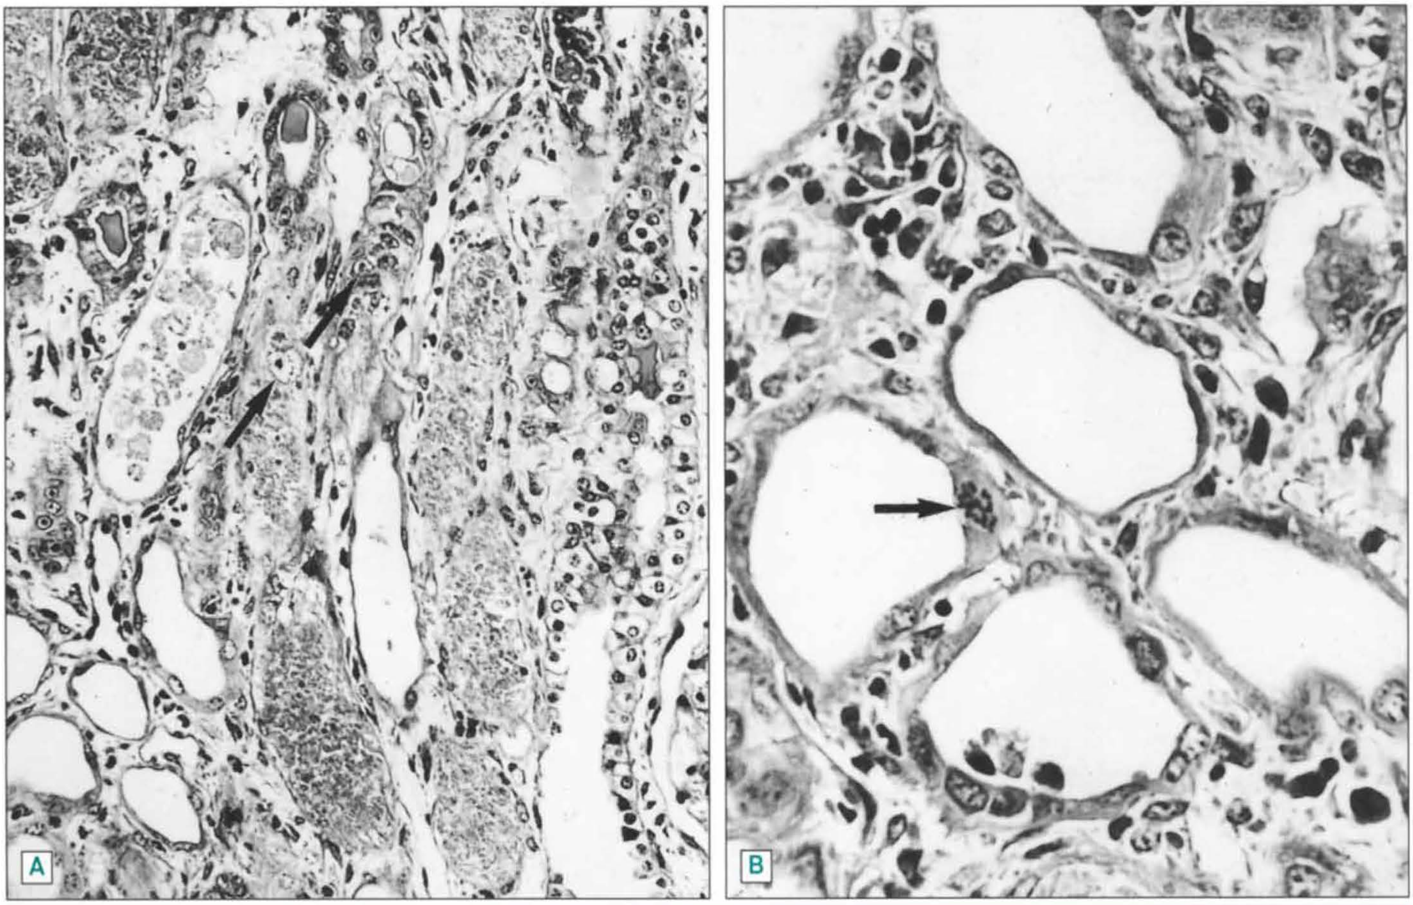

Figure 4.44 Nephrosis due to *Amaranthus retroflexus* toxicity in a calf. **A.** Granular and hyaline casts. Tubules lined by flattened epithelium. Regenerating epithelial cells in tubules (arrows). **B.** Mitotic figure in regenerating tubule (arrow).

structures are affected (discussed above). Massive hemolysis is a cause of acute tubular necrosis and produces an ischemic pattern known as *hemoglobinuric nephrosis*. Neither hemoglobin nor myoglobin are primary nephrotoxins, but they contribute to renal failure produced by other causes, such as hypotension. *Ischemic acute tubular necrosis is characterized histologically by focal necrosis along nephrons, particularly of the proximal tubules, and distal tubules to some extent, plus disruption of tubular basement membranes (tubulorrhexis) and occlusion of lumina by casts.* Eosinophilic hyaline and granular casts commonly occur in the distal tubules and collecting ducts and consist of Tamm–Horsfall mucoproteins, degenerate epithelial cells, hemoglobin, myoglobin, and other plasma proteins. Interstitial edema and accumulation of leukocytes in dilated vasa recta are common findings, and they may predate the occurrence of overt acute tubular necrosis. Glomeruli are usually normal. Vessel dilator, one of the atrial natriuretic peptides, stimulates regeneration of the brush borders of proximal tubules and may ameliorate acute tubular necrosis. After about 1 week, *epithelial regeneration* may be seen as tubules lined by flattened epithelium with hyperchromatic nuclei and mitoses (Fig. 4.44). The renewed cells are smaller than normal initially and may appear close-packed on the basement membrane. Their relationship with each other is also abnormal and they frequently tend to pile up in small clusters that eventually disappear. If the initial injury is mild and/or supportive therapy is adequate, *recovery* of architecture may be complete within about 2–3 weeks.

Nephrotoxic acute tubular necrosis, or exogenous toxic nephrosis, is contrasted here with ischemic acute tubular necrosis, and specific examples are given below. Renal tubules, and especially proximal tubules, are particularly susceptible to a wide variety of toxic agents as a consequence of their great metabolic activity and their exposure to agents in the large volume of ultrafiltrate that they resorb in the process of urine formation. Their enzyme systems are thus exposed to, and inactivated by, agents such as heavy metals, which bind to sulfhydryl groups. *Nephrotoxic acute tubular necrosis is usually characterized histologically by extensive necrosis of predominantly proximal tubules, but with preservation of tubular basement membranes* (Fig. 4.45). These two features distinguish toxic from ischemic acute tubular necrosis, in which necrosis is patchy and disrupts basement membranes. Preservation of tubular basement membrane is necessary to provide the framework for epithelial regeneration, and hence ischemic damage to tubules often has a worse prognosis for the kidney and the animal than does toxic damage. Ischemia often complicates toxic acute tubular necrosis because the swelling of tubular epithelial cells caused by the toxin impairs intrarenal blood flow.

The *pathogenesis* of acute renal failure and oliguria in either ischemic or toxic acute tubular necrosis remains controversial. Obstruction of tubular flow by cellular debris and casts and by interstitial edema appears to be an important factor (Fig. 4.46). Other proposed mechanisms include preglomerular vasoconstriction, possibly

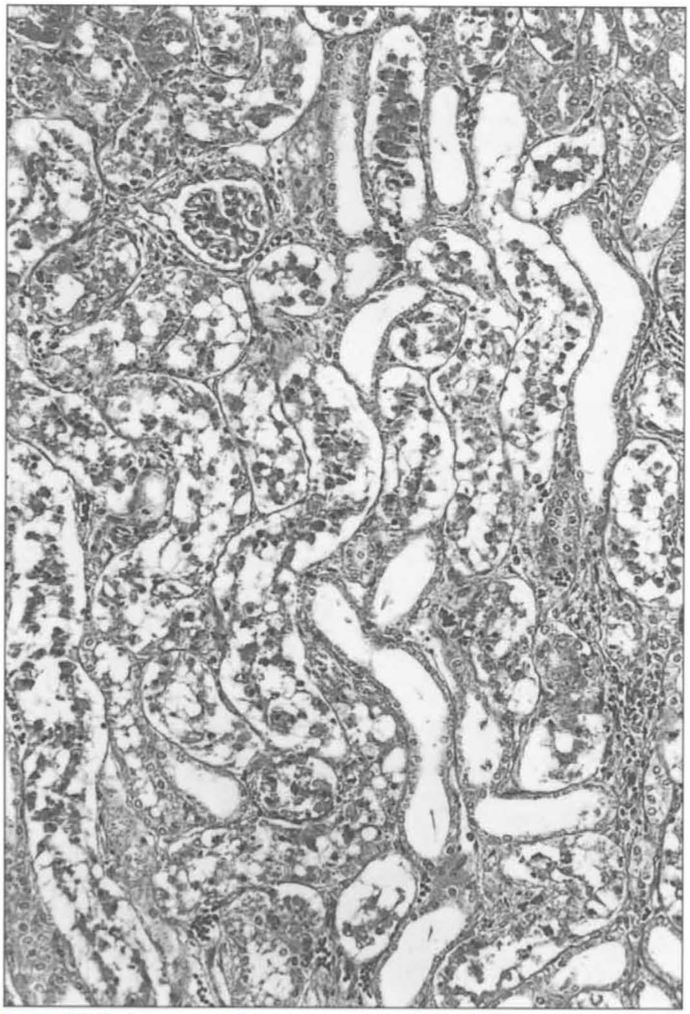

Figure 4.45 Acute tubular necrosis due to mercuric chloride poisoning. Necrosis, fragmentation, and shedding of tubular epithelium.

due to activation of the renin–angiotensin system; leakage of tubular fluid into the interstitium (tubular backleak); and impaired glomerular permeability or vascular reactivity. Disruptions of the actin cytoskeleton of proximal tubular cells and breakdown of apical membrane microvilli occur due to ischemia. Redistribution of tubular cell membrane proteins causes loss of cell polarity, abnormal ion transport across tubular cells, and hence increased delivery of sodium to the distal tubule; the resulting tubuloglomerular feedback leads to vasoconstriction. *Oliguria* is the result of various combinations of these factors. At the oliguric stage of acute renal failure, hyperkalemia is a life-threatening event. If the animal survives the oliguric phase, diuresis occurs and electrolyte imbalances, such as hypokalemia, may contribute to death. As tubular regeneration proceeds, azotemia resolves and tubular function slowly returns.

Nephrotoxic tubular necrosis

Numerous toxic substances can cause acute tubular necrosis in domestic animals (Table 4.2). Some of these agents are no longer important as nephrotoxins; for example, organomercurials were commonly used as fungicides on seed grains that were occasionally inadvertently fed to animals and humans with disastrous results. This use of mercury has been banned. Similarly, highly chlorinated naphthalenes, which cause hyperkeratosis and nephrosis in cattle, have been excluded from the farm environment. Sulfonamides were formerly important as nephrotoxins, but newer formulations are more soluble and less toxic. Some newly introduced agents have nephrotoxicity as a side-effect, e.g., aminoglycosides. Numerous additional antibiotics that are toxic to humans, e.g., penicillin, semisynthetic penicillins, and polymixins, may also prove to be toxic to domestic animals. The toxicity of many of the exogenous agents is exacerbated by various systemic states, such as dehydration or shock, which concomitantly impair renal function in the affected animal. Discussion of specific examples of nephrotoxins follows.

Aminoglycosides

These antibiotics are widely used against gram-negative infections, and include, in decreasing order of nephrotoxicity, **neomycin, kanamycin, gentamicin, streptomycin, tobramycin**, and **amikacin**. *Aminoglycosides are obligate nephrotoxins*; in cats, aminoglycosides are ototoxic as well as nephrotoxic. Foals are particularly prone to nephrotoxicosis. Aminoglycosides are not metabolized but are eliminated from the body primarily by glomerular filtration; they selectively accumulate in, and cause damage to, proximal tubules. The *tubulotoxic effects* of aminoglycosides include damage and loss of the brush border, and formation of cytosegrosomes and myeloid bodies; this overloading of lysosomes with phospholipids (lysosomal phospholipidosis) results from aminoglycoside-induced inhibition of phospholipases. Lysosomal dysfunction and/or leakage may lead to tubular cell necrosis. Damage is dose-related and is enhanced by pre-existing renal impairment. Toxicity is manifest clinically by inability to concentrate urine, polyuria, enzymuria, proteinuria, hematuria, cylindruria, and azotemia. Acute renal failure may ensue. Aminoglycoside nephrotoxicity is reversible; recovery from the nephrosis may occur even in the face of continued therapy because the regenerating cells have increased resistance to aminoglycoside toxicity.

Tetracyclines

Tetracyclines cause several syndromes of renal disease in humans: progressive azotemia due to their antianabolic effect, a reversible Fanconi syndrome due to the use of outdated tetracycline containing degradation products, and reversible nephrogenic diabetes insipidus. An overdose of oxytetracycline can produce acute tubular necrosis and renal failure in dogs. Tetracycline administration has been reported to cause acute nephrosis and death in calves due to the presence of tetracycline degradation products; high doses of oxytetracycline can cause acute nephrosis in treated cattle. *Use of tetracyclines is contraindicated in animals in renal failure*; tetracyclines are excreted from the body primarily by the kidneys, thus renal dysfunction leads to increased serum drug concentrations and enhanced nephrotoxic potential. Doxycycline, a newer semisynthetic tetracycline, is not reported to be nephrotoxic.

Sulfonamides

Severe nephropathy may follow the ingestion of excessive doses of sulfonamides, especially if treated animals are dehydrated. Toxicity was much more common previously when only less-soluble forms of the drug were available, e.g., sulfapyridine, sulfathiazole, and sulfadiazine. *Crystalline nephropathy is now rare as the newer shorter-acting*

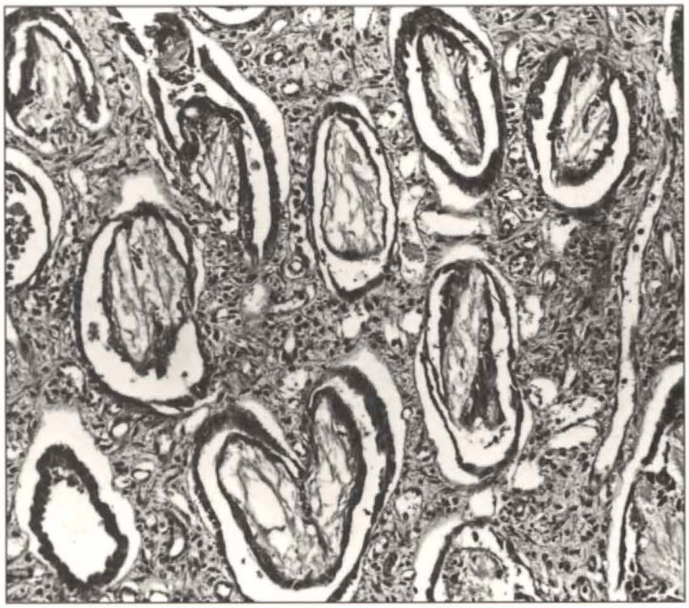

Figure 4.47 Sulfonamide nephrosis in a calf. Sulfa crystals (removed in processing) have been covered by epithelium from collecting tubules.

sulfonamides have greater solubility. Affected kidneys are slightly enlarged and congested, and the sulfonamide crystals are grossly visible in the medulla, pelvis, and in some cases even in heavy deposits in the bladder. The deposits are yellow, and form pale radial lines in the medulla. Crystals are not observed in section as they are dissolved during processing. The epithelium of the proximal convoluted tubules and of Bowman's capsule undergoes severe hydropic degeneration. There is little evidence of necrosis in the distal and collecting tubules, but epithelial proliferation and swelling are prominent and the tubules become densely populated with large dark-staining cells. Some papillary formations into the lumen may even be present, and commonly in the collecting tubules there is more or less complete duplication of the epithelium, the inner epithelium enclosing a faintly basophilic hyaline precipitate (Fig. 4.47). There is a diffuse but mild interstitial reaction about the corticomedullary junction. It appears that the *renal lesions are due to both local toxic and mechanical (tubulo-obstructive) effects* and that hypersensitivity does not play a role in animals, as it apparently does in humans.

Amphotericin

Amphotericin B is an antifungal agent, a polyene antibiotic, whose most important toxic effect is renal dysfunction. It causes decreased renal blood flow and glomerular filtration due to *renal vasoconstriction*, and is also *directly toxic* to renal tubular epithelial cells. Necrosis of proximal and distal tubules occurs, and there is mineralization of intratubular casts. Nephrotoxicity of amphotericin B has been reduced by complexing the drug with lipids or entrapping it in liposomes.

Ethylene glycol

Dogs and cats are commonly poisoned by ingestion of ethylene glycol. The seasonal incidence of this poisoning coincides with the changing of engine antifreeze solutions in the spring and autumn. Cattle are also occasionally poisoned. Ethylene glycol, which is present in a 95% concentration in antifreeze solutions, has a sweet taste and is usually voluntarily ingested, especially by young male dogs. Cats are more susceptible, but less commonly affected, than dogs; the minimum lethal dose is 1.5 mL/kg for cats and 6.6 mL/kg for dogs.

Ethylene glycol, which itself is of low toxicity, is rapidly absorbed from the gastrointestinal tract, and most is excreted unchanged in the urine. A small percentage is oxidized by alcohol dehydrogenase in the liver to glycoaldehyde, which is in turn oxidized to glycolic acid, glyoxylate, and finally oxalate. *Glycoaldehyde and glyoxylate are the primary nephrotoxic metabolites*; they act by causing adenosine triphosphate depletion and membrane phospholipid and enzyme destruction. Other end-products of metabolism are lactic acid, hippuric acid, and carbon dioxide.

Depression, ataxia, and osmotic diuresis develop within a few hours after ingestion of ethylene glycol. Although oxalate crystals are deposited around cerebral vessels and in perivascular spaces (Fig. 4.48), nervous signs are due to the effect of aldehydes and possibly to the severe metabolic acidosis that develops as a result of accumulation of lactic acid, glycolate, and glyoxylate. Over the next 12 hours, pulmonary edema, tachypnea, and tachycardia occur. If the animal survives for 1–3 days after ingestion, acute renal failure develops, primarily due to renal tubulotoxic damage. Severe renal edema impairs intrarenal blood flow and contributes to nephrosis and renal failure. Soluble calcium oxalates in the blood precipitate in the ultrafiltrate of the renal tubules as the pH of the fluid decreases. Calcium oxalate crystals may be found in tubular lumina (Fig. 4.49), in tubular cells, and in the interstitium; they are light yellow, arranged in sheaves, rosettes, or prisms, and are birefringent with polarized light. Tubular lesions, which are most severe in proximal tubules, range from hydropic degeneration to necrosis to regeneration.

In animals surviving the acute toxic insult, calcium oxalate crystals are thought to be of importance in causing renal failure. *Large numbers of crystals in tubules are virtually pathognomonic of ethylene glycol poisoning*; a few crystals may be seen with chronic tubular obstruction. Occasional calcium oxalate crystals are normally seen in urine

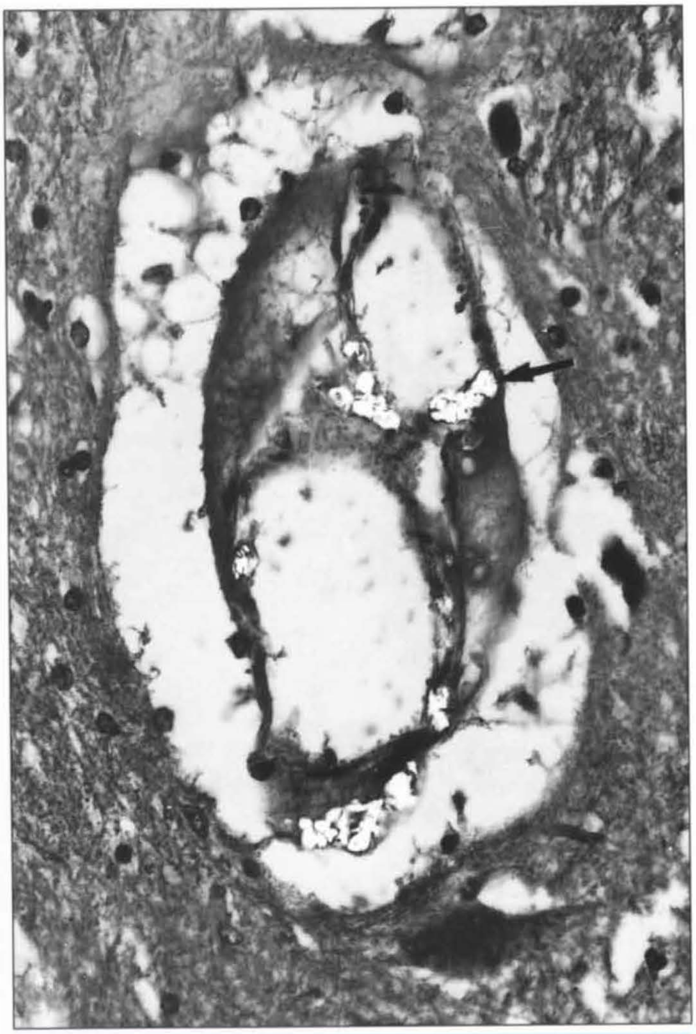

Figure 4.48 Oxalate encephalitis in a dog, caused by ethylene glycol poisoning. Partially crossed polarization filters. (Courtesy of RW Wilson.)

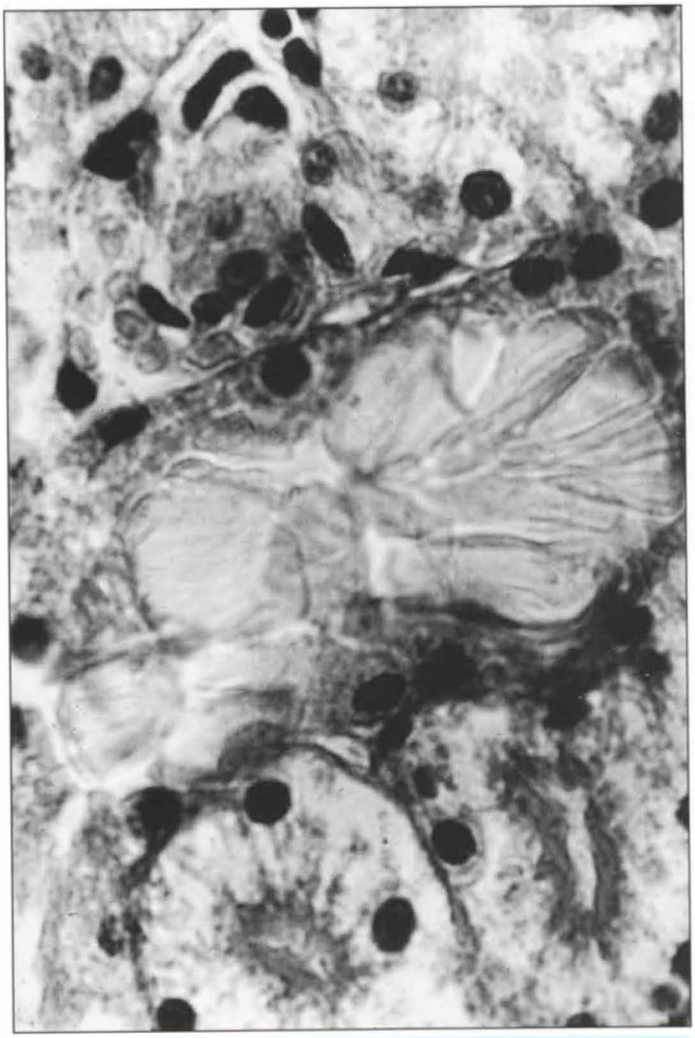

Figure 4.49 Oxalate crystals in proximal tubule in a dog.

sediment of dogs; large numbers of these crystals are highly suggestive of poisoning. Hypocalcemia due to the formation of crystals is usually mild in dogs. Animals that survive the acute exposure toxicity may have renal interstitial fibrosis. Few crystals may be left in the tubules; they tend to be removed in the weeks following their deposition. The diagnosis may be confirmed by detection of ethylene glycol in stomach content or blood by gas chromatography early in the toxicosis, or by detection of glycolic acid in urine, serum, or ocular fluid by mass spectrometry later in the toxicosis.

Oxalate

Plants are the usual source of oxalate poisoning in sheep and cattle. **Plants** that may contain toxic amounts of oxalate are *Halogeton glomeratus*, halogeton; *Sarcobatus vermiculatus*, greasewood; *Rheum rhaponticum*, the common garden rhubarb; *Oxalis cernua*, soursob; *Rumex* spp., sorrel, dock. Plants of lesser importance are *Portulacca oleracea, Trianthema portulacastrum,* and *Threlkeldia proceriflora,* as well as some cultivated species such as mangels and sugar beet. Young plants may contain the equivalent of 7% or more of potassium oxalate; the amount decreases with maturity and drying of the plant. The above-listed plants are only eaten in unusual circumstances and not readily.

Species of **grasses** in the genera *Cenchrus, Panicum,* and *Setaria,* which are widely cultivated in tropical and subtropical areas and which accumulate large amounts of oxalate, have been associated with renal oxalosis in cattle and sheep and with skeletal disease in horses, the latter due to conditioned calcium deficiency (see Vol. 1, Bones and joints).

The **fungi** *Aspergillus niger* and *A. flavus* can produce large quantities of oxalates on feedstuffs. Large doses of **ascorbic acid** (vitamin C) have caused oxalate nephrotoxicosis in humans and in a goat; ascorbic acid is a metabolic precursor of oxalate. **Primary hyperoxaluria**, a rare inherited metabolic condition, occurs in humans, cats (inbred colony of domestic shorthairs), dogs (family of Tibetan spaniels (Shih Tzus)), and in Beefmaster cattle (likely autosomal recessive). **Pyridoxine (vitamin B_6)** deficiency and **methoxyflurane** anesthesia can also cause renal oxalosis.

Mortality rates of 10% may occur in sheep when, as frequently happens in some areas, these animals graze on almost pure stands of halogeton or of soursob. It is more usual, however, for fatalities to be sporadic. Under natural conditions, sheep may ingest up to 75 g of oxalate a day; *the rumen degrades the salt efficiently by metabolism of oxalate to bicarbonate and carbonates.* Depending on the diet before exposure to oxalate-containing plants and, therefore, on the microbial composition of the rumen, some variation is to be expected in the ability of ruminal contents to degrade the salt. Cattle are less commonly affected under range conditions than are sheep, but cattle and sheep are equally susceptible to experimental poisoning. Horses are resistant to oxalate-induced nephrosis and succumb to acute gastroenteritis only after receiving unnaturally large amounts of the chemical; they may develop osteodystrophia fibrosa with prolonged exposure.

Chelation of calcium by unmetabolized oxalate in the ingesta contributes to hypocalcemia. Following absorption, oxalates combine with calcium to form insoluble calcium oxalate; hypocalcemic tetany may result. Calcium oxalate may crystallize in vessel lumens or walls, causing vascular necrosis and hemorrhage, or in renal tubules, causing tubular obstruction and acute renal failure. The nephrotoxicity of oxalates involves more than mechanical obstruction, and may be due in part to intracellular chelation of calcium and magnesium and hence interference with oxidative phosphorylation. Clinically, weakness, prostration, and death may follow within 12 hours of ingestion of oxalate-containing plants.

Oxalates are produced endogenously in the degradation of glycine, an important constituent amino acid of collagen and elastin. Uptake of normal dietary oxalate may increase in a variety of enteric diseases (enteric oxalosis). *Oxalosis can be prominent in the kidneys of aborted bovine fetuses*, and may reflect maternal intake of oxalate-containing plants or moldy feed. A few oxalate crystals can frequently be found in scarred tubules in any species; these crystals are usually without significance.

Mycotoxins

Aspergillus and *Penicillium* spp. produce a number of nephrotoxic mycotoxins, namely **ochratoxins, citrinin, fumonisin, oxalate**, and **viridicatumtoxin**, which can contaminate feed grains. *Ochratoxin A (OTA)* is of most significance in disease; the toxicity of OTA is enhanced by penicillic acid, which is co-produced by *Penicillium ochraceus*. In pigs, OTA and citrinin produce proximal tubular degeneration and atrophy, cortical interstitial fibrosis, and glomerular hyalinosis; the renal insufficiency produced is usually subclinical. Acute renal disease occurs very rarely, and is manifested by severe perirenal edema resembling that produced by redroot pigweed (*Amaranthus retroflexus*, see below). Ochratoxicosis also increases the susceptibility of pigs to secondary bacterial infections. Ochratoxin A has been suggested as the cause of endemic (Balkan) nephropathy in humans. Ochratoxins are normally degraded in the rumen; thus, toxicity is unlikely to occur in ruminants.

Moldy feed also produces mycotoxic nephropathy in horses. Citrinin produces tubular degeneration in swine, horses, and sheep. *Fumonisins*, mycotoxins produced by *Fusarium* fungi, alter sphingolipid metabolism and cause leukoencephalomalacia in horses and pulmonary edema in pigs; they are hepatotoxic in all species. Fumonisins are nephrotoxic in sheep and cattle; renal lesions include vacuolar change, apoptosis, karyomegaly, and tubulo-obstructive changes in proximal tubules.

Amaranthus

Ingestion of redroot pigweed, *Amaranthus retroflexus*, causes perirenal edema and acute renal failure due to toxic nephrosis in swine and cattle, and uncommonly in horses. The nephrotoxic principle of *A. retroflexus* has not yet been identified; the plants often contain high levels of nitrate and oxalate, but neither nitrate nor oxalate poisoning usually occurs and does not produce perirenal edema. Phenolic compounds have been identified in the leaves of *Amaranthus*, and may be of similar importance to those in *Quercus* spp. (oak, see below). Lush growth of pigweed occurs in early summer and this plant often dominates the weed growth in disused lots and yards to which animals are moved when other pasture is depleted. Weakness, recumbency, and often death follow 5–10 days after grazing begins.

Grossly, there is marked perirenal edema, which may be blood-stained and may be accompanied by edema of mesenteries, bowel wall, and ventral abdominal wall, with moderate ascites and hydrothorax. The kidneys are pale but not usually enlarged. Histologically, there is degeneration and coagulative necrosis of both proximal and distal tubules (Figs 4.44 and 4.46); there may also be mild glomerular epithelial injury and hypercellularity. Tubules contain granular casts. The perirenal edema seen in acute cases is apparently due to tubular backleak, with subsequent lymphatic drainage and leakage into perirenal connective tissue. The probable cause of death is heart failure due to hyperkalemia. Survivors may develop renal interstitial fibrosis and tubular dilation (Fig. 4.50).

Other plant toxicoses

Poisoning of ruminants and occasionally of horses by *blossoms, buds, leaves, stems, and acorns* of **oak shrubs and trees (*Quercus* spp.)** occurs wherever these grow, and in areas where the acorns are accepted as a dietary staple in late autumn and early winter. There are many species and varieties of oaks but not all are palatable. They are all potentially poisonous by virtue of the *tannins* they contain, but, in small quantities, they are eaten with impunity. Ingestion of large amounts of the material can cause hydrothorax, ascites, marked perirenal edema, alimentary tract ulceration, and acute tubular necrosis and can result in large death losses. The toxic substances are *gallotannins*; they are hydrolyzed to tannic acid, gallic acid, and pyrogallol, which appear to be the active toxic metabolites. Binding of tannins to endothelial cells results in *endothelial damage* and accounts for perirenal edema and fluid leakage into body cavities. The alimentary lesions are due to the strong ability of oak tannins to bind to peptide linkages and precipitate protein; this astringent effect of tannins is used in leather tanning. The gastrointestinal and mesenteric edema and ulcerative enterocolitis that develop in poisoned horses are also partly the product of disseminated intravascular coagulation.

In acute oak poisoning, there is marked perirenal edema and hemorrhage, the kidneys are swollen and pale and, in cattle, are rather uniformly sprinkled with cortical hemorrhages of 2–3 mm diameter. The glomeruli are ischemic but otherwise normal except for dilation of the urinary space after several days. There may be microscopic hematuria. Necrosis of the epithelium of the proximal tubules can be complete, to produce dense homogeneous casts within the basement membranes. In less severe injury, adjacent groups of tubules may vary considerably in the extent of degeneration (Fig. 4.51). Some animals may recover but, in others, the renal lesion progresses with shrinkage and diffuse fibrosis and scattered collections of mononuclear cells. *The completeness of the necrosis in groups of tubules with intratubular hemorrhage distinguishes the nephrosis of acute oak poisoning from that of most other causes.*

Poisoning by the **yellow wood tree, *Terminalia oblongata***, in Australia is reputed to produce lesions similar to those of oak poisoning. Yellow wood produces at least two toxic factors: punicalagin, a tannin that is hepatotoxic, and terminalin, a condensed tannin that is nephrotoxic. In acute yellow wood poisoning of cattle and sheep, coagulative periacinar hepatic necrosis predominates, accompanied in cattle by acute renal tubular necrosis. Subacute and chronic intoxications are characterized by renal fibrosis and atrophy.

Several species of the genus ***Isotropis*** are toxic to ruminants. In both cattle and sheep, reference is made to abomasitis and enteritis, petechial hemorrhages throughout the gastrointestinal tract, perirenal edema, and accumulation of fluid in the body cavities and subcutis. The renal lesions are dominated by necrosis of proximal tubular epithelium. In many acute poisonings, there is abundant proteinaceous fluid in Bowman's space.

Various members of the **lileaceae family** of plants can cause acute tubular necrosis in animal species, for example, *Narthecium ossifragum* (bog asphodel) in ruminants, several lilies, and their hybrids (*Lilium* spp.) in cats.

Grapes and raisins contain an unknown toxic principle that causes proximal renal tubular degeneration and/or necrosis in dogs.

Specific tubular dysfunctions

Renal tubular dysfunction may occur secondary to other conditions; for example, glucosuria occurs when the tubular transport maximum for glucose is exceeded in diabetes mellitus and acute enterotoxemia, and heavy-metal toxicity causes glucosuria and aminoaciduria due to tubular degeneration. The primary tubular transport defects identified in domestic animals are *hyperuricosuria in Dalmatian dogs, essential cystinuria, the syndrome of multiple resorptive defects in Basenji dogs, renal tubular acidosis*, and *primary renal glucosuria*. Hyperuricosuria and cystinuria are of importance because they predispose to urolithiasis, and are discussed in that section.

Basenjis and several other breeds of dogs may develop a *proximal renal tubular disorder* similar to the "**Fanconi syndrome**" in humans; the condition is hereditary in Basenjis. The syndrome in dogs is characterized by polyuria, polydipsia, hyposthenuria, glucosuria, normoglycemia, hyperphosphaturia, proteinuria, and aminoaciduria. The aminoaciduria may be generalized or limited to cystinuria. Affected dogs have impaired renal tubular reabsorption of glucose, phosphate, sodium, potassium, uric acid, and amino acids, possibly due to alterations in membrane transport proteins. Polyuria results from the glucosuria and natriuresis. The syndrome develops in adult dogs and is usually slowly progressive. Dehydration and acidosis result in renal papillary necrosis and death due to renal failure. Histologic renal changes are nonspecific, and include interstitial fibrosis and tubular atrophy. Affected dogs often have marked karyomegaly in occasional tubular cells. Ultrastructural abnormalities have not been noted in tubular cells. A congenital Fanconi syndrome in Border Terriers was associated with rickets, likely as the result of hyperphosphaturia and decreased hydroxylation of 25-$(OH)_2D_3$. Acquired Fanconi syndrome has been reported in dogs in association with gentamicin nephrotoxicity, ethylene glycol nephrotoxicity, and primary hypoparathyroidism. A presumptive case of Fanconi syndrome with marked growth retardation has been reported in a young Simmental bull.

The renal tubular acidosis that occurs as part of the Fanconi syndrome is the most common example in dogs of **proximal, or type II, renal tubular acidosis**, in which proximal tubules fail to reabsorb filtered bicarbonate. Proximal renal tubular acidosis is usually a self-limiting disease that is not evident clinically. **Distal, or type I, renal tubular acidosis** occurs in dogs, cats, and horses, is caused by defective excretion of hydrogen ions by distal tubules, and produces hyperchloremic metabolic acidosis that is more severe than that in the proximal form of renal tubular acidosis. Untreated distal renal tubular acidosis can result in osteomalacia, nephrocalcinosis, nephrolithiasis, and renal failure. Transient renal tubular acidosis is a feature of amphotericin B nephrotoxicity.

Primary renal glucosuria may occur as a singular transport abnormality without other defects. This defect is an inherited disorder in Norwegian Elkhounds.

The mannosidoses, hereditary **lysosomal storage diseases,** can cause vacuolation of neurons, renal tubular epithelial and other cells in humans, cattle, goats, and cats; similar lesions are caused by some plant intoxications, e.g., *Swainsona, Astragalus, Oxytropis*. Salers calves affected with *β-mannosidosis* primarily have a variety of neurologic deficits but also have greatly enlarged kidneys that are characterized by marked vacuolation of the cytoplasm of proximal tubular epithelial cells (Fig. 4.52); this lysosomal storage disease is inherited as an autosomal recessive trait. Although the renal lesion is histologically dramatic, renal dysfunction is not reported (see Vol. 1, Nervous system).

Pigmentary changes

Following acute hemolytic crises of any cause, *the kidneys may be very dark, almost black*, as a consequence of concentrated **hemoglobin**. Initially, the discoloration is uniform, but shortly most of the hemoglobin is dispersed, except from scattered clusters of nephrons in which it persists for many days to produce diffuse brown speckling of the cortices. The color alone provides a good distinction between this pigmentary change and the red or blue speckling that occurs in acute hemorrhagic glomerulitis. It is particularly characteristic of the hemolytic crisis of chronic copper poisoning in sheep. Microscopically, the hemoglobin appears as fine red granules in the epithelial cells of the tubules (Fig. 4.53) and as red casts in the lower reaches of the nephron, especially Henle's loop and the collecting tubules. The same histological picture occurs following incompatible blood transfusions and in paralytic myoglobinuria of horses, in which disease the pigment is **myoglobin**. Nutritional myopathy of young animals does not produce this renal lesion because the myoglobin content of their muscle is very low. Hemoglobin and myoglobin pigmentation persist after hemoglobin or myoglobin are no longer detectable grossly in urine samples. As noted above, *neither hemoglobin nor myoglobin is a primary nephrotoxin*, but they contribute to renal failure produced by other causes, such as hypotension. Tubular obstruction by myoglobin casts can contribute to acute renal failure in horses with severe rhabdomyolysis.

Hemosiderosis occurs in the course of chronic hemolytic anemia and as residue from acute hemoglobinuric episodes. The pigment is found in epithelial cells of proximal tubules, where it is produced by the degradation of resorbed hemoglobin, and it may be sufficient to produce a distinctive brown coloration of the cortex.

Lipofuscinosis of the kidneys of adult cattle consists of the *deposition of brown iron-free pigments* with staining characteristics of lipofuscin (Fig. 4.54A). The pigmentation also affects striated muscles, giving them a dark-brown appearance. On the cut surface of the kidney, the pigmentation occurs in radial dark lines in the cortex but spares the medulla. Microscopically, it is present as fine, brown granules in the epithelial cells of the convoluted tubules. An *environmental lipofuscinosis* of the liver, kidney, and other organs is discussed in Vol. 2, Liver and biliary system. Mild brown discoloration of renal cortex, liver, and lymph nodes, and yellow-brown discoloration of gray matter of brain and spinal cord occur in sheep with the *acquired lipofuscin storage disease* caused by poisoning with the plant *Trachyandra divaricata*.

Cloisonné kidney is a nonclinical pigmentary condition in goats. The renal cortices are uniformly brown or black, due to thickening and *brown pigmentation of basement membranes* restricted to the convoluted portions of the proximal tubules (Fig. 4.54B). The basement membrane thickening is due to the deposition of *ferritin and*

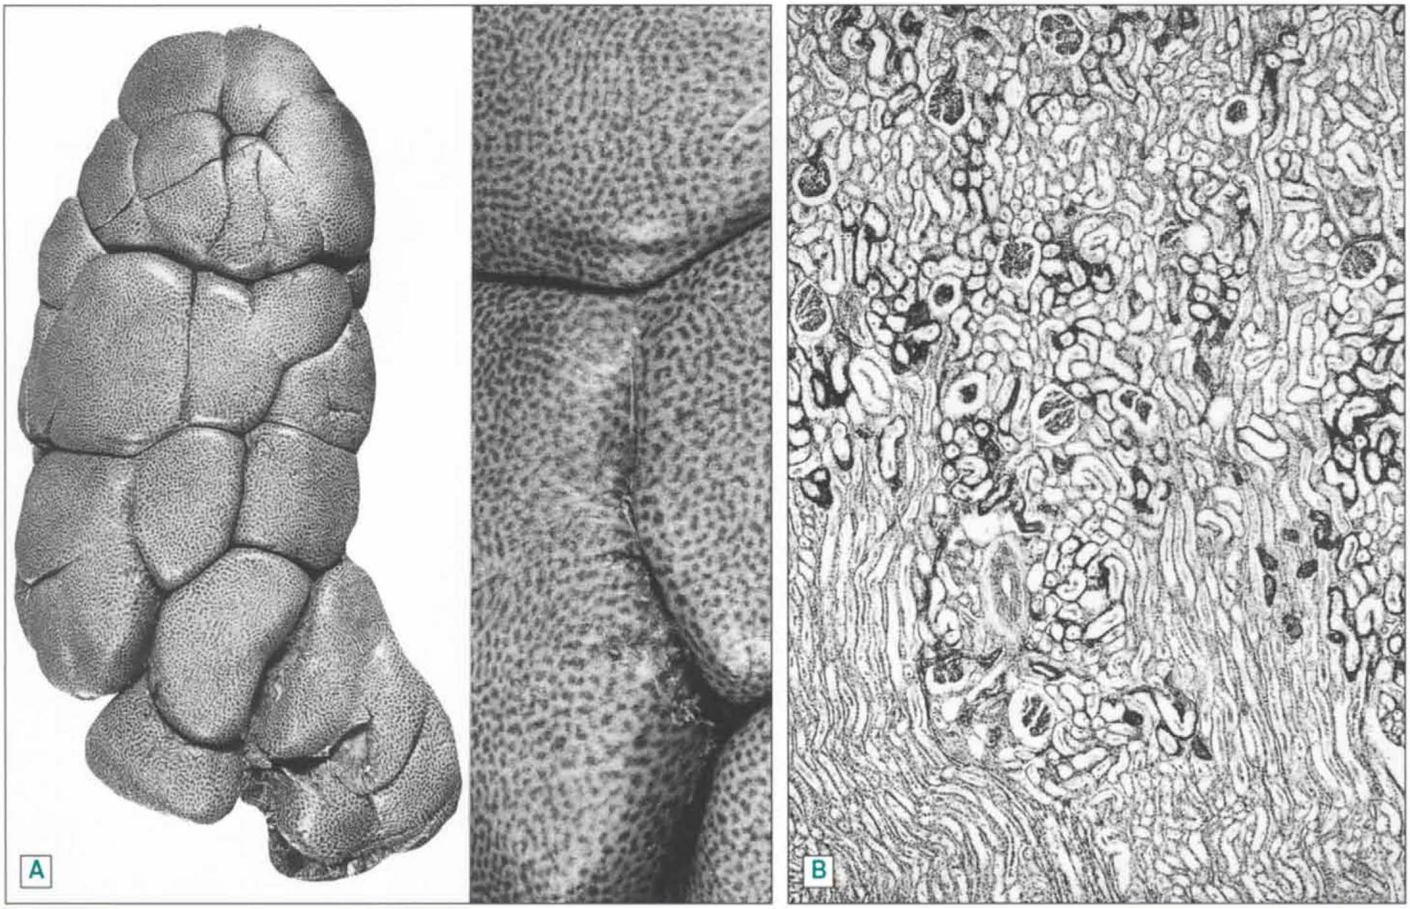

Figure 4.54 A. Lipofuscinosis in a bovine kidney. Inset: close-up of subcapsular surface. **B. Cloisonné kidney** from a goat. (Courtesy of A Zubaidy.)

hemosiderin, which is presumably the result of repeated episodes of intravascular hemolysis. A similar renal discoloration and basement membrane thickening has been reported in a horse, but was found to be due to lipofuscinosis.

In congenital **porphyria** of cattle, swine, and cats, *brown pigmentation* affects the cortex. Histologically, the pigment is present in the tubular epithelium and the interstitial tissue. The pigment is excreted in the urine that, if allowed to stand in light, develops a port-wine color due to photic activation of porphyrins. The urine and tissues fluoresce blue-green in ultraviolet light.

A *green-yellow pigmentation* of swollen kidneys is common in **icterus** of hepatic origin and less notable in hemolytic icterus unless there is concomitant hepatic injury. It is described below in the section on Hepatorenal syndromes. Olive-green coloration of the renal cortex is common in newborn lambs, calves, and foals. The pigment is bilirubin and its presence is probably due to immaturity of hepatic conjugating mechanisms.

Light green to green-yellow discoloration of liver, and hepatic, renal, and other lymph nodes is occasionally observed in cattle at slaughter. Histologically, numerous brown acicular crystals are present in the cytoplasm of hepatocytes, macrophages, and renal tubular epithelial cells. Crystals may be present in renal tubules, and renal calculi are rarely present. The crystals are **2,8-dihydroxyadenine**, a metabolite of the purine adenine. The crystal deposition and pigmentation are of little significance, and the cause of this condition is unknown.

Hepatorenal syndromes

The term **hepatorenal syndrome** is applied to *functional renal failure that occurs in human patients with cirrhosis and ascites*; an exact parallel has not yet been identified in domestic animals. Marked renal hypoperfusion results from renal vasoconstriction, which may be a manifestation of underfilling of the arterial circulation that occurs subsequent to splanchnic vasodilation. Cirrhosis leads to an imbalance of vasodilators, e.g., nitric oxide, and vasoconstrictors, e.g., endothelin. Although the kidneys themselves have minimal pathologic changes, prognosis is grave.

Hypotension may result from the vasodepressor, cardiodepressor, and diuretic effects of cholemia; thus, the uremia in jaundiced patients may be of prerenal origin. Concentrations of bilirubin and bile acids may be greatly elevated in the blood, especially in obstructive jaundice, and the pigment accumulates in tubular epithelial cells, which are frequently swollen and hydropic ("**cholemic nephrosis**"); the actual toxicity of bilirubin and bile salts is still under debate. Some nephrotoxins are also (or mainly) hepatotoxic, e.g., carbon tetrachloride and *Lantana camara*.

Pseudohepatorenal syndromes include conditions in which liver and kidneys are both affected, but in which renal disease is not secondary to hepatic disease; included are a wide variety of infectious, circulatory, genetic, and other systemic disorders.

Glycogen nephrosis

In diabetes mellitus in dogs and cats, glycogen is deposited in the tubular epithelium, producing marked vacuolation of the epithelium in the outer medulla and inner cortex. Glycogen can be readily demonstrated by appropriate techniques. The deposition occurs in the ascending limb, disappears following insulin administration, and has no effect on renal function. Often in diabetes mellitus of long duration there is hyaline thickening of the afferent arteriole, which may extend to the capillary basement membranes of the glomerulus.

Nephrogenic diabetes insipidus

This condition has been reported in dogs and foals with polyuria, polydipsia, and hyposthenuria. Affected animals are unresponsive to water deprivation, to exogenous administration of antidiuretic hormone (vasopressin), and to infusion of hypertonic saline. The basis of the defect is a *lack of responsiveness of the cells of the distal tubules and collecting ducts to the hormone*. The defect may be *congenital* (possible X-linked disorder in two foals), or *acquired* as the result of tubulointerstitial diseases such as pyelonephritis or hypercalcemic nephropathy, or due to the effect of drugs such as tetracycline.

Hypokalemic nephropathy

Chronic potassium depletion, caused by diarrhea, adrenal overactivity, and some renal diseases, can result in impaired urine concentration and polyuria. *Coarse vacuolation of the proximal convoluted tubules* is due to reversible dilation of intercellular spaces. Chronic potassium depletion can lead to lymphoplasmacytic tubulointerstitial nephritis and interstitial fibrosis, perhaps due to increased renal ammoniagenesis. Vacuolar degeneration of proximal tubular cells has been reported in ewes deliberately given 11–17 times the recommended dose of *thiabendazole*. Many of the ewes developed hypokalemia, hypoproteinemia, and uremia before death; potassium loss was thought to occur through the kidneys. In a possible case of hypokalemic nephropathy in a dog, *chronic vomition* due to a gastric foreign body was thought to be the cause of potassium depletion. *Corticosteroids* produce hypokalemia and reversible vacuolar degeneration of tubular cells. Hypokalemia may be related to the tubular dilation commonly seen in baby pigs with *diarrhea*, and is related to experimental production of renal cysts.

Miscellaneous tubular conditions

In addition to the standard patterns of parenchymal cell degeneration, there are several miscellaneous histologic changes that may be found in renal epithelium. *Some of the* **pyrrolizidine alkaloids** *cause megalocytosis in the proximal tubules*. The lesion is similar in type to that in hepatocytes but much less conspicuous and not observed to cause functional disturbance. Some pyrrolizidine alkaloid-containing plants, particularly *Crotalaria* spp., cause significant glomerular megalocytosis and sclerosis in pigs (see Vol. 2, Liver and biliary system).

Occasional nuclei in tubules of old dogs may be polyploid. *In the proximal tubules, eosinophilic, crystalline, intranuclear inclusions* ("**brick inclusions**") *are commonly encountered in old dogs.* Similar inclusions occur in the liver, their source is unknown and, although they resemble the inclusions produced in experimental animals by heavy metals such as bismuth, *they do not contain heavy metals*. In cells in the same location, *subacute* **lead poisoning** *produces amorphous acid-fast inclusion material in nuclei that are large, pale, and vesicular.*

Large, eosinophilic, intranuclear inclusions occur in hepatocytes and renal collecting duct epithelial cells in goats. The pathogenesis of this **nuclear glycogenosis** is unknown, and it does not appear to be of functional significance. Nuclear hyperglycogenation occurs in humans with type I glycogen storage disease.

Eosinophilic intracytoplasmic inclusion bodies have been reported in the renal collecting duct epithelial cells of dogs. The inclusions consisted of **iridovirus** particles, and the infection appeared not to be significant.

TUBULOINTERSTITIAL DISEASES

This term comprises *diseases that involve primarily the interstitium and tubules*, and acknowledges that inflammatory and degenerative diseases of the interstitium almost always impair tubular function. Hence, **interstitial nephritis**, which may be acute or chronic, focal or generalized, suppurative or nonsuppurative, and **pyelonephritis** are classified as tubulointerstitial diseases. There is obviously overlap with the previous category of acute tubular necrosis, since animals that survive acute tubular necrosis often develop interstitial inflammation and fibrosis. Also included as tubulointerstitial disease may be nephropathy due to any of hypercalcemia, hypokalemia, analgesics, and oxalates, as well as immunologically mediated tubulointerstitial disease. In humans, and likely also in domestic animals, *tubulointerstitial nephritis can be caused by a vast array of agents*, including infections, toxins, immunologic disorders, chemicals, and therapeutic drugs (Fig. 4.55).

Interstitial inflammation and fibrosis and tubular atrophy and degeneration are predominant histologic features of these diseases. Interstitial nephritis is usually hematogenous and part of systemic disease, or it may occur secondary to glomerular disease; pyelonephritis is usually urogenous. Both interstitial nephritis and pyelonephritis are usually due to infectious agents, although agents are often not identified, especially in chronic cases. Acute renal injury, including glomerular injury, leads to release of a wide array of cytokines and growth factors from tubular epithelial cells and peritubular capillaries, causing interstitial inflammation and ongoing tubulointerstitial damage. Monocytes are recruited, interstitial fibroblasts are activated,

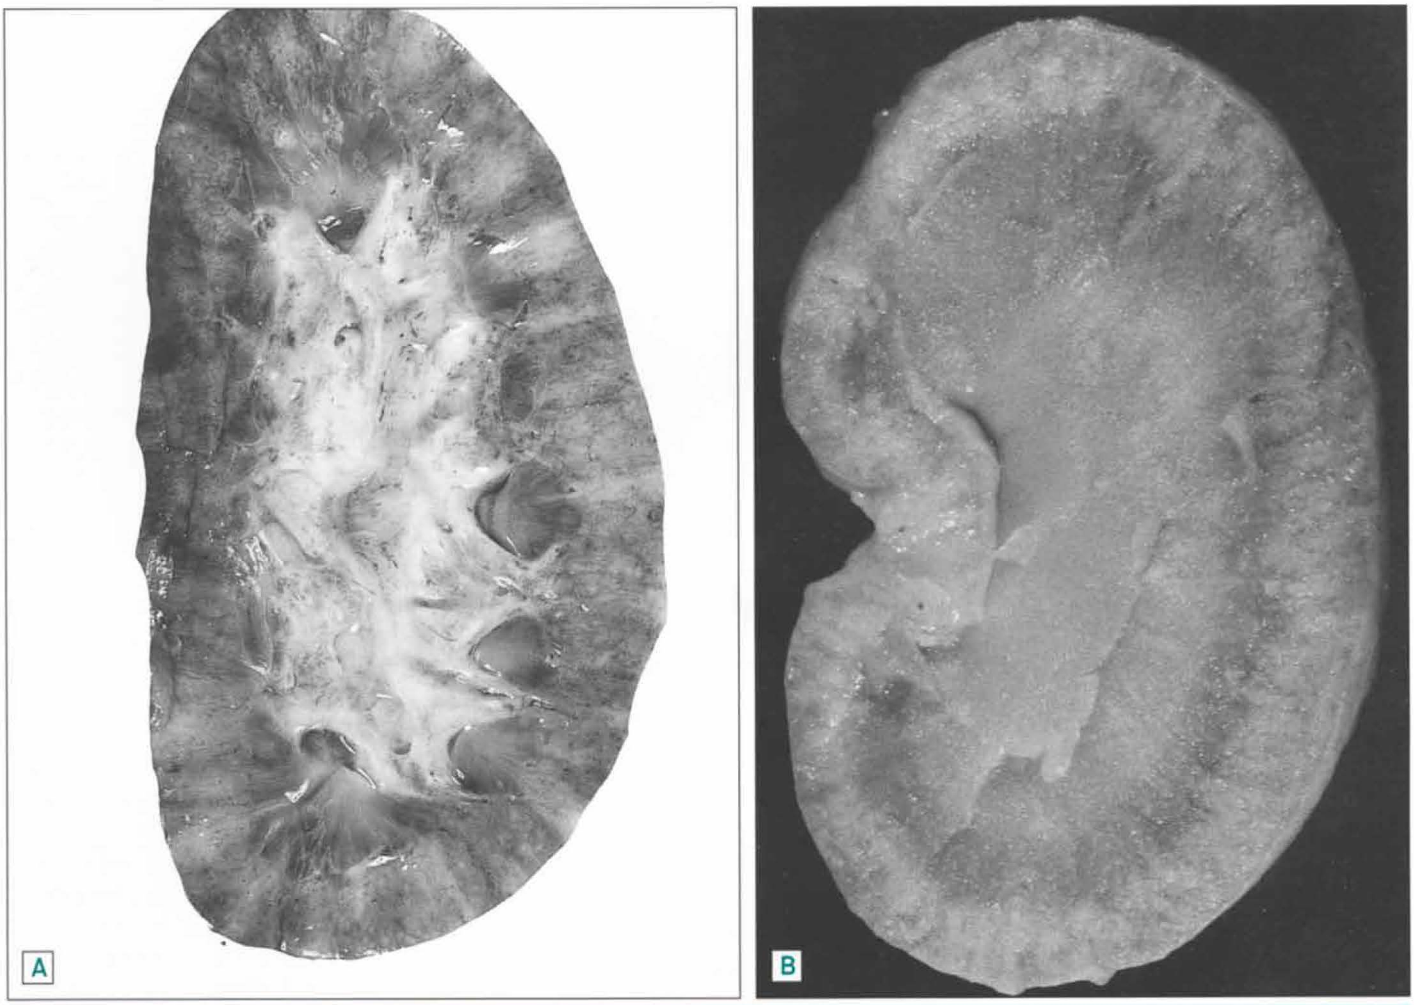

Figure 4.55 A. Acute interstitial nephritis in a pig. **B.** Chronic renal fibrosis and mineralization (**"end-stage kidney"**) in a Shih Tzu dog.

interstitial myofibroblasts appear, and fibrosis ensues. Primary glomerulopathy can incite the above sequence of events through the action of filtered proteins on tubular epithelial cells. Injury to glomeruli and vessels may of course also occur secondarily in tubulointerstitial disease because of the interdependence of renal structures. In any case, *the process of destructive fibrosis and loss of nephrons underlies progressive renal disease*.

The hallmark of glomerular disease is persistent proteinuria, whereas tubulointerstitial diseases are more likely to demonstrate defects of concentrating ability or specific tubular defects of resorption or secretion. However, the endpoint of both classes of renal disease and the usual clinical presentation is decompensated renal failure with isosthenuria and uremia.

Immunologically mediated tubulointerstitial disease has been identified in humans, and rarely in domestic animals. Hypersensitivity reactions occur to a variety of drugs, e.g., methicillin. Tubular immune-complex disease occurs in some patients with lupus nephritis and glomerulonephritis, indicating that autoantibodies may cross-react with glomerular and tubular basement membranes; antitubular basement membrane autoantibody has been identified in a dog.

Nonsuppurative interstitial nephritis

Focal inflammation with slight scarring and accumulations of lymphohistiocytic cells is common in kidneys. The causes are seldom known and probably not specific; some lesions may be primarily inflammatory and some may be foci of antigen persistence in scars of other origins.

As a form of nephritis, this may be acute or chronic, and multifocal or generalized, probably depending upon the intensity of the insult and the efficiency of the host's responses. **Acute interstitial nephritis** *is characterized by acute clinical onset, and histologically by interstitial edema, leukocytic infiltration, and focal tubular necrosis*. In **chronic interstitial nephritis**, *there is mononuclear cell infiltration, interstitial fibrosis, and generalized tubular atrophy*. Many infectious agents are capable of causing nonsuppurative interstitial nephritis, and some are discussed here, but agents are often not identified in naturally occurring cases, especially in the chronic stages.

Interstitial nephritis is common in dogs and cats, both as a primary disease and secondary to glomerular diseases. *Leptospira* serovar *canicola* has commonly been associated with acute generalized interstitial nephritis in dogs, although its importance has declined because of the efficacy of vaccination; serovar *icterohaemorrhagiae* and *Canine adenovirus 1* (infectious canine hepatitis) are also commonly involved. According to serologic evidence, leptospirosis is common in domestic animals and, in severe cases, interstitial nephritis often occurs. In survivors of acute infections, inflammatory cells gradually disappear, marked interstitial fibrosis and loss of nephrons cause contracture of the kidney, and chronic interstitial nephritis results. Diffuse interstitial nephritis is less common in large domestic animals than in dogs; the usual end-result of leptospirosis in cattle and swine is multifocal interstitial nephritis. Leptospirosis is discussed in detail below.

Encephalitozoon cuniculi, an obligate intracellular microsporidian parasite, causes diffuse nonsuppurative to granulomatous interstitial nephritis and granulomatous encephalitis in immature dogs. The renal lesion is characterized by heavy, almost pure, interstitial infiltrates of plasma cells. The gram-positive organisms occur in tubular epithelial cells, tubular lumina, and in vessel walls. The disease is discussed in Vol. 1, Nervous system.

The best-known form of multifocal nonsuppurative interstitial nephritis is the "*white-spotted kidney*" of calves. This is common and appears to be of little significance because it is largely an incidental finding in young calves and is probably obliterated with advancing age. The cause is usually undetermined but is most likely the result of bacteremia; *Escherichia coli* can occasionally be recovered from the lesions. *Salmonella* and *Brucella* are other suggested causes. Affected kidneys contain multiple small white nodules of up to 1 cm diameter throughout the cortex. The larger nodules may bulge from the capsular surface of the kidney and adhere to the capsule (Fig. 4.56A). Histologically, the initial lesion is a microabscess, which is soon replaced by numerous lymphocytes and occasional plasma cells and macrophages. Progressive fibrosis results in healing by scar tissue. The inflammation and scarring may cause tubular obstruction and/or atrophy (Fig. 4.56B).

Multifocal interstitial nephritis also occurs in cattle in the course of *malignant catarrhal fever, theileriosis, lumpy-skin disease*, and as a fatal *autosomal recessive disorder* in Japanese Black cattle (Wagyu); in sheep, in *sheep-pox*; and in the horse, in *equine infectious anemia*. The renal lesions do not contribute significantly to the course of these diseases but are of some diagnostic importance; their gross and histological features are given elsewhere. Multifocal pyogranulomatous lesions are a rather consistent finding in the kidneys of cats with *feline infectious peritonitis*. *Canine herpesvirus* produces severe necrotizing nephritis as part of the systemic disease in puppies (see Vol. 3, Female genital system). Other causes of nonsuppurative interstitial nephritis in dogs include *Leishmania* spp., *Borrelia burgdorferi, Hepatozoon canis*, and *Canine adenovirus 1*.

Cattle and horses grazing *vetch* (*Vicia* spp.) can develop dermatitis, diarrhea, and ill-thrift and develop lesions in skin, kidney, and other internal organs, characterized by multifocal eosinophilic granulomatous inflammation. Similar lymphocytic to lymphogranulomatous lesions are reported in cattle fed *citrus pulp*.

Suppurative interstitial nephritis

Bacterial infection of the kidneys may be either **hematogenous** (Fig. 4.57), and cause embolic suppurative nephritis, or **urogenous**, and cause pyelonephritis. Pyelonephritis means inflammation of both the pelvis and renal parenchyma, and, while pelvic inflammation may result from septic renal foci (Fig. 4.58), most cases of pyelonephritis arise from ascending urinary infections.

Adenoviral infection of sheep is most significant as a cause of pneumonia, but also causes mild, multifocal, suppurative interstitial nephritis, with characteristic large, basophilic, intranuclear inclusion bodies in endothelial and/or interstitial cells.

Embolic suppurative nephritis

This is analogous to abscess formation in any organ, and occurs when any of a wide variety of bacteria is seeded in the kidneys in the course of bacteremia or septic thromboembolism. Bacteria alone or in small clumps, and small septic emboli, lodge mainly in glomerular and peritubular capillaries (Figs 4.30A and 4.59), and may produce multiple small abscesses or fewer large ones. Larger emboli lodge in afferent vessels and produce septic infarcts that may be unilateral.

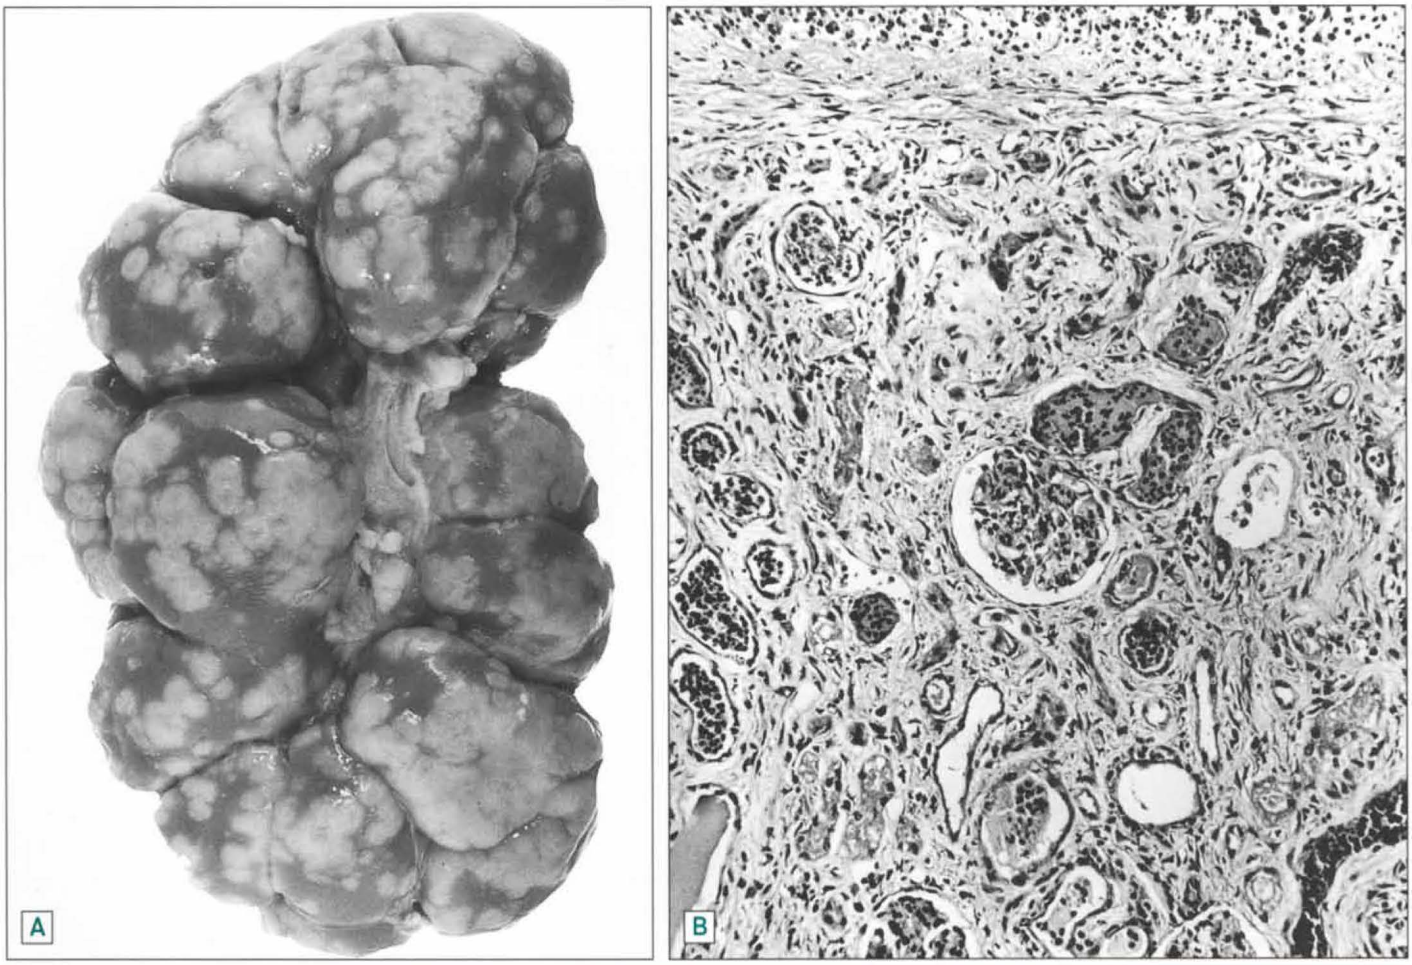

Figure 4.56 A. "White-spotted kidney" from a calf. **B.** Section of cortex in (**A**) showing interstitial reaction.

Many bacteria undoubtedly pass through the glomerular capillary walls into the tubules, where they are probably harmless unless there is stasis of urine. Developed abscesses are generally cortical rather than medullary, but in bacteremia caused by gram-negative enterobacteria, microscopic suppurative foci may be scattered in the medulla. If healing of the suppurative lesions occurs, it is by scar formation. The healed lesions of isolated abscesses are occasionally seen, but extensive renal scarring as a sequel to multiple abscessation is rare as the animal is likely to die of the primary disease or from renal insufficiency early in the course of the disease.

In *horses*, the most common cause of embolic suppurative nephritis is *Actinobacillus equuli,* which is acquired in utero, during parturition, or shortly after birth; it is probably an umbilical infection (Fig. 4.60). Death may occur due to fulminating septicemia. In foals that survive for several days, typical microabscessation is seen in the kidneys and other organs, and polyarthritis is present. The abscesses are usually green-yellow foci of up to 3 mm diameter that contain a small droplet of pus. The most common cause of embolic nephritis in *swine* is probably *Erysipelothrix rhusiopathiae.* Embolic glomerulonephritis may be seen grossly as glomerular hemorrhages; microabscesses form in the interstitium. In adult *cattle*, most cases are caused by *Arcanobacterium pyogenes* from valvular endocarditis, the septic emboli often producing large, randomly distributed abscesses and infarcts. In *sheep and goats*, renal abscessation caused by *Corynebacterium pseudotuberculosis* is common.

Leptospirosis

John F. Prescott

Leptospirosis is an important, largely hidden, complex, neglected, and intriguing spirochetal infection of animals and humans caused by serovars of *Leptospira interrogans* (sensu lato). *It is particularly important as a cause of abortion and stillbirth in farm animals but also causes loss through acute disease (septicemia, hepatitis, nephritis, meningitis) in these and other animals.* Many aspects of leptospirosis are poorly understood because of difficulties in diagnosis, the changing pattern of disease because of vaccination and antibiotic use, and the complexities of host–leptospiral relationships. Although generalizations are helpful, leptospirosis may best be understood in terms of the individual relationship between specific serovars and particular host species rather than as a single disease with a common epidemiology, host response, and approach to control.

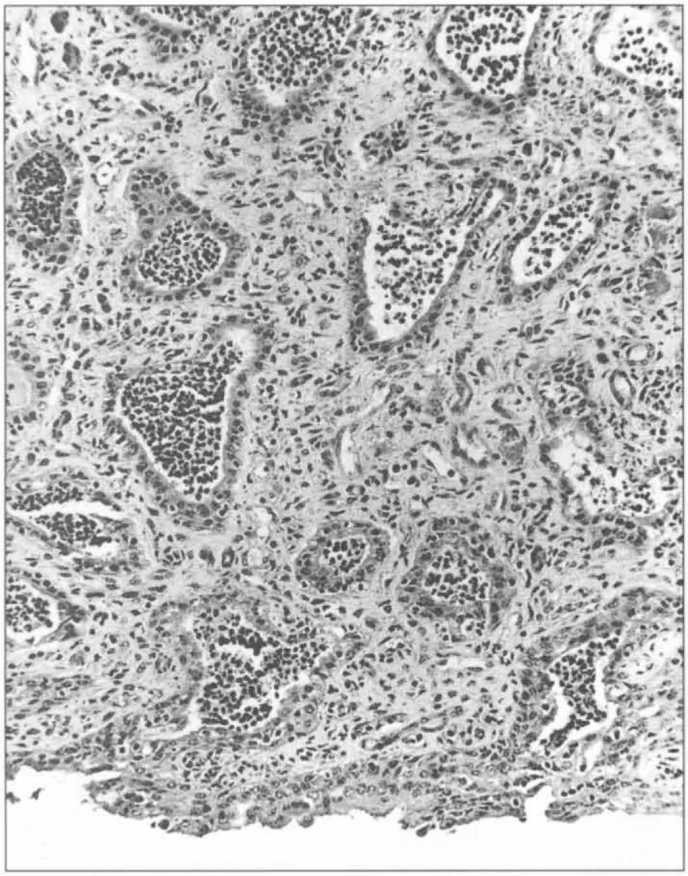

Figure 4.58 Descending pyelonephritis in "white-spotted kidney" from a calf.

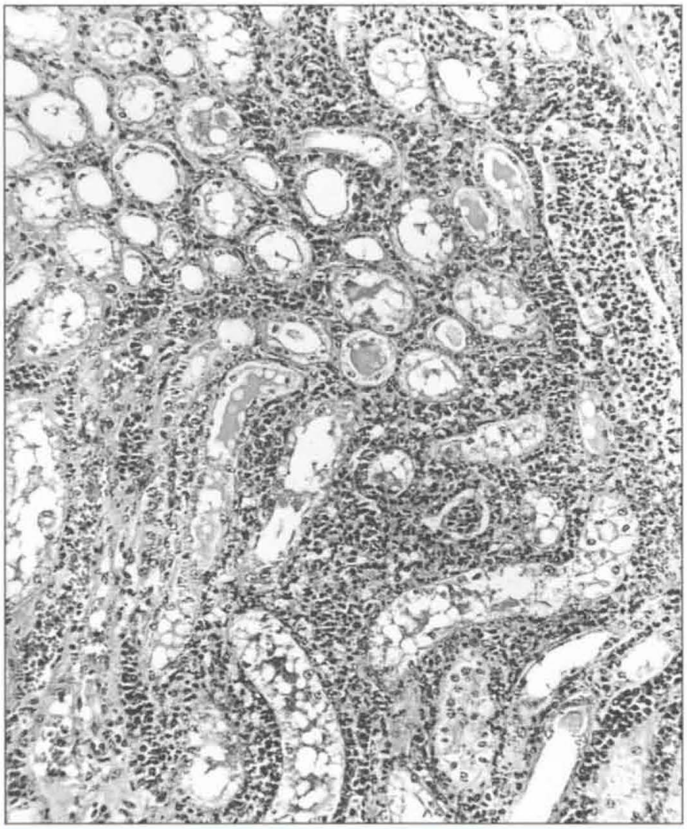

Figure 4.59 Hematogenous interstitial nephritis in a dog with *Klebsiella pneumoniae* bacteremia.

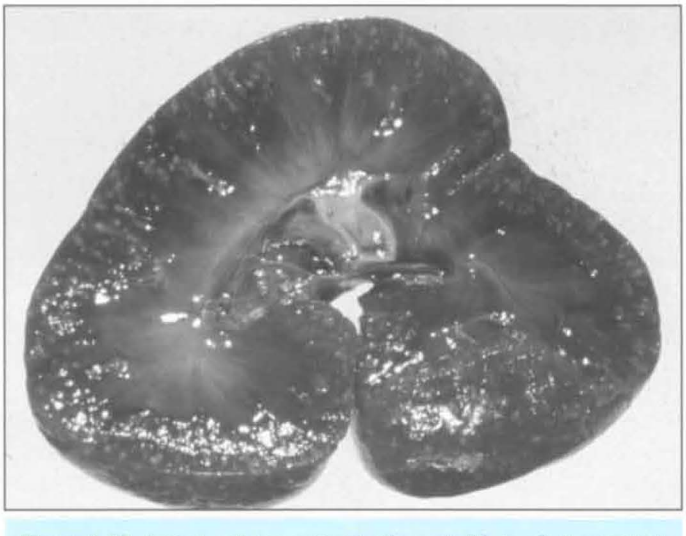

Figure 4.60 *Actinobacillus equuli* **embolic nephritis** in a 2-day-old foal.

Leptospirosis can be caused by any of the 180 serovars belonging to the 19 serogroups of what used to be recognized as one species, *Leptospira interrogans* (sensu lato), but which now contains 10 species of pathogenic *Leptospira*. Unfortunately, neither serogroup nor serovar reliably predicts the species of *Leptospira*, since the same serogroup (i.e., shares some common antigenic determinants) or serovar (i.e., antigenically indistinguishable isolate) may occur within two or more species. Thus, some genetically unrelated leptospires, belonging to one of the 10 species in what used to be described as *L. interrogans*, may be antigenically identical. For example, serovar *hardjo* is found within *L. borgpetersenii*, *L. interrogans*, and *L. meyeri*. *The use of serotyping is increasingly being replaced by restriction enzyme analysis of chromosomal DNA to identify "genotypes."* Thus, using the same example, genotyping has divided serovar *hardjo* into two distinct types, hardjo-bovis and hardjoprajitno, which correspond with the species (*L. borgpetersenii*, *L. interrogans*, respectively) to which these types belong and which differ in both geographic distribution and in virulence. Restriction enzyme analysis has also assigned most North American serovar *pomona* isolates to genotype kennewicki, and further identified pig-associated and cattle-associated subtypes. The scheme used in this section is to use the species and serovar name (e.g., *Leptospira borgpetersenii* serovar *hardjo*) with genetic type where relevant. The current taxonomy of *Leptospira* is confusing, because some leptospirologists are naturally reluctant to abandon the serological scheme, but is described well by Levett (2001).

Although many serovars are recognized globally, only a limited number are usually endemic to a particular region (Table 4.3). Geographic differences in the distribution of serovars are marked, but the true incidence and prevalence of leptospirosis are largely undetermined for most countries and regions. Serological surveys tend to be flawed because antigens chosen may not represent serovars present in the country, because serological prevalence does not necessarily indicate disease significance, because sampling is often done on the basis of convenience rather than in a carefully designed manner, and because titers designated as "significant" (usually ≥1:100 in the

Table 4.3 Common leptospiral serovars of disease significance in domestic animals

Serovar	Maintenance host	Distribution	Species disease significance
autumnalis	Rodents	Global, tropics especially	+ ?Dogs

[a] *Arbitrary scale for comparison.*

microscopic agglutination test, MAT) may underestimate the true seroprevalence of some host-adapted serovars.

Each serovar is adapted to and may cause disease, in particular "maintenance" hosts, although they may cause disease in any other species, the "incidental" hosts. The general distinctions between these types of host are shown in Table 4.4. For some serovars and hosts, there may also be "intermediate" forms between the two major categories of host–parasite relations, because the phenomenon of host adaptation appears to be an ongoing characteristic of pathogenic leptospires.

The natural reservoir of pathogenic leptospires is the proximal convoluted tubules of the kidney, and in certain maintenance hosts the genital tract. In maintenance hosts particularly, transmission may be direct, through urine splashing, in postabortion discharges, venereally, through milk, or transplacentally in congenitally affected animals. Infection of incidental hosts is more commonly indirect, through environmental contamination by the urine of carrier animals. Close contact of maintenance hosts aids spread but, especially for incidental hosts, environmental conditions determine the success of indirect transmission. Optimal conditions for survival of leptospires are moist, warm (optimal 28°C), and neutral or mildly alkaline conditions ("flood fever," "swamp fever"). Under ideal conditions, leptospires may survive weeks or months in waterlogged soil ("mud fever") or stagnant water. Under adverse conditions, survival is measured in minutes. *Leptospirosis thus occurs especially in the autumn in temperate climates ("fall fever"), and in the winter in tropical climates,* seasons that also often coincide with the greatest population sizes of wildlife shedders.

Leptospires penetrate exposed mucosal surfaces or water-softened skin and disseminate throughout the body, in a leptospiremic phase lasting up to 7 days, but multiply especially in the liver, kidneys, lungs, placenta, udder, and cerebrospinal fluid. The development of agglutinating and opsonizing antibody ~6 days after infection clears the organisms from sites other than those that immunoglobulins penetrate poorly (proximal convoluted tubules of the kidney, cerebrospinal fluid, vitreous humor of the eye), and, for certain serovars, the genital tract (oviducts, uterus, vagina in females, testes, epididymes, prostate, and seminal vesicles in males) of maintenance hosts.

Most leptospiral infections are supposedly subclinical, particularly in nonpregnant and nonlactating animals, only detected by the presence of antibody or of *minor lesions of interstitial nephritis at slaughter.*

Infection may also cause *acute or subacute systemic disease* (nephritis, hepatitis, endotoxemia, sometimes hemoglobinuria) during the leptospiremic phase or, after leptospiremia has ceased, *chronic disease* in the form of abortion or stillbirth, infertility, or recurrent uveitis.

Acute and often severe disease may occur in the leptospiremic phase, particularly in young animals. *Jaundice is a common manifestation of acute disease* and occurs because of hemolysis due to hemolysin production, and because of hepatocellular injury of both toxic and ischemic origin. The clinical disease is characterized by fever, jaundice, hemolytic anemia, hemoglobinuria, pulmonary congestion, and occasionally meningitis. Capillary injury caused by inflammatory cytokine release occurs in acute disease. Anemia is initially the result of *hemolysins* but may later be due to *antibodies* causing an intravascular hemolytic anemia by reaction with leptospiral products coating red blood cells. *Postsepticemic localization of leptospires in the kidneys is associated with focal or diffuse interstitial nephritis and with acute, transient tubular degeneration.*

Renal failure is a clinically recognized consequence of infection with *canicola* and other serovars in dogs but is not often described in other animals, even though interstitial nephritis, especially in pigs, can be extensive. *Interstitial nephritis can be caused by all serovars.* Leptospires reach the kidney hematogenously and migrate randomly, persist briefly in the interstitial spaces, and enter tubules at all levels of the nephron. Once antibody develops, the leptospires localize to the proximal convoluted tubules, where they may multiply. The physiological changes to glomerular filtrate lower in the nephron, and in formed urine, damage leptospires. The *interstitial phase* is accompanied by marked vascular alterations that produce hyperemia, edema, and endothelial swelling. Tubular epithelial degeneration is likely the combined result of hypoxia due to hypovolemia and red cell loss, of poorly described bacterial toxins including lipooligosaccharides and sphingomyelinases, of free hemoglobin, and of the interstitial inflammatory reaction to leptospires. Leptospiral antigen is demonstrable by immunoperoxidase staining in epithelial cell phagosomes, and is the counterpart of minute, round, black spherical bodies seen with silver stains. Tubular degeneration is well established by 2 weeks and is accompanied by *interstitial infiltration of plasma cells and lymphocytes*, which may be focal or diffuse. Leptospiral antigen is present in peritubular macrophages. The renal lesions may be insignificant, or may cause chronic debility or death in uremia.

Abortion, stillbirth, or the birth of congenitally infected young may follow weeks or months after maternal leptospiremia and is the most important form of the disease in ruminants and pigs. Serovar *bratislava* may also cause infertility in swine, as may serovar *hardjo* infection in cattle. Horses are particularly likely to develop *recurrent uveitis* ("periodic ophthalmia") following serovar *pomona* infection, but uveitis can develop in other species following leptospirosis.

Leptospires are delicate, slender spirochetes (6–20 × 0.1 μm), with hooked ends like question marks, which led to the name *L. interrogans*. They do not stain with the usual aniline bacterial dyes but may be stained by Giemsa or, in tissue, by silver-impregnation techniques of Levaditi or Warthin–Starry. Dark-field microscopy is generally used in routine laboratory study. *Demonstration of leptospires by dark-field microscopy of fluids, or silver staining of tissue sections, are insensitive methods that give both false-negative and false-positive results*, the latter being a ready trap for the inexperienced. *Immunofluorescence* of urine, or of homogenates of tissues such as fetal lung and kidney or of placenta, is an excellent diagnostic technique, almost equivalent in sensitivity to isolation in experienced laboratories. It is a method of choice in the diagnosis of leptospirosis. Difficulties may be experienced with serovar *bratislava* because of the small size of these organisms. *Polymerase chain reaction (PCR)-based diagnosis* will increasingly challenge immunofluorescence as a diagnostic method of choice. A number of PCR procedures are available which generally are more reliable for urine than for tissues. Leptospires die readily in tissues or body fluids unless kept at 4°C. Results may be improved if tissues are submitted to laboratories in leptospiral transport medium.

Culture is expensive and often time-consuming, and usually restricted to highly specialized laboratories. *The microscopic agglutination test (MAT)*, which is serovar-specific and to some extent serogroup-specific, has been a mainstay of diagnostic approaches to leptospirosis and is often made by comparison of acute and convalescent titers, since it is important to rule out "background" infection in making a serological diagnosis. In the diagnosis of abortion, the MAT suffers sometimes from the low titers that may occur with host-adapted serovars in their maintenance host, and also from difficulties in interpretation of titers. These may fail to rise between acute and convalescent because abortion may follow many weeks after infection in a maintenance host. In fetuses, MAT on fetal fluids is often a useful diagnostic approach, but dilutions should start at 1:10. The diagnostic interpretation of MAT titers is discussed by Bolin and Prescott (1999).

Cattle

Species and serovars of major importance are *L. borgpetersenii* serovar *hardjo* type hardjo-bovis and *pomona* type kennewicki in North America, and, in Europe, *L. interrogans* serovar *hardjo* type hardjoprajitno and *L. borgpetersenii* serovar *hardjo* type hardjo-bovis. There is serologic evidence of infection with other serovars, including *canicola*, *grippotyphosa*, and *icterohaemorrhagiae*, among others, but these serovars are not often implicated in disease, although geographic variations will occur. Serovar *hardjo* has become increasingly recognized with a concomitant, apparent decline in importance of serovar *pomona*. Cattle and sheep are reservoir hosts for *hardjo*. Serovar *hardjo* type hardjoprajitno, which is recognized in Europe but not in North America or Australia and New Zealand, appears to be more virulent than type hardjo-bovis. In Northern Ireland, where serovar *hardjo* type hardjoprajitno occurs, *hardjo* was recognized in one study as responsible for nearly half of all abortions. This type was isolated from most aborted or stillborn fetuses, whereas type hardjo-bovis was mainly isolated from the kidney and genital tract of carrier cows. In one large study in Ontario, Canada, where only hardjo-bovis rather than hardjoprajitno is thought to occur, serovar *hardjo* was identified in about 6% of abortions; no serovar *pomona* was recognized.

The most severe (but uncommon) manifestation of acute infection occurs in calves infected with incidental serovars, especially *pomona*. Hemoglobinuria is usually the first sign noticed and may be transient or last 2–3 days. In fatal cases, it gives the urine a port-wine color. Hematuria from hemorrhage into renal tubules may give rise to blood clots in the urinary tract. There is fever, anemia, icterus, dyspnea because of pulmonary congestion, and occasionally meningitis. High levels of albumin and bilirubin are present in the urine. In cows, agalactia with small quantities of blood-tinged milk, which may be yellow-stained and thickened like colostrum, is also typical. Abortion may occur during the acute phase or several weeks later during convalescence. The fetus is frequently decomposed, indicating death some time before abortion.

The most common form of the disease is a less severe, "subacute" form characterized in dairy cows by a 2–10-day drop in milk production with transient pyrexia. In this "milk drop syndrome" or "flabby udder mastitis" form, the milk has the consistency of colostrum, with thick clots and yellow staining, and the udder has a soft texture. This form is commonly associated with serovar *hardjo* type hardjoprajitno, but may be caused by all serovars.

The chronic form of the disease, most commonly associated with serovars *hardjo* and *pomona*, is fetal infection in pregnant cows, seen as abortion, stillbirth, or the birth of premature and weak infected calves. Abortion and stillbirth is often the only manifestation of infection, but may be related to an episode of illness up to 6 weeks (*pomona*) or 12 weeks (*hardjo*) earlier. Serovar *hardjo* type hardjoprajitno appears to be more virulent, and to cause more abortion, than *hardjo* type hardjo-bovis.

The hematologic changes are mild in cases not characterized by hemoglobinuria, and severe in those that are. Animals with *acute intravascular hemolysis* will have moderate to marked anemia, but hemoglobin levels may be erroneously high because of the measurement of free hemoglobin associated with hemoglobinemia.

The postmortem appearance of an animal that dies of acute leptospirosis is characterized by mild icterus and severe anemia. Hemorrhages may be absent, or ecchymoses may be numerous on serous membranes and in the subcutis. The lungs are pale, edematous, and expanded, and fluid, stained by bilirubin, widens the septa. The liver is enlarged, friable, anemic, and bile-stained. It may contain hemorrhages and small zones of necrosis about the central veins, but necrotic foci are not usually seen grossly. Hemoglobinuria is to be expected but may not be present. The kidneys are swollen; during a hemolytic crisis they are dark, but later the pigmented foci become restricted to small groups of tubules and have an appearance suggestive of numerous small hemorrhages. Still later, the kidneys show more or less numerous small gray foci of interstitial reaction that are rather indistinct and more numerous in the cortex than in the medulla (Fig. 4.61). It is doubtful whether cattle die of chronic interstitial nephritis caused by leptospires, but in animals that have recovered from the acute diseases, foci of renal inflammation are the only morphologic traces remaining. "White-spotted" kidneys in neonatal calves may be the result of congenital leptospirosis caused by serovar *hardjo*, which is probably common, but this speculation has not been examined.

The histologic changes in bovine leptospirosis are neither prominent nor specific. Edema of the lungs is apparent, and in scattered groups of alveoli and septal lymphatics, there are thin laces of fibrin. Zonal necrosis occurs in the liver; it is usually periacinar and typically a change of severe anemic anoxia. Kupffer cells are hyperplastic and contain excessive amounts of hemosiderin, and there is diffuse but mild cellular infiltration in the portal triads. In the uncommon infections caused by *icterohaemorrhagiae*, necrosis in the liver and dissociation of the cords of hepatic cells are more likely to occur than in infections caused by the other serovars. If the survival period in the acute hemolytic disease is sufficiently long, the biliary canaliculi become distended with bile.

In the acutely fatal disease, there are often marked degenerative changes in the epithelium of the cortical renal tubules, the changes varying in severity from hydropic swelling to necrosis and desquamation. The desquamated epithelium produces, in the tubules, granular and cellular casts in addition to the hyaline ones of albuminuria and hemoglobinuria and those due to direct bleeding into the tubules. Pigmentation by intracellular hemoglobin and biliary pigments does not become fully evident until 2 days, and the tubules, which are then strikingly involved, occur in clusters. There is also edema of the kidneys, with distension of the interstitial tissues with fluid, and in this there is mild but diffuse infiltration of plasma cells and lymphocytes. *In the acute disease, the organisms can often be demonstrated by appropriate stains in the liver,* in which they are partly intracellular, *and in the kidneys,* in which they occur in the tubular epithelium and frequently as clusters in the tubular lumen (Fig. 4.62).

In recovery from the acute disease and in due course in subclinical illness, the organisms localize in *microcolonies in the kidneys.* The microcolonies are in intratubular clumps; it is exceptional to find organisms in the interstitial tissue. The organisms are shed in the urine. *Renal localization is associated with more or less widespread focal interstitial nephritis* (Fig. 4.63). The nonsuppurative inflammatory reaction is virtually confined to the cortex; lymphocytes and plasma cells predominate. The reaction subsides very slowly, and inflammatory cells decrease in number as the focal lesions scarify. An odd feature of the active lesions is the atypical regenerative pattern of tubular epithelium within the areas of inflammation; the regenerating cells produce a few bizarre syncytia as well as a few giant cells morphologically similar to those of a foreign-body reaction (Fig. 4.63B).

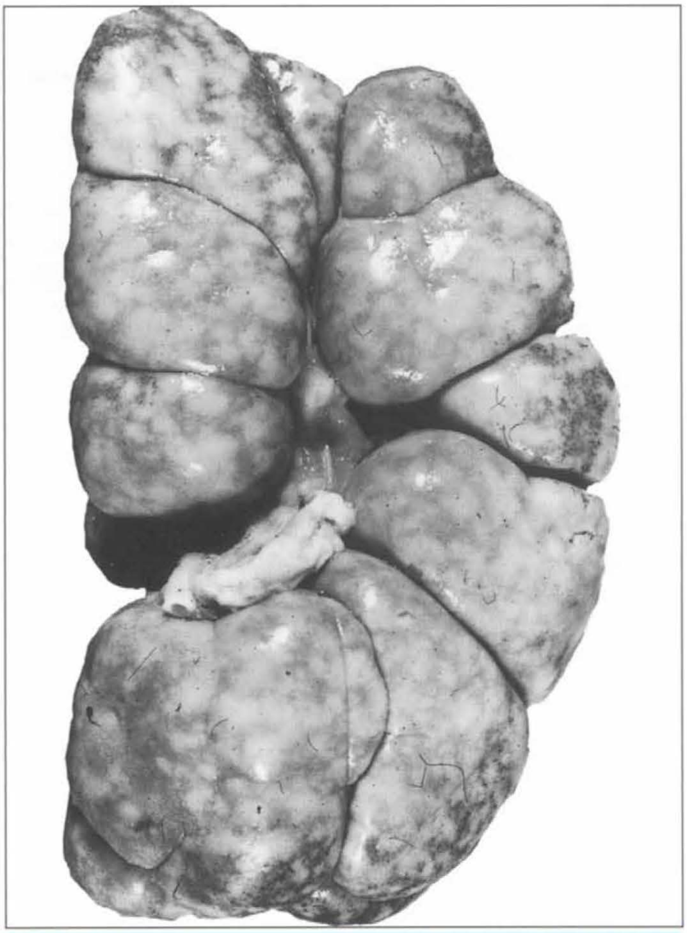

Figure 4.61 Interstitial nephritis caused by *Leptospira* serovar *pomona*, bovine kidney.

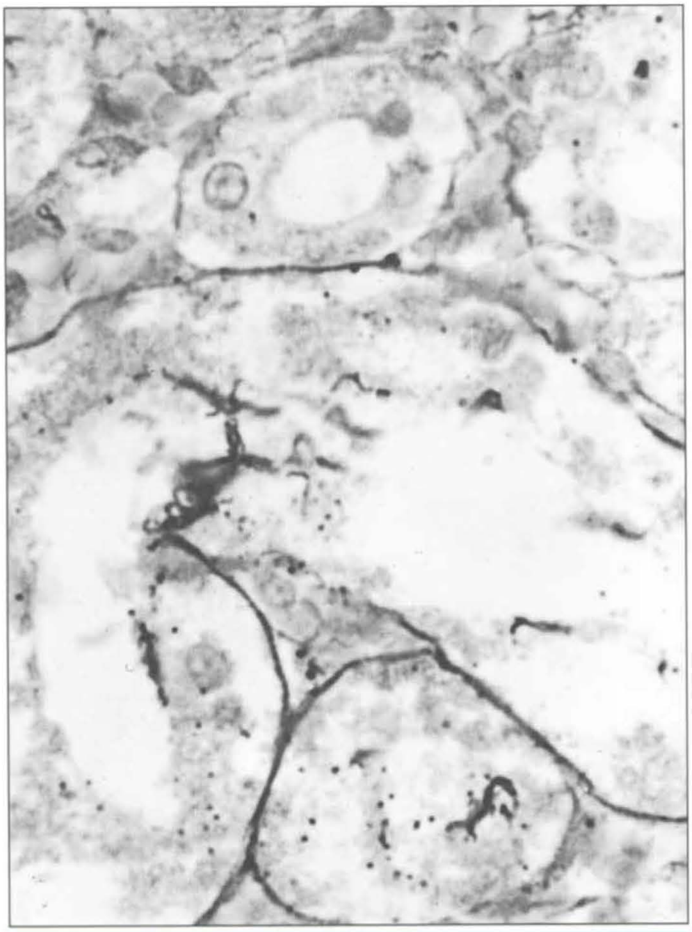

Figure 4.62 Intratubular leptospires in a bovine kidney; silver stain.

Aborted fetuses show no specific changes, although the organism can often be demonstrated in fetal tissues (see Vol. 3, Female genital system). The fetuses are sometimes edematous, but the edema is not specific, and in many cases there is advanced autolysis or putrefaction by the time the fetus is aborted. The placenta may show mild microscopic changes of placentitis; there is a tendency for it to be unduly retained.

Sheep, goats, and deer

Sheep, goats, and deer may be less susceptible than cattle to clinical leptospirosis. The major serovar in sheep is *hardjo*, which is maintained in a maintenance cycle independent of cattle. Other serovars may also cause disease. Acute disease in lambs resembles that described above in calves. *Hardjo* infection of ewes may cause late-term abortion, stillbirth, and weak lambs, and agalactia in recently lambed ewes. Other serovars may sometimes cause abortion. Leptospirosis in goats is not often described, but clinical and pathological changes are similar to those described for cattle. Fatal nephritis of farmed young red deer due to serovar *pomona* has been described in New Zealand. Kidneys were 2–3 times normal size and showed histologic changes of severe chronic active nephritis, characterized by extensive, segmental inflammation of cortical interstitial tissue.

Dogs

Dogs are susceptible to infection with a number of serovars, but those best recognized to cause severe disease are *canicola* and *icterohaemorrhagiae*. *Canicola* is host-maintained in the dog, but widespread use of vaccination has virtually eradicated this infection from dogs in many countries. *Icterohaemorrhagiae* is generally acquired from rats, and other serovars (*autumnalis*, *bratislava*, *pomona*) from their respective hosts (Table 4.3). Serological evidence of infection with serovar *bratislava* is increasingly recognized and this organism may cause nephritis and abortion in dogs; it has been suggested that this serovar is host-adapted to the dog, in addition to the pig and possibly the horse. Clinical infections with serovars *canicola* and *icterohaemorrhagiae* are now usually rare because of vaccination in dogs, but infection with other serovars may be underreported. In recent years, leptospirosis in urban dogs has resurged in northeastern North America and elsewhere, associated with *grippotyphosa*, *pomona*, possibly *autumnalis*, and rarely other serovars acquired from raccoons, from skunks, and to a lesser extent other wildlife found in suburban and urban environments. Clinically normal dogs can shed pathogenic leptospires in urine, which may pose a zoonotic risk; serologic testing is a poor predictor of urinary shedding. Current *canicola*- and *icterohaemorrhagiae*-based vaccines provide only serovar-specific protection.

It is not possible to separate, on the basis of clinical evidence, acute infections caused by different serovars, although, as a generalization, *icterohaemorrhagiae* exerts its effect more specifically on the liver, *canicola* on the kidney, and other serovars in a less severe way on both organs. *Icterohaemorrhagiae* is associated with severe icterus, and *canicola* with severe renal injury, but the syndromes shown by these and other serovars overlap.

Hyperacute infection, which is usually one of puppies and usually caused by *icterohaemorrhagiae*, is acute in onset, with the course of a fulminating septicemia; death occurs in a few hours to 2–3 days. There is fever, dehydration, hypersensitivity, and a marked tendency to hemorrhage, providing for hematemesis, melena, epistaxis, and petechiae on the mucous membranes. In the *acute disease*, in which icterus is a prominent feature, the onset may be sudden, with the development of icterus delayed, or the onset may be insidious, with icterus as the first abnormality observed. There is frequently an oculonasal discharge, which may suggest distemper, especially in younger animals. Body temperature is usually only mildly elevated at the time of clinical evaluation.

Widespread hemorrhages characterize both the hyperacute and the acute disease, although icterus is usually absent in the former. The most consistent gross lesions occur in the kidneys, and in acute cases consist of *subcapsular hemorrhages with multifocal ecchymotic and petechial hemorrhages throughout cortical areas but most prominent in subcapsular regions*. With chronicity, these foci become pale and the capsule is increasingly adherent. Residual lesions in dogs given viable *canicola* and killed 100 days later consisted of symmetrically enlarged kidneys with nodular and wedge-shaped lesions 4–8 mm in diameter at the corticomedullary junction. Lesions have been described in the liver of dogs with spontaneous infections of *grippotyphosa* that vary from gross enlargement, with focal lesions, sclerosis, ascites, and atrophy, to fibrosis and nodular hyperplasia.

In animals dying acutely, focal necrosis is frequent in the liver but may not be present. *The characteristic, but not specific, change is dissociation of the cells of the parenchymal cords.* The dissociated cells become discrete

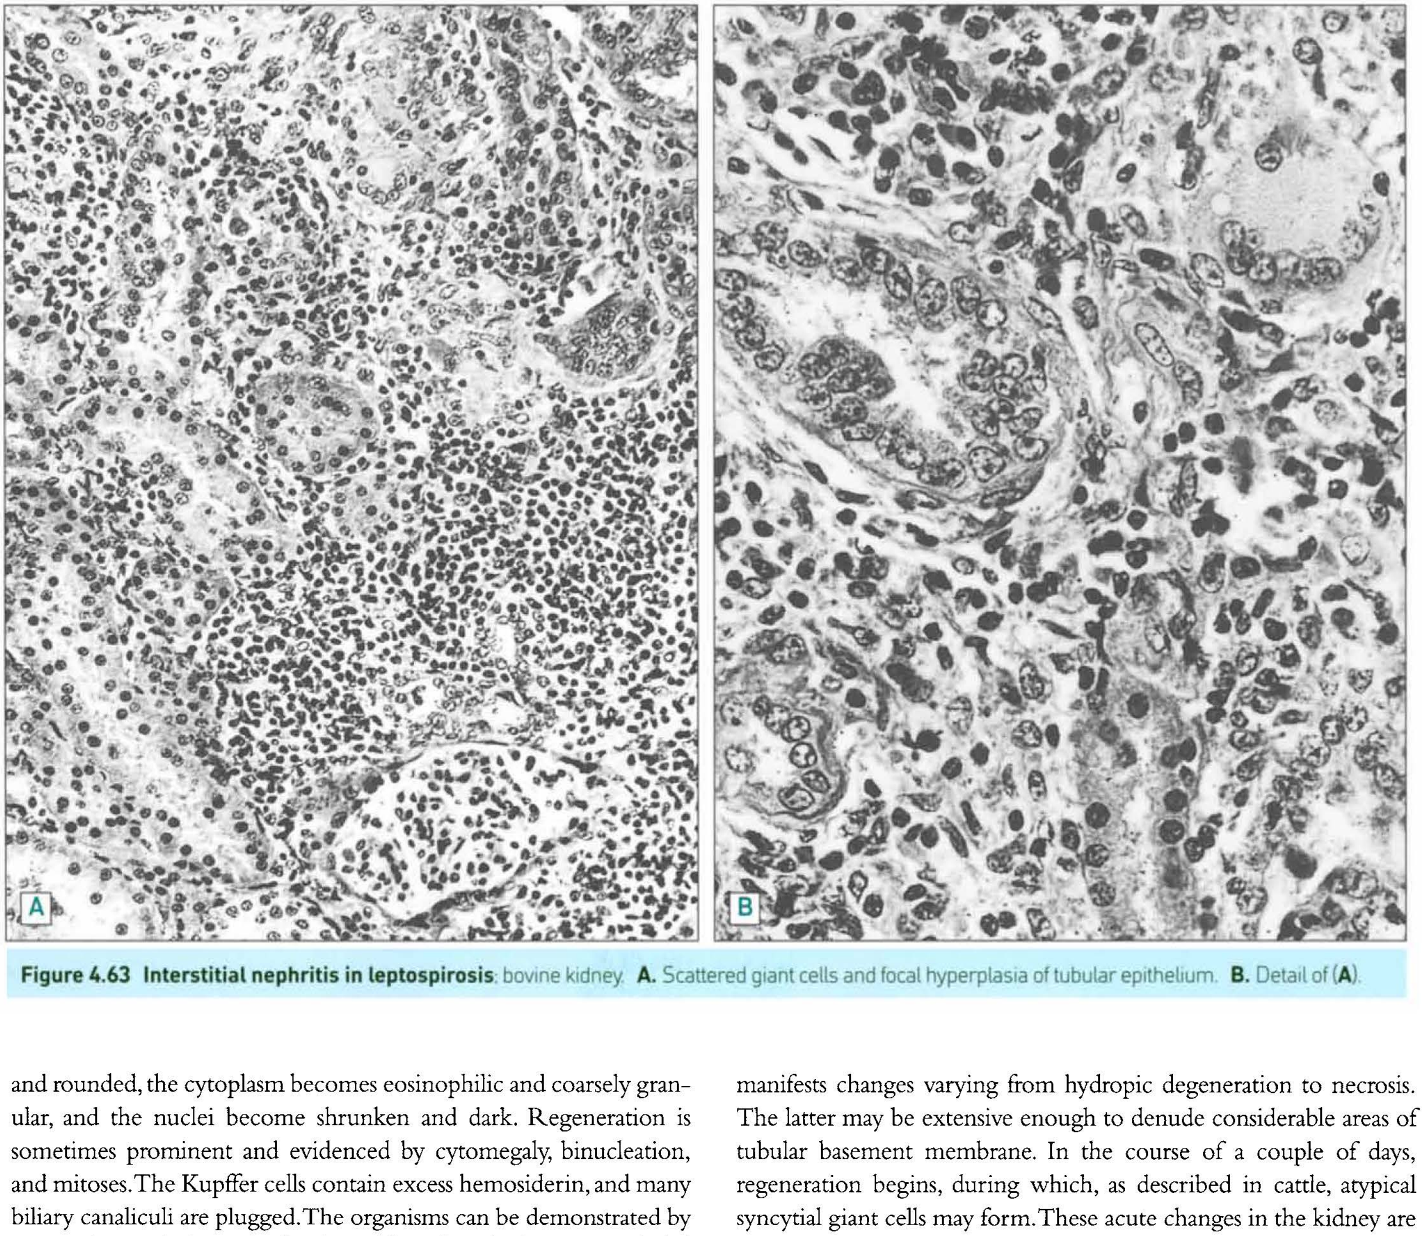

Figure 4.63 Interstitial nephritis in leptospirosis; bovine kidney. **A.** Scattered giant cells and focal hyperplasia of tubular epithelium. **B.** Detail of (**A**).

and rounded, the cytoplasm becomes eosinophilic and coarsely granular, and the nuclei become shrunken and dark. Regeneration is sometimes prominent and evidenced by cytomegaly, binucleation, and mitoses. The Kupffer cells contain excess hemosiderin, and many biliary canaliculi are plugged. The organisms can be demonstrated by appropriate techniques in the sinusoids and in the hepatic epithelial cells. Serovar *grippotyphosa* may cause chronic active hepatitis, with peribiliary fibrosis, and lobular disarray, with irregular fibrosis.

In dogs that survive the acute septicemic, icteric type of disease, or fail to manifest a septicemic phase at all, the clinical and pathological emphasis shifts from the liver to the kidneys. The resultant syndrome is the usual way in which infections by *canicola* and the incidental serovars (*grippotyphosa, pomona*) are manifest. The signs are those of *renal insufficiency* and vary in their severity and rapidity of progression; death may supervene rather rapidly from the renal failure of acute diffuse nephritis, but it also appears that initially inapparent infections, particularly with *canicola*, may set in motion a train of events in the kidneys that, after a long time, possibly many years, results in the renal failure of chronic interstitial nephritis. In these, *the renal syndromes*, the lesion caused directly by the leptospires is *acute diffuse interstitial nephritis*, from which recovery may occur to a focal pattern, or which may progress to *subacute and chronic interstitial nephritis*.

In the acute phase, the renal changes are severe but largely characterized by degeneration rather than by reaction. The brunt of the injury is borne by the convoluted tubules, the epithelium of which manifests changes varying from hydropic degeneration to necrosis. The latter may be extensive enough to denude considerable areas of tubular basement membrane. In the course of a couple of days, regeneration begins, during which, as described in cattle, atypical syncytial giant cells may form. These acute changes in the kidney are accompanied by interstitial edema and a diffuse but sparse infiltration by leukocytes, principally lymphocytes and plasma cells. Leptospires are demonstrable in the tubular epithelium and in the lumina of tubules, frequently in clusters. Early in the renal phase, the organisms may be found in any part of the cortex, but later they are more restricted in their distribution and are then mainly to be found in the more superficial, subcapsular areas. With chronicity, the interstitial cellular exudate is decreased and fibrosis increases, with mild diffuse and moderate focal interstitial sclerosis and thickened Bowman's capsule and basement membranes with focal periglomerular fibrosis. There is increased cellularity of the renal pelvis, and the fibrosis extends into the papillae. The lymph nodes and spleen may be enlarged and edematous or hemorrhagic, and microscopically there is depletion of lymphocytes and increase of sinusoidal reticular cells. Erythrophagocytosis is prominent.

Swine

Although any leptospiral serovar may cause disease in pigs, until recently the most important serovar recognized in North America was serovar *pomona* (type kennewicki), a subtype of which is host-adapted to swine. In Australia and some European countries, *tarassovi* (formerly *hyos*), another pig-adapted serovar, causes losses as serious as those of *pomona*. More recently, a new species, *Leptospira fainei*, has been isolated from pigs with reproductive problems in Australia, but its broad significance remains to be determined. Understanding of leptospirosis in swine is changing rapidly with the recognition of the widespread and dominant prevalence of antibodies to the Australis serogroup and the isolation of *bratislava* and *muenchen* from aborted and stillborn pigs. The role and importance of Australis serogroup leptospires are only partially understood, in part because of the difficulty of isolating these leptospires. Incidental infections with serovars *canicola, grippotyphosa, hardjo*, and other serovars have been locally important. Antibody to *icterohaemorrhagiae* is widespread, but the serovar is of rare disease significance.

Only a small proportion of infected animals develop clinical illness, usually an unrecognized transient episode of mild fever, anorexia, and depression. Hemoglobinuria and icterus may occur rarely in piglets.

The principal aspect of the disease in pigs, apart from transmissibility to other species, *is abortion and the birth of small litters of weak piglets*, which may reach outbreak proportions. This is particularly liable to occur if pregnant sows with no acquired immunity are exposed during the second month of pregnancy. Abortion is associated with heavy leptospiral infection of the fetus.

The usual pattern of leptospirosis in pregnant sows, caused by serovars other than those of the Australis serogroup, is for the litter to be delivered 1–3 weeks prematurely, with some of the fetuses dead and some born alive, only to die shortly afterward. The organism can usually be recovered from the fresher ones, some of which in each litter are expected to have lesions. Not all aborted fetuses in the litter will yield leptospires. Straw-colored pleural effusion, somewhat viscid, may be accompanied by effusion of lesser volumes in the other serous cavities. Petechial hemorrhages may be present in the pulmonary pleura, epicardium, renal cortex, and peripelvic tissue, and occasionally elsewhere. The liver and spleen are swollen and dark, and tan foci of necrosis, 2–5 mm in size, in the liver, especially near the margins, are characteristic when present.

Histologic changes are also inconstant, but part or all of the picture is usually seen in one or more of the piglets, especially in those dying at or very soon after birth. Hepatitis is acute, with infiltrated neutrophils and lymphocytes in portal areas and surrounding the foci of coagulative necrosis (Fig. 4.64A). Focal myocarditis with coagulative necrosis and mononuclear infiltration is less frequent than infiltration beneath epicardium and endocardium (Fig. 4.64B). These latter infiltrations, also of mononuclear cells, are light but quite diffuse. In addition to many minor foci of interstitial reaction in the kidney, large, fairly circumscribed infiltrates of mononuclear cells are present in the peripelvic parenchyma, sometimes involving

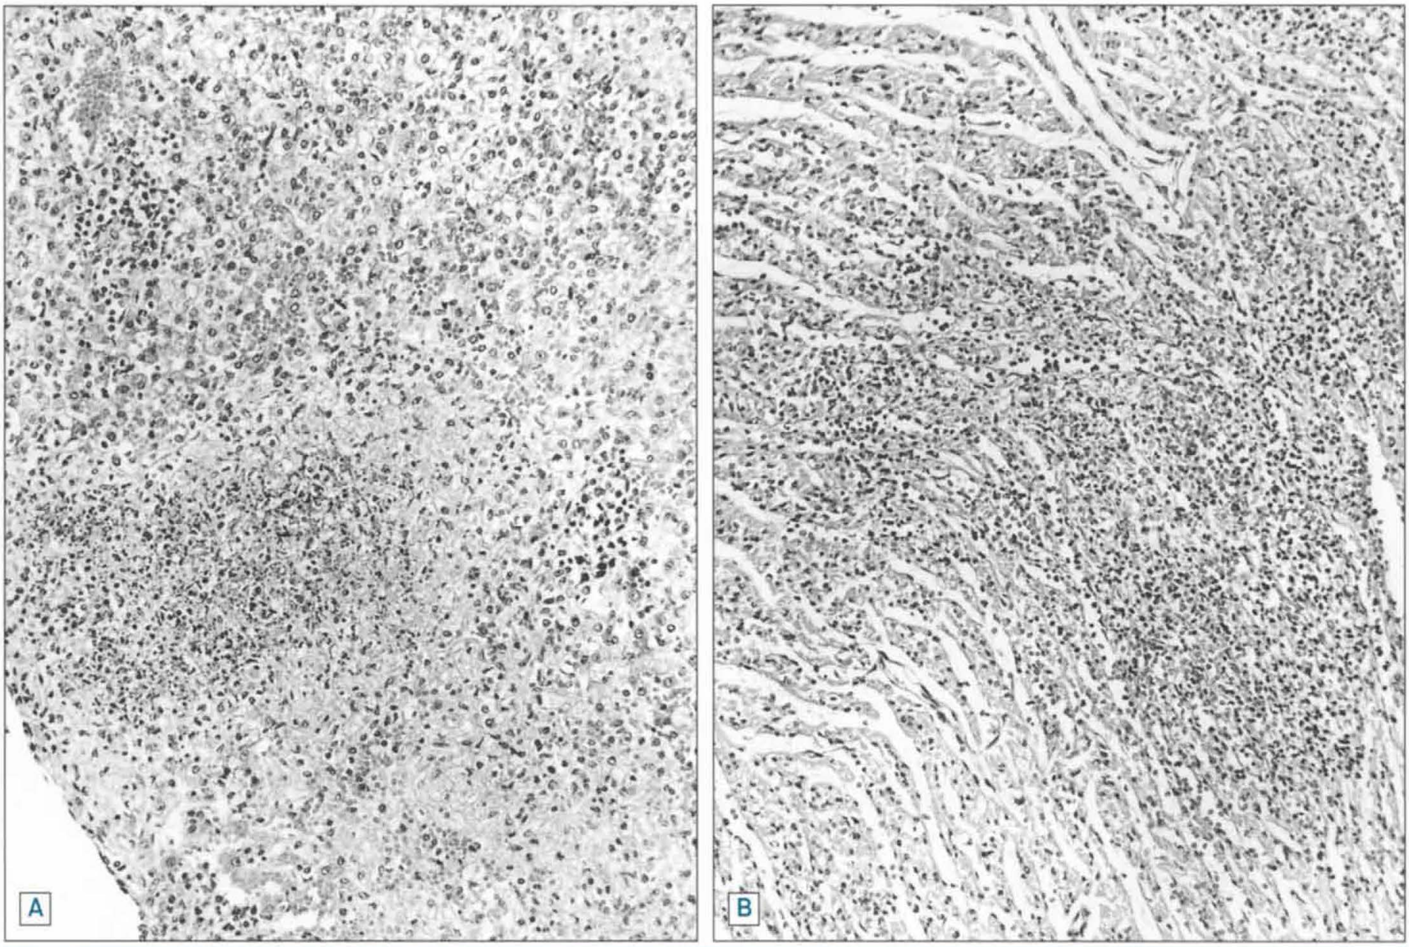

Figure 4.64 Leptospirosis in a porcine neonate. **A. Hepatitis** with subcapsular necrosis. **B.** Interstitial lymphocytic **myocarditis**.

the papilla (Fig. 4.65A) and encroaching on the parahilar cortex. The medullary tissues swarm with organisms (Fig. 4.65B).

The lesions as described are not specific for *pomona* infections. They have also been observed in *tarassovi* and can be anticipated with some other serovars.

Infection with serovars belonging to the Australis serogroup produce subtler losses than those described for *pomona* or other serovars. The lesions have not been described. In Northern Ireland and the USA, late-term abortion and stillbirth have been reported, characterized by the birth of live, dying, and dead piglets within a litter. Late-term abortion is less characteristic than production of small litters of viable piglets, accompanied by stillborn piglets and by piglets that die shortly after birth. Diagnosis is problematic because of the extreme difficulty of isolation of serovars *bratislava* and *muenchen*, but approaches include fetal and maternal serology, immunofluorescence of fetal lung and kidney homogenates, and in future PCR-based diagnosis.

A distinct *infertility ("repeat breeder") syndrome* associated with Australis serogroup infection has been described in Northern Ireland. Disease is most noticeable in sows bred to infected boars for the first time or when susceptible animals are introduced into infected herds. Serovars *bratislava* and *muenchen* are commonly isolated from the genital tracts of sows and boars in infected herds. Venereal transmission is thought to be common.

The majority of instances of chronic interstitial nephritis in pigs, lesions of which are often observed at slaughter, are leptospiral in origin, particularly associated with serovar *pomona*.

Horses

There is widespread serological evidence of leptospiral infection in horses but acute disease is apparently rare. Clinical features include fever, anorexia, depression, and icterus in the acute disease, and abortion, premature foaling, and chronic uveitis ("periodic ophthalmia") in the chronic disease. Improved diagnostic techniques have confirmed the importance of leptospirosis in horses. It is now recognized that horses are maintenance hosts for *bratislava*, that leptospires are involved in fatal hepatic and renal disease in foals, that leptospires may be more important in abortion than previously thought, and that leptospirosis continues to cause chronic uveitis in horses.

Leptospires of a variety of serovars have been isolated or identified by immunofluorescence in Northern Ireland in neonatal foals or adults with fatal icterus. Different serovars, including *bratislava, canicola, grippotyphosa, hardjo, icterohaemorrhagiae* but particularly *pomona*, may also cause subacute disease characterized by fever, but inconstantly by icterus, in adults. Although of generally minor significance per se, these infections have important chronic sequelae in the form of abortion or chronic uveitis. In North America, serovars in leptospiral

abortion are, in order of importance, *pomona, grippotyphosa*, and *bratislava*, the first two being incidental infections. Abortion therefore tends to be seasonal (late fall and early winter). *Giant cell hepatitis in aborted fetuses* has been associated with leptospiral infection; the lesions were characterized by dissociation of hepatocytes, disruption of hepatic cords, and numerous large, multinucleated hepatocytes. Recurrent uveitis may develop several months after leptospiral infection, particularly with serovar *pomona*. Antibody in the aqueous humor of the eye may considerably exceed serum antibody and assist in the diagnosis in such cases. Use of PCR and of isolation techniques has shown the presence of leptospiral DNA or organisms in a high proportion of these cases.

Pyelonephritis

Pyelonephritis is inflammation of the pelvis and renal parenchyma, usually resulting from infection ascending from the lower urinary tract; the hematogenous route of infection is very uncommon. It is characterized by inflammation, necrosis, and eventually deformity of the calyces, in association with areas of tubulointerstitial inflammation and necrosis, and is hence distinguishable from other forms of nephritis. It is usually accompanied by ureteritis and cystitis. In *acute pyelonephritis*, cellular infiltration and necrosis predominate, with pelvic and medullary involvement more severe and advanced than involvement of the cortex. In *chronic pyelonephritis*, fibrosis replaces inflammation. In both cases, the disease process is asymmetrical within the kidney, and chronic pyelonephritis may produce very irregular contracture of the kidneys with pelvic deformities. **Pyonephrosis** is the term applied to severe suppuration of the kidney in the presence of complete or nearly complete ureteral obstruction; the infected hydronephrotic kidney is converted to a sac of pus. Suppuration may extend through the renal capsule during the course of pyelonephritis to produce a **perinephric abscess**.

The pathogenesis of pyelonephritis begins with establishment of infection in the lower urinary tract; urinary tract infection in general is dealt with in the section on Cystitis, below. Organisms involved in urinary tract infection are usually endogenous bacteria of the bowel and skin, such as *Escherichia coli*, staphylococci, streptococci, *Enterobacter, Proteus*, and *Pseudomonas*, and more specific urinary pathogens, such as *Corynebacterium renale, C. cystitidis*, and *C. pilosum* in cattle, and *Actinobaculum (Eubacterium) suis* in pigs. Mycoplasmas are rarely involved in cattle. Infection is often mixed, and while *C. renale* may be present in bovine pyelonephritis, and is an obligate parasite of urinary mucosae, various enteric pathogens may be of more pathogenetic importance. Fungal infection is a rare cause of pyelonephritis in dogs.

Virulence of bacteria in the urinary tract, as elsewhere, is enhanced by the presence of pili on their surface. Pili assist adhesion of *C. renale* to urinary epithelium; this process is pH-dependent. The type of pili expressed by the bacteria may also be important later in the course of pyelonephritis; type 1 fimbriate *Escherichia coli* induce greater activation of neutrophils and hence more renal scarring than do nonfimbriate or P-fimbriate *E. coli*.

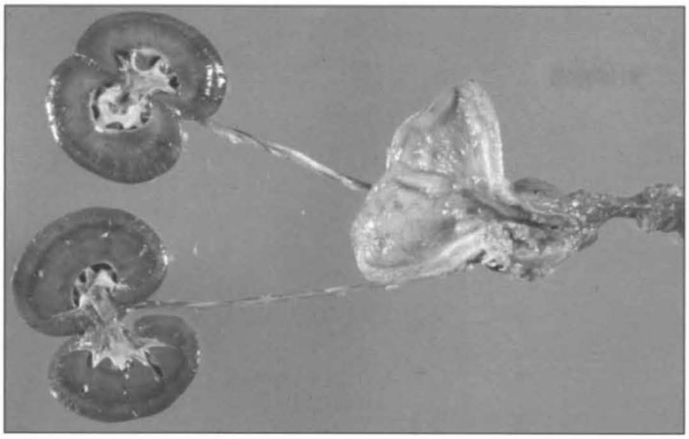

Figure 4.66 Prostatitis, hydronephrosis, and **pyelonephritis** in an 8-year-old male dog.

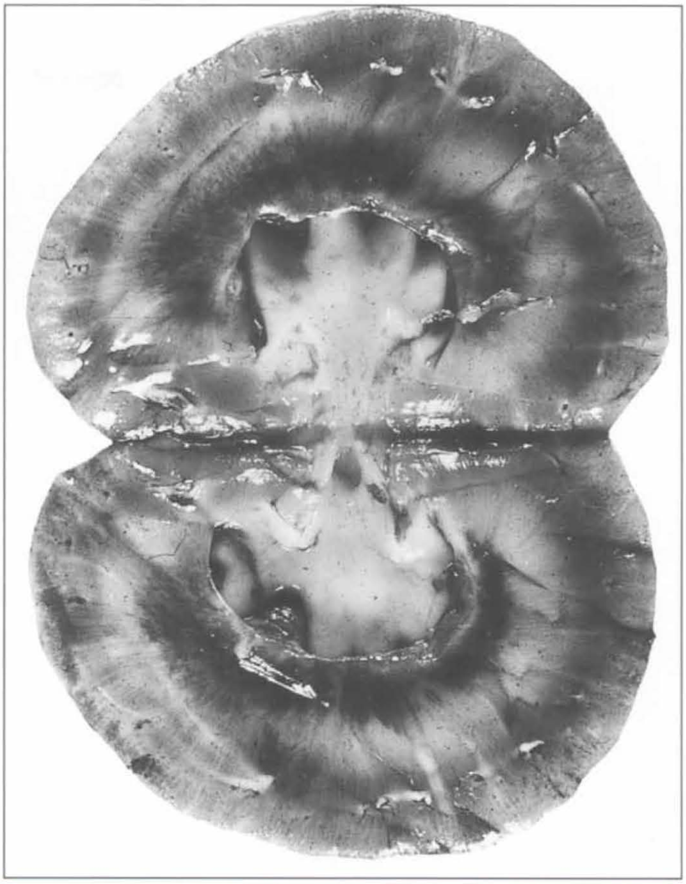

Figure 4.67 Acute pyelonephritis in a dog. There is ulceration of the renal crest and hemorrhage in medulla; pale streaks extend to the cortical surface.

One of the *urinary tract defenses* against bacterial infection and colonization is shedding of mature epithelial cells with attached bacteria. Normal voiding of urine, plus immune and other mechanisms, usually maintains sterility of the bladder, but once bacteria enter the bladder, e.g., via catheterization, they grow well in urine of low osmolality or alkaline pH. *Stasis of urine* is an important predisposing factor in the pathogenesis of cystitis and of pyelonephritis. Urinary obstruction may be caused by ureteral anomalies in young animals, kinked ureters in pigs, pregnancy, urolithiasis, and prostatic hypertrophy (Fig. 4.66). *Females are predisposed to urinary tract infection* because of their short urethras, urethral trauma, and possibly due to hormonal effects. Urethral catheterization can carry bacteria into the bladder. Clinically, urinary infection is indicated by bloody or cloudy urine, with pyuria and bacteriuria.

Once infection is established in the bladder, probably the most significant mechanism in causing renal infection is **vesicoureteral reflux**. This retrograde flow of urine up the ureters and into the kidney (*intrarenal reflux*) during micturition may carry bacteria as far as the urinary space of glomeruli. Reflux may occur during micturition, especially if there is urinary obstruction, or as a result of external compression of the bladder, as occurs during manual compression of the bladder in dogs and cats for collection of urine samples. Swine have a long intravesical ureter – 5 mm at birth, 36 mm at maturity – that should impede reflux in mature animals. Vesicoureteral reflux is very common in puppies, and is a function of the short intravesical length of the ureters and hence an easily overcome vesicoureteral valve; reflux decreases with age and the development of greater intravesical length of the ureter and its more oblique entry through the bladder wall. Vesicoureteral reflux of sterile urine does little renal damage; the ureteral muscular layers may hypertrophy. Cystitis may alter normal ureteral peristalsis, perhaps causing reversed peristaltic waves. Hence, persistent renal infection may result from vesicoureteral reflux, and possibly from reversed peristalsis, in animals with bladder infection and thus contribute to chronic active pyelonephritis. Progression of pyelonephritis probably depends upon persistence of bacterial infection, or at least of bacterial antigens.

For a number of reasons, *the medulla is the part of the kidney most susceptible to infection*. It is relatively hypoxic because of the low hematocrit in vasa recta; hypertonicity depresses the phagocytic activity of leukocytes, and ammonia may interfere with activation of complement. In pigs, the renal poles are more susceptible to infection because the collecting ducts of their compound papillae do not collapse as readily as do those of the simple papillae of the central lobes, when exposed to the increased pelvic pressure of vesicoureteral reflux; hence, intrarenal reflux is more common at the poles. Invasion of the kidney from the pelvis probably progresses by way of the collecting ducts, as is suggested by the early development of lines of suppuration along the straight tubules and the presence of bacterial colonies in the tubules, and by direct invasion across the degenerate eroded pelvic epithelium.

Pyelonephritis is often bilateral, but not necessarily symmetrical. *Acute disease is seen most commonly in sows, and chronic pyelonephritis in cows and dogs*. A general description will be given of acute and chronic pyelonephritis before species differences are noted in more detail. **Acute disease** characteristically begins with necrosis and inflammation of papilla or renal crest ("necrotizing papillitis") in an irregular pattern (Fig. 4.67). Bacteria may be abundant in the collecting tubules (Fig. 4.68). Associated wedge-shaped areas of parenchyma are swollen, dark-red, and firm. Hyperemia subsides and *suppurative tubulointerstitial nephritis and tubular necrosis* then predominate in these radially distributed wedges. Tubules are obliterated by the inflammation, tubular obstruction and dilation occur, and glomeruli, although initially resistant, may be obliterated. Leukocytic casts are present in tubules, and hence may be found on urinalysis. As the process becomes **chronic**, mononuclear cells replace neutrophils, and fibrosis proceeds and

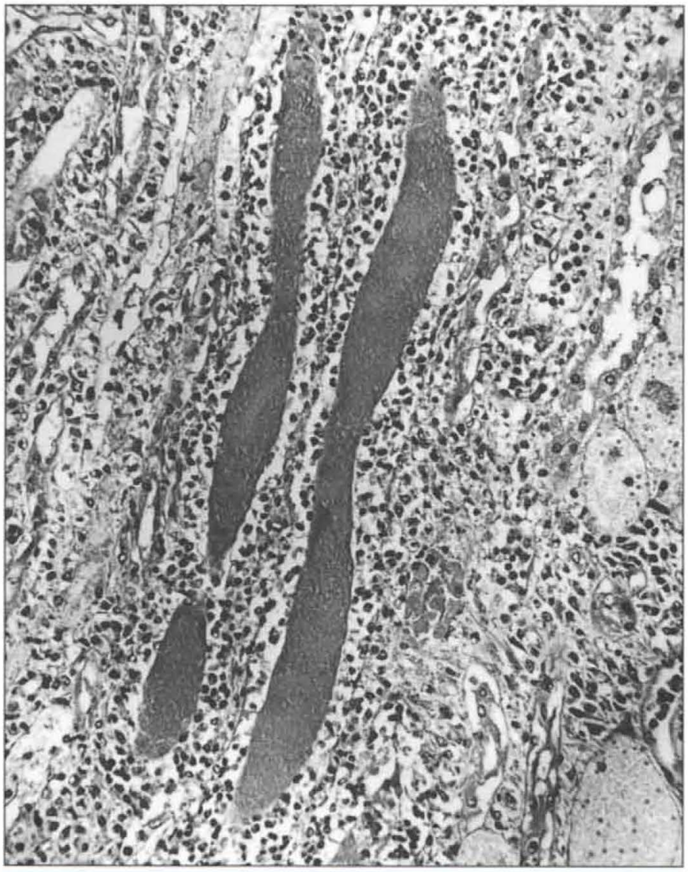

Figure 4.68 Acute ascending pyelonephritis in a cow. Bacterial colonies are present in collecting tubules, with suppuration.

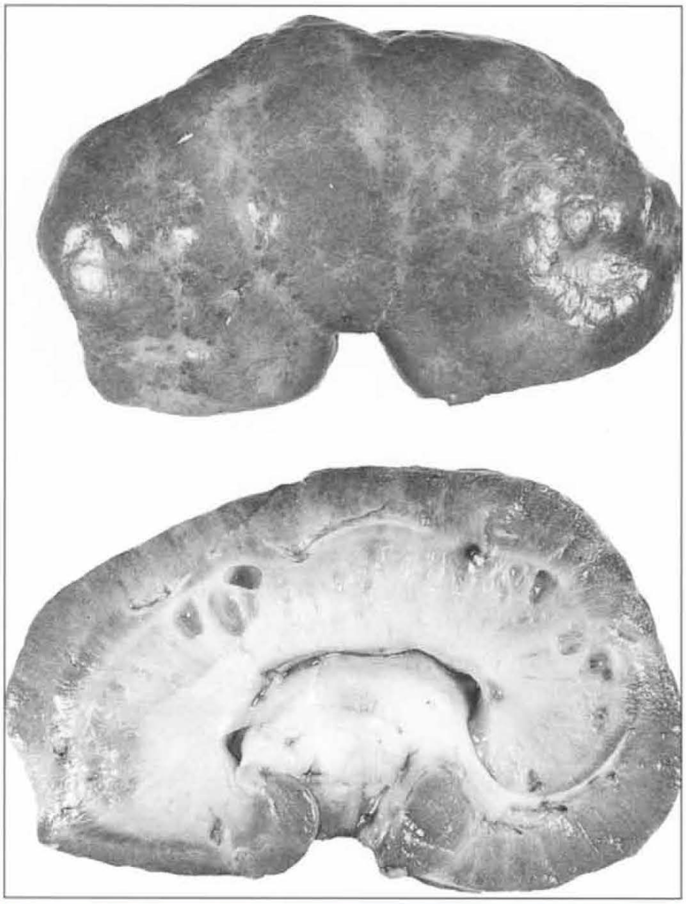

Figure 4.69 Chronic pyelonephritis in a dog. Ulceration of renal crest and deep irregular scars that are most prominent at the poles.

eventually predominates. Contraction of the scars and loss of renal substance result in a wide variety of patterns of renal scarring, usually with deep cortical depressions. The *scars in pyelonephritis* extend from capsule to pelvis and are distinguished from those of other nephritides and infarcts by the associated fibrosis and deformities of the renal papilla and dilation of calyces and pelvis. The pelvis often contains exudate and debris. The papillary defects may be small and difficult to detect in mild cases. More or less total involvement of the kidney may produce a firm pale shrunken kidney with an irregular surface (Fig. 4.69) that may be difficult to differentiate from other end-stage kidneys resulting from ischemic lesions.

In **dogs** and **cats**, acute pyelonephritis is not often detected, but scars attributed to chronic pyelonephritis are common. In dogs, accumulation of colloid-like material in tubules and glomerular capsules dilated due to scarring may produce a thyroid-like histologic appearance ("thyroidization") (Fig. 4.70). Calculi may form in the pelvis on the nidi provided by cellular debris.

In **swine**, acute pyelonephritis is seen occasionally, but the chronic disease is rare. Shortening of the intravesical portion of the ureter and widening of the ureteric orifices, as occurs in sows as a consequence of cystitis, may facilitate vesicoureteral reflux and development of pyelonephritis. *Acute pyelonephritis occurs in sows postpartum or 3–4 weeks postbreeding*; young males are occasionally affected, and some of these have urinary tract anomalies. Blood-stained urine or discharge may be seen, but it is not unusual for prostration and death to occur in 12 hours or so. Severe cystitis and

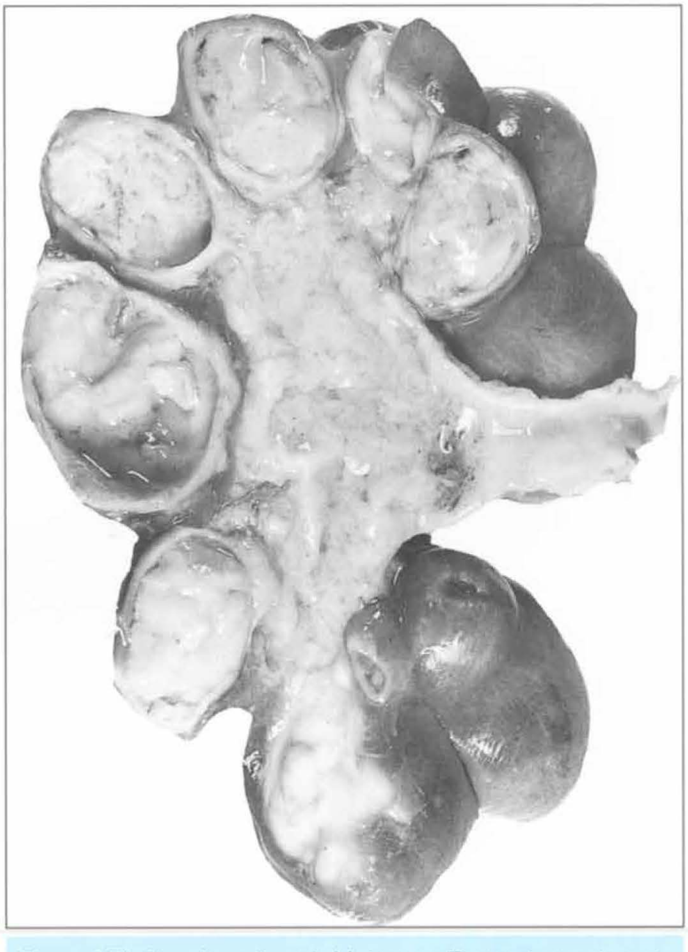

Figure 4.73 Chronic pyelonephritis in a cow. The renal parenchyma is scarred and atrophic, and exudate fills the distended, thickened calyces.

ureteritis are usually present with yellow-brown or bloody mucoid exudate. The renal poles are preferentially involved, and the infection may be fulminant and erupt through the renal capsule to produce retrorenal hemorrhage and inflammation. Less severe examples of tubulointerstitial nephritis also occur, and are seen as pale areas of cellular infiltration involving wedges or entire lobes.

In **cattle**, chronic pyelonephritis is a significant sporadic disease in cows, but acute pyelonephritis (Fig. 4.71) is usually only an incidental finding. Tubulointerstitial nephritis in affected cows may be minimal, and slowly progressive, suppurative destructive papillitis may predominate. The medulla of each lobe is fairly uniformly destroyed (Fig. 4.72). Eventually the cortex remains as a narrow capsule surrounding large amounts of pus in the calyces (Fig. 4.73). Alternatively, and perhaps more commonly, the pattern of radially distributed tubulointerstitial nephritis develops as described above. Enlarged tan lobes are granular due to interstitial inflammation, and interstitial fibrosis may become extensive (Fig. 4.74). Rupture of the kidney occurs in males with obstructive urolithiasis after development of fulminant pyelonephritis, but rupture is less common in cattle than in swine. Pyelonephritis is uncommon in **sheep**.

Pyelonephritis is also uncommon in **horses**, but may occur for the usual pathogenetic reasons; it can cause renal hemorrhage that may first become evident because of hematuria.

Hypercalcemic nephropathy

Hypercalcemia occurs often in dogs and cats, and may be sufficiently severe to cause renal failure (hypercalcemic nephropathy).

- The *leading cause is the hypercalcemia of malignancy, or pseudohyperparathyroidism*, a paraneoplastic syndrome. A nonendocrine tumor, usually lymphosarcoma or adenocarcinoma of the apocrine glands of the anal sac, stimulates bone resorption via parathyriod hormone-related protein (PTHrp), a peptide that resembles parathyroid hormone (see Vol. 3, Endocrine glands and Vol. 3, Hematopoietic system). Hypercalcemia of malignancy is less commonly caused by osteolytic neoplasms.
- Poisoning by *rodenticides containing vitamin D* (0.075% cholecalciferol) has become an important cause of hypervitaminosis D and hypercalcemia in dogs and cats; the same syndrome follows ingestion of *human antipsoriatic preparations* that contain synthetic vitamin D analogues, e.g., calcipotriol, tacalcitol. Diagnosis of cholecalciferol rodenticide poisoning may be aided by determination of the renal $25(OH)D_3$ concentration; as well, the renal calcium to phosphorus ratio is <0.1 in normal dogs, but 0.4–0.9 in cholecalciferol-poisoned dogs, and >2.5 in dogs dead of ethylene glycol poisoning.
- *Other less common causes* of hypercalcemia are primary hyperparathyroidism, chronic renal failure with secondary hyperparathyroidism, and hypoadrenocorticism.
- Hypercalcemia resulting in nephrocalcinosis and mineralization of other soft tissues is well known in grazing animals. Leading examples of *plants containing vitamin D_3* sterol are *Solanum malacoxylon, Cestrum diurnum, Trisetum flavescens*, and *Medicago sativa.*

Hypercalcemia results in inactivation of adenyl cyclase, and hence decreased cyclic adenosine monophosphate formation; sodium transport is impaired in the ascending limb of the loop of Henle, the distal tubule, and collecting ducts. Natriuresis results. As well, hypercalcemia interferes with antidiuretic hormone receptors in the collecting ducts, resulting in renal diabetes insipidus. The resultant polyuria and compensatory polydipsia are reversible if the primary cause of the hypercalcemia is removed. If hypercalcemia persists, *progressive renal mineralization* occurs, beginning with tubular basement membranes and epithelium, particularly in the outer zone of the medulla (Fig. 4.75) and eventually involving the interstitium, vessels, and glomeruli. Tubular epithelial mineralization and cast formation cause tubular obstruction, and eventually loss of nephrons.

Other less significant examples of renal mineralization also occur. The deposition of calcium salts in the form of clumps of granules

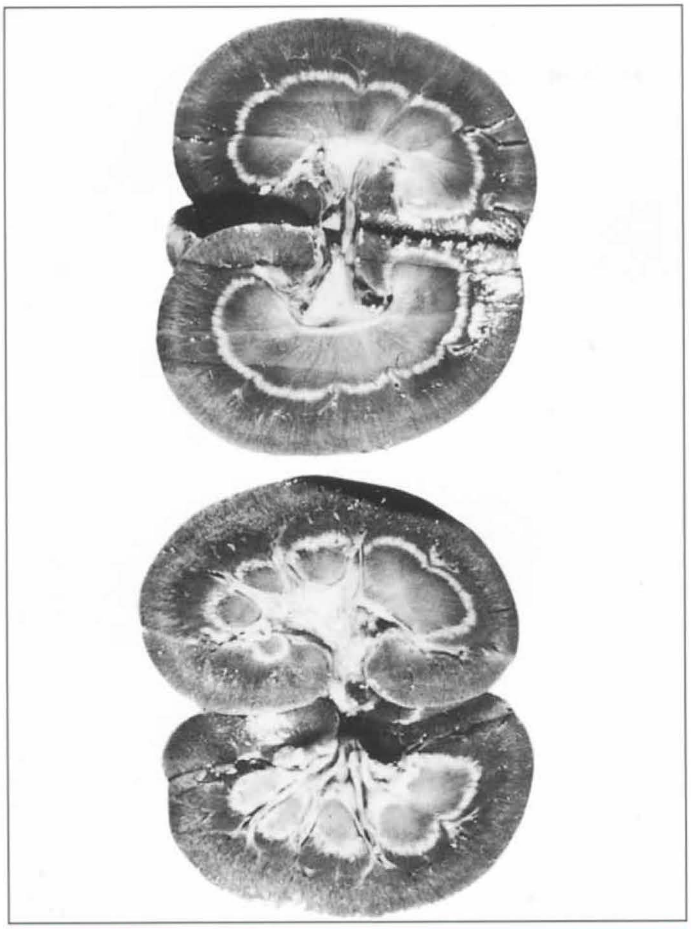

Figure 4.75 Hypercalcemic nephropathy in a dog.

in the lumen and lining of collecting tubules and in the adjacent interstitium is rather common. They are associated with hypomagnesemia in some species; they are not significant.

Mineralization is very common in dogs, most unusual in other species, and occurs very quickly in casts, in dead and degenerate epithelium, and in injured basement membranes. In uremia, it may also involve the glomeruli and small blood vessels. Renal mineralization is a frequent result of secondary hyperparathyroidism induced by *chronic renal insufficiency* and coexists with similar deposits in the lungs, gastric mucosa, and other organs (see section on Renal disease, renal failure, and uremia, above). Dogs fed a high-phosphorus diet similarly develop diffuse renal mineralization.

Miscellaneous interstitial lesions

Extramedullary hematopoiesis occurs in the kidneys of dogs under a variety of circumstances, all of which probably have a common denominator of bone-marrow depression or injury. When the kidneys are sites of hematopoiesis, it is usual that the liver, lymph nodes, spleen, adrenals, and lungs are also. The most pronounced hematopoiesis occurs in canine pyometra.

Bone occasionally develops in association with urinary tract tissue, for example, following urinary tract surgery or in hydronephrotic kidneys. Transitional epithelium stimulates transformation of mesenchymal cells to osteoblasts.

Renal telangiectasis occurs in cattle, dogs, cats, mink, and ferrets; it is familial in Pembroke Welsh Corgis. It is a rare cause of hematuria in dogs.

Parasitic lesions in the kidneys

Toxocara canis

The most common parasitic lesion in the kidneys is the focal scar of reaction to the larvae of *Toxocara canis* in canine kidneys (Fig. 4.76A). These small granulomas, 2–3 mm in diameter, are found on the surface and cross-section of the cortex. In the early stages of development, the lesions are gray-yellow and have soft centers; later they become firm and white and the superficial ones cause dimpling of the cortex. *Each granuloma surrounds an entrapped larva* (Fig. 4.76B), which is usually hard to find in sections. The granuloma is largely composed of epithelioid cells and lymphocytes with an occasional eosinophil. Healing of the lesions occurs after the death and removal of the larvae; the residual scars are typical and consist of dense concentrically arranged fibrous tissue. Similar lesions are produced in calves by the migratory larvae of *T. cati* and *T. canis* acquired by fecal contamination of feed, and by *T. (Neoascaris) vitulorum,* especially in buffaloes. In cats, *T. canis* can produce disseminated granulomatous disease marked by the presence of large numbers of eosinophils in granulomas. Occasionally, ascarid larvae are found in other sites occupying granulomas similar to those in the canine kidney (Fig. 4.77).

Stephanurus dentatus

Stephanurus dentatus is the *kidney worm of swine.* It is widely distributed in tropical and subtropical countries, and the prevalence in grazing swine in such areas can be very high. *The worms encyst in perirenal fat and adjacent tissues, the cysts communicating with the renal pelvis.*

The life cycle of *S. dentatus* can be direct or, experimentally, involve earthworms as transport hosts. The latter mechanism has not been shown to occur naturally. Eggs are passed in the urine of the pig, sometimes in immense numbers, and the larvae hatch in 2–3 days. The infective stages are vulnerable to sunlight and drying. Infection may occur by penetration through the skin or by ingestion, and prenatal

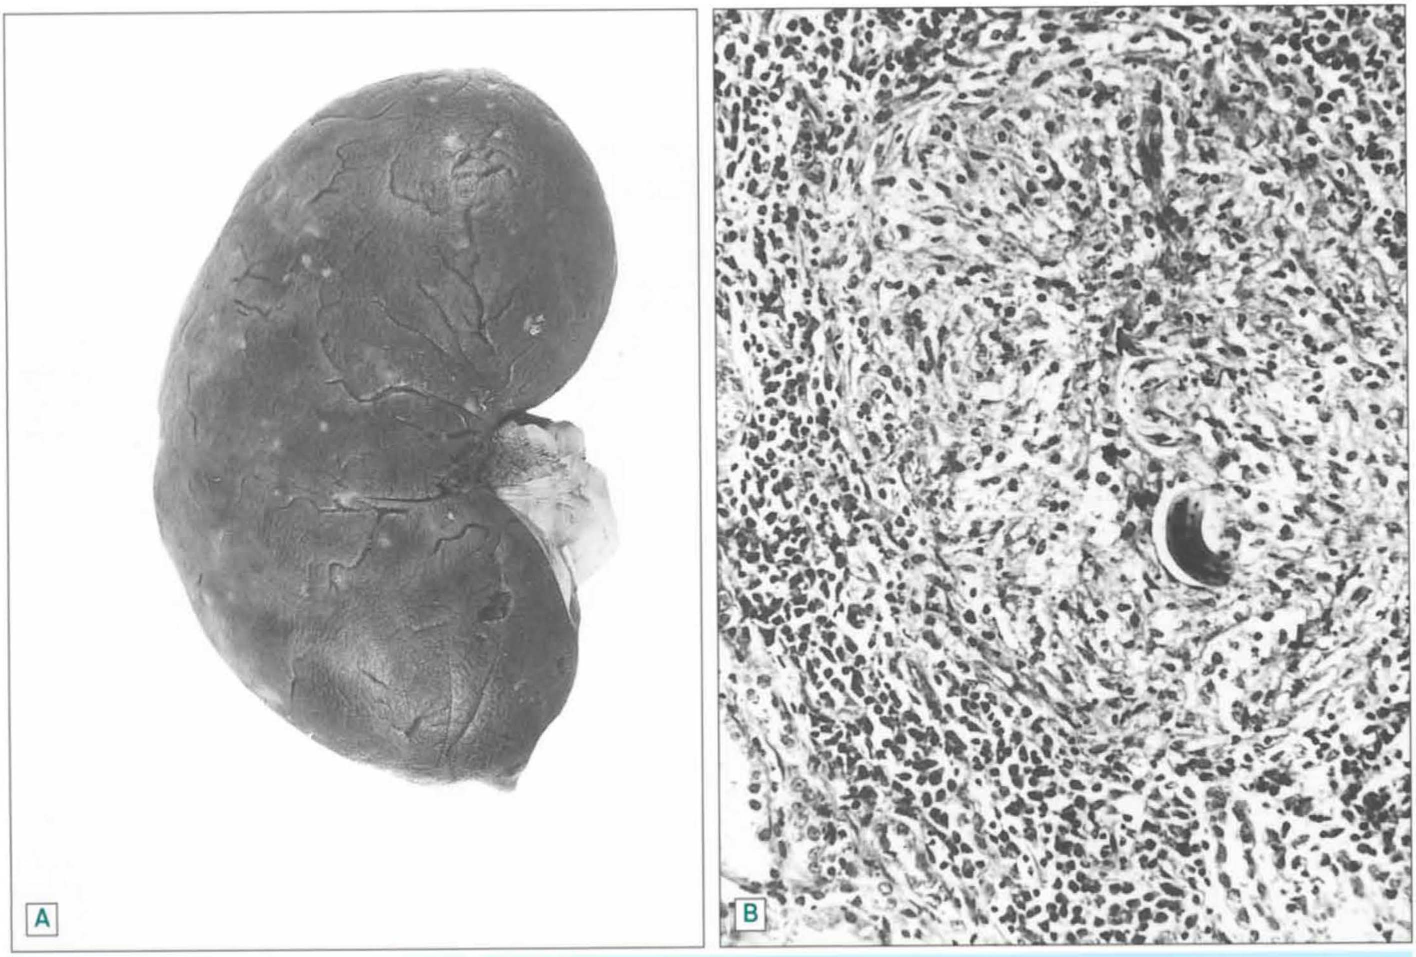

Figure 4.76 A. Cortical granulomas caused by *Toxocara canis* in a canine kidney. **B.** Section from (**A**) showing larva in granuloma.

infections occur. Following oral infection, third-stage larvae migrate from the small and large intestine via the portal circulation and mesenteric lymphatics to the liver. A few migrate across the peritoneal cavity. After skin infection, most larvae migrate to the lungs and reach the intestines following tracheal migration. Deaths due to peritonitis and intestinal intussusception occur in some pigs 20–30 days after heavy infections and are associated with larval migration from the mesenteric nodes to the liver. The infective larvae migrate in the tissues of the pig, especially in the liver, where they may stay for several months. The hepatic migrations provoke considerable injury and severe interstitial hepatitis with lesions of the same character but much more severe than those produced by the larvae of *Ascaris suum*. *S. dentatus* also produces portal phlebitis with thrombosis in some pigs (see Vol. 2, Liver and biliary system). The liver is usually enlarged and may be very hard. It is pale and the lobulation is remarkably emphasized by the perilobular fibrosis that develops. Many lobules are obliterated by contracting and proliferating scar tissue in the portal areas, and all lobules are more or less reduced in size in the diffuse hepatitis of heavy or prolonged larval infestation.

Many larvae are destroyed in the liver, being encapsulated in small abscesses that are eventually obliterated. *From the liver, the larvae migrate across the peritoneal cavity to the perirenal region.* Many become encysted in abscesses in adjacent tissue, especially the pancreas, and it is not unusual for some to invade the vertebral canal and cause paraplegia. The definitive site is the tissue around the renal pelvis and ureter wherein the adults encyst (Fig. 4.78). Occasionally, the cysts may be found in the kidney itself. The cysts communicate with the lumen of the ureter, allowing escape of eggs. Developmental stages in the definitive host take a long time, and patency may not be established for 9 months or more. Once patency is established, the mature females may lay eggs for 3 years or longer.

Dioctophyma renale

Dioctophyma renale is the *giant kidney worm*, the largest of parasitic nematodes. It has a worldwide distribution but its incidence is unknown. The worm is red and cylindrical, and in dogs the females measure 20–100 cm long and 4–12 mm in diameter. Males are 14–45 cm long and 4–6 mm in diameter. *D. renale* is usually found in dogs, mink, cats, and other fish-eating mammals, but is recorded in the pig, ox, and horse. The definitive hosts are wild fish-eating carnivores, mink in particular, in which the worms are smaller and usually located in the kidney.

The life cycle involves two aquatic intermediate hosts. Eggs passed in the urine are very resistant to the external environment and may survive for 2–5 years. Embryonation requires 1–7 months depending on the climatic conditions. The embryonated eggs are ingested by the intermediate hosts, which are aquatic oligochaetes ("mud worms;" *Lumbriculus variegatus*), and develop through first and second larval stages. Third- and fourth-stage larvae can either

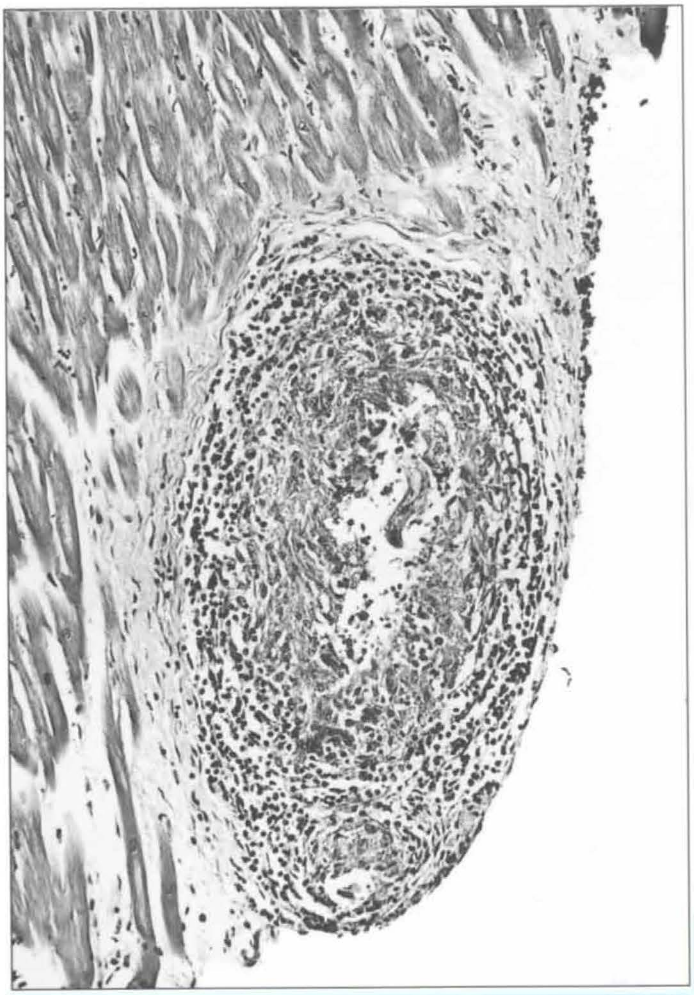

Figure 4.77 Myocardial granuloma containing an **ascarid larva**, from a dog. (Courtesy of GW Thomson.)

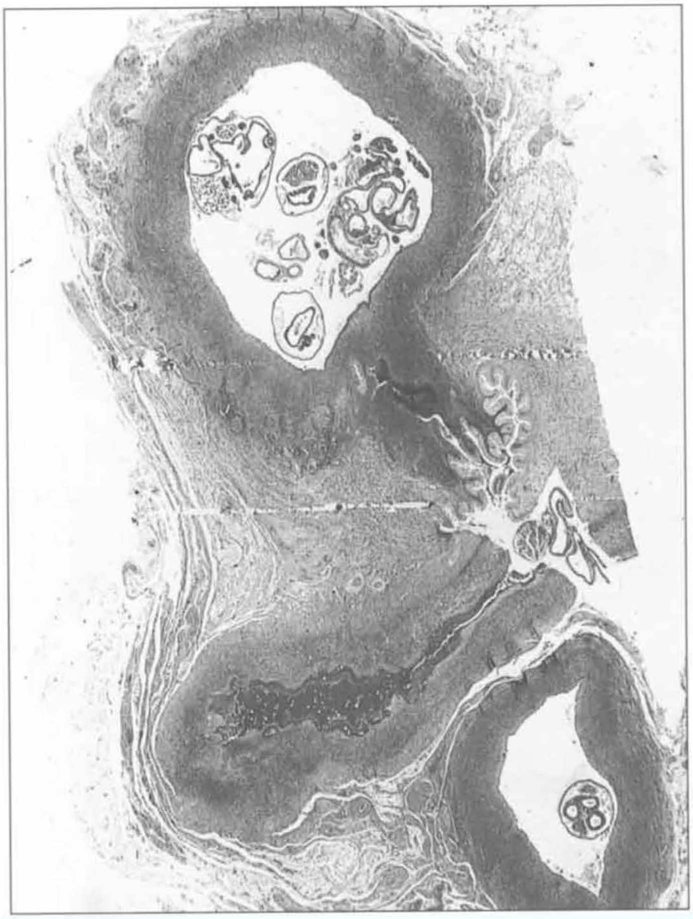

Figure 4.78 Encysted **Stephanurus dentatus** in hilus of a porcine kidney.

develop directly in the worm, or within fish or frog intermediate hosts, e.g., the northern black bullhead (*Ictalurus melas*), green frog (*Rana clamitans*). Following ingestion by mammals, infective third- or fourth-stage larvae penetrate the gut wall and migrate across the peritoneal cavity to the kidney. The life cycle from egg to adult requires 3.5–6 months, but may take 2 years.

The adult worms live in the renal pelvis but may encyst in a body cavity, the uterus, mammary gland, or bladder. The adults are very destructive, causing initially hemorrhagic pyelitis that shortly becomes suppurative, and the parenchyma is progressively destroyed until only the tunic contains the worm and exudate (Fig. 4.79).

Dogs, the domestic species usually affected by *D. renale*, are regarded as abnormal hosts because usually only one or a very small number of worms is present, and worms of both sexes are found in only about one-third of infections. *Intrarenal parasites in dogs and mink are more common in the right kidney than the left*, but in ~60% of infected dogs, parasites are in the peritoneal cavity only. In the peritoneal cavity, *D. renale* often entwines a lobe of the liver and may cause erosion of the hepatic capsule with hemoperitoneum, or produce infarction and rupture. On occasion they rear up to startle surgeons engaged in exploratory laparotomy. Simultaneous renal and peritoneal infections occur in ~15% of dogs. Thus, most canine infections are not patent.

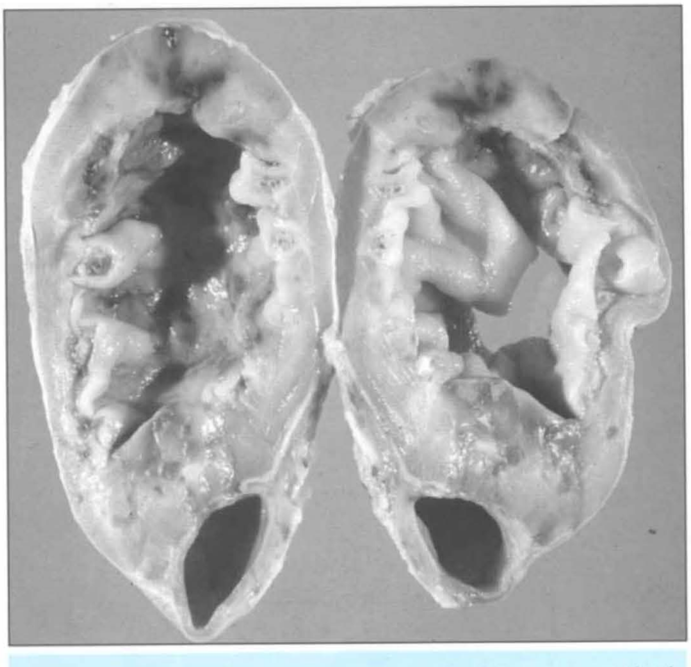

Figure 4.79 Marked destruction of renal parenchyma as a result of **Dioctophyma renale** infection.

Pearsonema (Capillaria) plica

Pearsonema (Capillaria) plica may be found in the lumen of the renal pelvis, ureter, or urinary bladder of dogs, foxes, and smaller carnivores. Although widely distributed, it is not a common parasite. The life cycle is not clearly known but is probably indirect, earthworms being intermediate hosts. Ingestion of earthworms from infected premises causes patent infections in 61–68 days. Pathologic effects are not usually attributed to *P. plica* infection but hematuria and dysuria are occasionally produced; worms embedded in bladder, ureter, or pelvis may invoke mild submucosal inflammation.

Other species of *Pearsonema* occur in urinary bladder of other animals – *P. mucronata* in mink and *P. feliscati* in the cat; the latter may be the same as *P. plica*. Light infestations are common but harmless; the rostral end of the worm embedded in the surface layer of epithelium provoking at most a light cellular infiltration of the lamina propria.

Klossiella equi

Klossiella equi is a *sporozoan parasite of the kidney of the horse and its relatives,* including the zebra, donkey, and burro. It is apparently *quite rare and harmless.* The life cycle is not fully known. It is thought that, following infection with sporocysts from the environment, sporozoites are released and enter the circulation. One schizont generation develops in glomerular endothelium and another in proximal tubular epithelium. Sporogony occurs in the epithelium of the thick limb of Henle's loop and sporocysts are passed in the urine (Fig. 4.80). Heavy infections can result in rupture of tubules and lymphoplasmacytic interstitial nephritis.

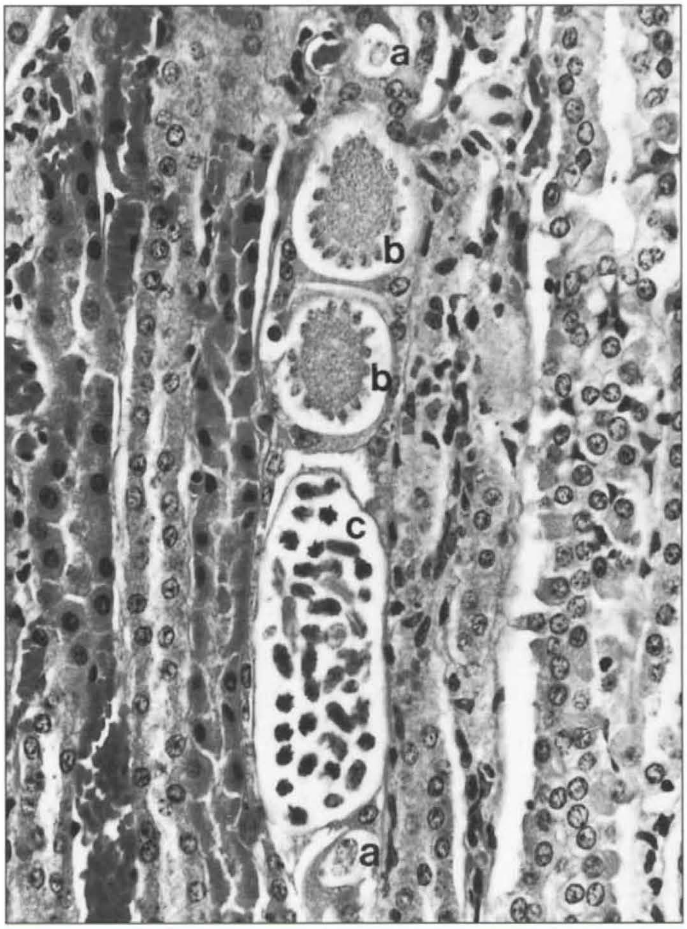

Figure 4.80 ***Klossiella equi*** in an equine kidney. Within tubular epithelial cells are gamonts (a), sporonts (b), and sporocysts (c).

Granulomas may be found in the renal pelvis in *schistosomiasis* of cattle and sheep (see Vol. 3, Cardiovascular system) and larvae of *Setaria digitata* may produce granulomas in the bladder of cattle in Asia (see Vol. 2, Alimentary system).

Halicephalobus gingivalis

Halicephalobus gingivalis (formerly *Micronema deletrix*), a saprophagous nematode that produces granulomatous masses in the nasal cavity of horses and is occasionally responsible for cerebral vasculitis and hemorrhagic necrosis, also localizes in the kidney. *Renal infections are characterized by multifocal to coalescing granulomas* containing numerous larval and adult rhabditiform nematodes plus occasional embryonated eggs; the cream-colored renal masses may resemble neoplasms macroscopically.

RENAL NEOPLASIA

Primary renal tumors are uncommon. One abattoir survey in the UK found 8.5, 0.9, and 4.3 cases per million animals in cattle, sheep, and pigs respectively. Renal tumors were found in ~0.15% of horses in two large surveys. Primary renal tumors comprise about 1% of all canine neoplasms and 1.5–2.5% of feline neoplasms. In one large retrospective study of primary canine renal neoplasms, most were of epithelial origin (85.2%), demonstrated metastatic disease, and had an associated poor prognosis (mean survival 6.8 months).

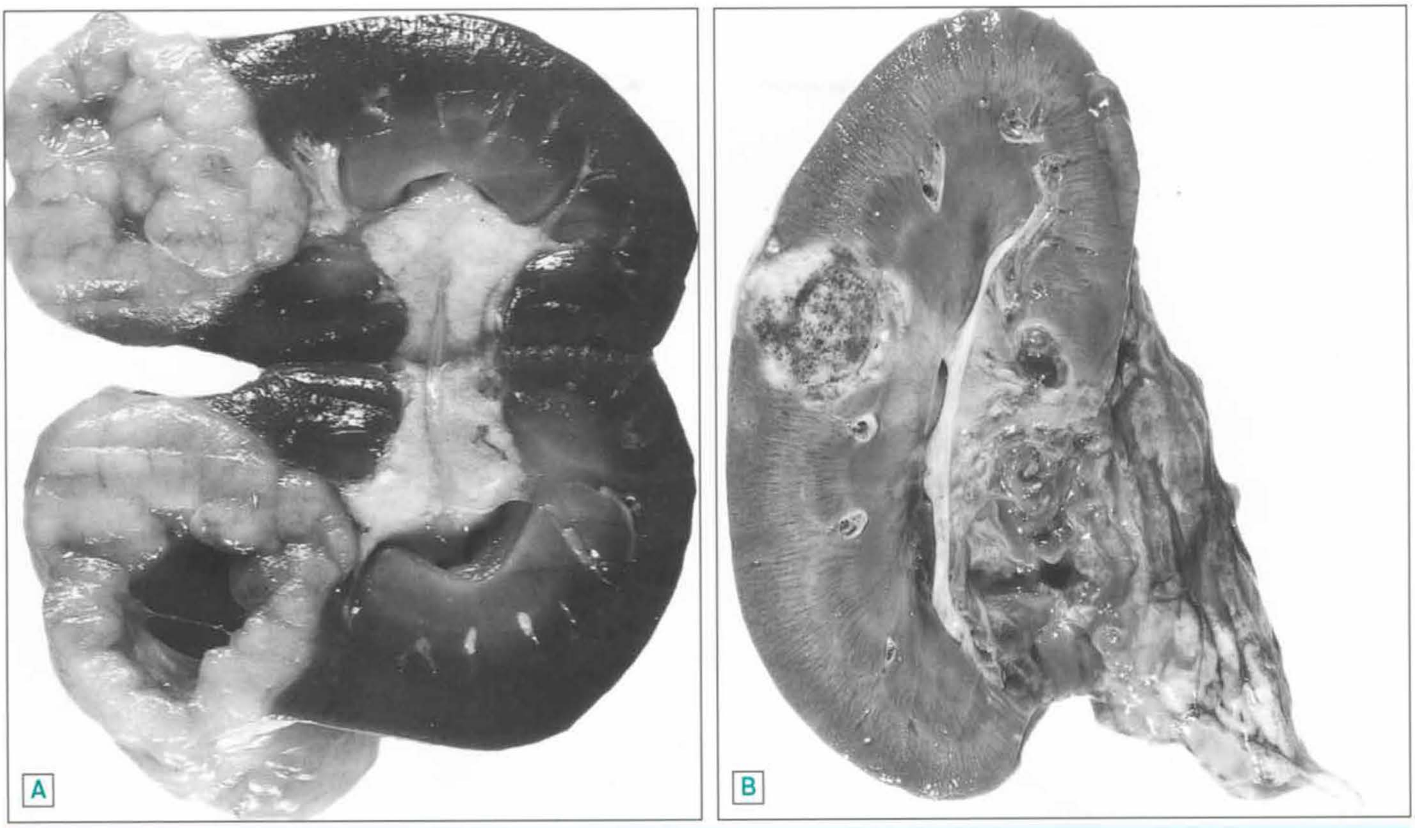

Figure 4.81 **A. Renal carcinoma** showing cystic degeneration, from a sheep. **B. Renal carcinoma** from a dog, with extension to pelvis and pelvic structures.

The vast majority of renal neoplasia is metastatic to the kidney, by hematogenous or lymphatic spread or by direct extension.

Renal adenoma

Renal adenomas are rare; they are said to occur more often in cattle and horses than in other species. In dogs, they comprise about 15% of primary renal epithelial tumors. *Adenomas are usually incidental autopsy findings.* Renal adenomas arise from epithelium of the proximal convoluted tubules. Grossly, they tend to be *solitary nodules* less than 2 cm across but occasionally are larger. They grow expansively. Microscopically, the tumor cells are cuboidal with moderate to abundant acidophilic cytoplasm. They form solid sheets, or papilliform or tubular structures, and stromal tissue is scant. Tumors with mixed architectural patterns occur. Histologic differentiation of adenoma and renal carcinoma is sometimes impossible; a few "adenomas" may be small, well-differentiated carcinomas. In cattle, adenocarcinomas are virtually always microscopically multiple, in contrast to the solitary nature of adenomas in this species.

Renal carcinoma

Carcinomas are the most common primary renal tumors of dogs, cattle, and horses. There are only sporadic reports in cats, sheep, and pigs. These tumors occur in mature and old animals; thus, their incidence is relatively low in some species. The average age of affected dogs is ~8 years, although this tumor has been reported in dogs less than 2 years of age. Males are affected about twice as often as bitches. This is in contrast to the overwhelming higher occurrence in cows, likely because of a preponderance of females in the aged cattle population. Common presenting signs are hematuria, palpable abdominal mass, and weight loss. Polycythemia associated with excessive erythropoietin production is very rarely seen in animals, but paraneoplastic erythrocytosis occurs in 1–5% of humans with renal adenocarcinoma. Polycythemia typically resolves after removal of the tumor. Hypertrophic osteopathy may be seen in cases of renal carcinoma with pulmonary metastases. Disseminated intravascular coagulation, extreme neutrophilic leukocytosis, leukemoid blood response, and bone infarcts are additional rare canine renal adenocarcinoma-associated paraneoplastic syndromes.

Grossly, renal carcinomas are spherical or ovoid masses, typically located in one pole of the kidney (Fig. 4.81A). Usually they are well demarcated from the remainder of the kidney, which is atrophic and compressed. Often the tumor is much larger than the original size of the host kidney but still has a discrete border. The tumor is usually gray or light yellow, often with darker areas of necrosis and hemorrhage. Invasion of the renal pelvis, ureter, renal vein, and hilar lymphatics may be visible (Fig. 4.81B).

In humans, five types of renal carcinoma are recognized based on cell morphology and origin, including clear cell, chromophilic, chromophobic, oncocytic, and collecting-duct variants (Bellini's duct tumors). Immunohistochemistry for lectins can be useful for distinguishing origin because these are site-specific within the various levels of the nephron. *Histologically*, there are a variety of cell types and architectures found in the animal forms (Fig. 4.82) but, if examined carefully, small or large areas composed of renal "clear cells" are found most commonly. These cells have vacuolated cytoplasm and only the basal nucleus and cytoplasmic outline are visible. The

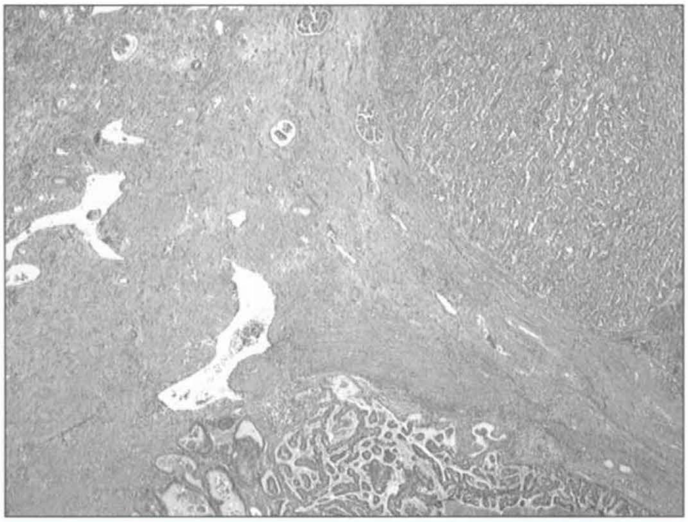

Figure 4.82 Renal carcinoma, consisting of sheets, tubules, and papillary structures, invading and compressing renal cortical tissue.

vacuoles contain fat. The presence of clear cells, even in metastases, should suggest renal carcinoma but is not pathognomonic – similar cells occur in certain endocrine tumors and other carcinomas. In other areas, the cells are cuboidal with denser acidophilic or basophilic cytoplasm. They may be arranged in sheets, papillary or tubular structures, and occasionally they line small cystic spaces. All of these patterns may occur in a single tumor, and apparently there is no prognostic value associated with any pattern. The stroma of renal carcinomas is scant but highly vascularized, which predisposes to the extensive necrosis often seen grossly.

Renal carcinomas tend to grow expansively, but satellite nodules often develop from local permeation. Invasion of the renal vein is always possible but may not result in metastases. Peritoneal implantation sometimes occurs. Usually by the time a dog is presented for examination, widespread metastases are present, especially in lungs and liver, but also in brain, heart, and skin. Such behavior is not invariable, and in some cases unilateral nephrectomy is curative. In contrast, in **cattle** there is a low rate of systemic metastasis but bilateral renal involvement is common. This may be explained by multiple de novo development and less by intrarenal metastasis. Additional characteristic findings in bovine renal cell carcinomas are corpora amylacea, proteinaceous secretions, and hemosiderin. There is a report of clear cell renal carcinoma in a **horse** manifesting initially as an aggressive metastatic oral tumor. The oncocytic form of renal carcinoma has been reported infrequently in rats and dogs.

Renal carcinomas are rarely diagnosed in **cats**, but typically occur unilaterally, in older cats (mean 9 years), with no sex or breed predilection and only sporadic metastases. Bilateral de novo development has also been documented.

Middle-aged and older German Shepherd **Dogs** with generalized *nodular dermatofibrosis* concurrently also have **renal cystadenocarcinomas** or cystadenomas, which are usually bilateral (Fig. 4.83); the carcinomas will occasionally metastasize to regional lymph nodes, peritoneum, liver, spleen, lung, and bone. Affected bitches also often have multiple uterine leiomyomas; the syndrome may be the result of a paraneoplastic process in which renal tumor-derived growth factors stimulate accumulation of fibrous tissue in various sites. The syndrome is apparently *inherited in an autosomal dominant mode in German Shepherd Dogs*, and caused by a tumor suppressor gene located on chromosome 5. Because cases of nodular dermatofibrosis with various degrees of cystic renal pathology have been reported in a variety of dog breeds, some postulate that there is concurrent initiation of fibrosis in both the skin and the kidney, the latter leading to outflow obstruction of renal tubules with expansion and eventual cyst formation. There may be progression through a continuum of lesions, including renal epithelial cyst, cystic adenomatous hyperplasia, renal cystadenoma, and cystadenocarcinoma, with purebred dogs perhaps being prone to more rapid transformation to malignancy. Thus, all dog breeds are potentially at risk.

Nephroblastoma

Nephroblastoma (embryonal nephroma, Wilms' tumor) is the most common primary renal tumor of pigs and chickens. Abattoir surveys of pigs in the UK found 3.5 per million swine slaughtered, and in the USA 43.5 per million, with a frequency of 197 cases per million in one area. Nephroblastomas occur far less often in calves and in dogs, and are very uncommon but reported in sheep, horses, and cats. They are usually seen in young animals and sometimes in fetuses, but also in mature sows and are more common in adult dogs than in pups. In rats, various carcinogens, including dimethylnitrosamine, can induce formation of nephroblastomas amongst other tumors.

Nephroblastomas are *true embryonal tumors* that arise in primitive nephrogenic blastema and in foci of renal dysplasia. The presence of tissues not typically associated with the kidney, such as cartilage and skeletal muscle, indicates an origin in pluripotential mesenchyme of the metanephron. These tumors establish the important principle that all component tissues of the kidney arise from a common blastema and that this neoplasm may represent a form of arrested development. Finding nephrogenic rests of nodular renal blastema in dogs suggests this species shares a similar pathogenesis and histogenesis to that seen in Wilms' tumors in humans.

Grossly, nephroblastomas may attain a huge size and cause abdominal enlargement. They are often multiple in the affected kidney, growing expansively and compressing the adjacent parenchyma, and they are encapsulated. They are usually unilateral but a few are bilateral (Fig. 4.84A) and these sometimes unite across the midline to form a single large mass. Widespread metastases to lung and liver occur in over half the canine cases, but are rare in pigs and calves.

Rarely these tumors are seen as primary extramedullary and intradural spinal canal masses between T10 and L2. German Shepherds and male dogs seem to be overrepresented with the spinal form, which may occur in the absence of renal involvement. There is a report of spinal cord nephroblastoma with suspected intraspinal metastasis. The cut surface of nephroblastomas is variegated or lobulated and the larger ones have extensive areas of hemorrhagic necrosis. The characteristic cut surface reveals a myxomatous soft, gray-white or tan tissue, which feels spongy.

Histologically, the characteristic features are primitive glomeruli with primitive Bowman's spaces, abortive tubules, and a loose spindle-cell stroma (Fig. 4.84B) that may show some differentiation to a variety of mesenchymal tissues, including striated muscle, collagen, cartilage, bone, and adipose tissue. The mesenchymal components may predominate over epithelial elements in certain tumors, especially in ruminants. When all three components (blastemal, epithelial, and stromal) exist in equal proportions, these forms are referred to as *triphasic (mixed) nephroblastomas*. Commercially available antibody to the human Wilms' tumor gene product C-19 successfully stains canine nephroblastomas. These tumors are also typically glial-fibrillary-acidic-protein-negative and variably vimentin- and cytokeratin-positive. Tubular and glomerular differentiation indicate a good prognosis; anaplasia and a sarcomatous stroma are associated with metastasis and a poor prognosis. Rarely, polycythemia is seen as an associated paraneoplastic syndrome.

Other tumors

Transitional cell papilloma and **carcinoma** of the renal pelvis are very rare tumors, which occur in the dog, cow, pig, and horse. Squamous and glandular metaplasia develop in the carcinomas. Primary pelvic **squamous cell carcinoma** is extremely uncommon, but in dogs they have been noted in association with pelvic calculi. Transitional cell tumors are discussed in the section on the Urinary bladder, below.

Primary mesenchymal tumors of the kidney occur but may be diagnosed only after very careful examination to exclude a primary focus in some other tissue. The prognosis associated with renal mesenchymal neoplasms is usually grave. Fibrous and vascular tumors are the most common types. **Hemangioma** is the most frequently encountered benign renal neoplasm in dogs; hematuria is the most consistent accompanying sign. An intracapsular **angiomyolipoma** (mesenchymal hamartoma) has been reported in the kidney of a cat. A case of primary feline renal **hemangiosarcoma** has been reported. Renal **interstitial cell tumors** occur in the cortex and medulla of old dogs and arise from cells distinct from interstitial fibroblasts. **Benign cortical fibromas** also occur in older dogs. A vimentin-positive tumor termed a **congenital mesoblastic nephroma** has been reported in a dog; the tumor was composed of fibromatous and myxomatous areas. Other rare primary renal tumors include neurofibroma, malignant fibrous histiocytoma, and oncocytoma. **Renal oncocytomas** are rare, usually unilateral, benign tumors composed of oncocytes, which are large polygonal cells with bright eosinophilic granular cytoplasm. Periodic acid–Schiff stain accentuates the cytoplasmic granules, which on electron microscopy are mitochondria. The cells are typically arranged as compact nests, cords, or tubules. The histogenesis is unclear but it is thought that these tumors originate from intercalated cells of the collecting ducts; the cells express cytoplasmic keratin.

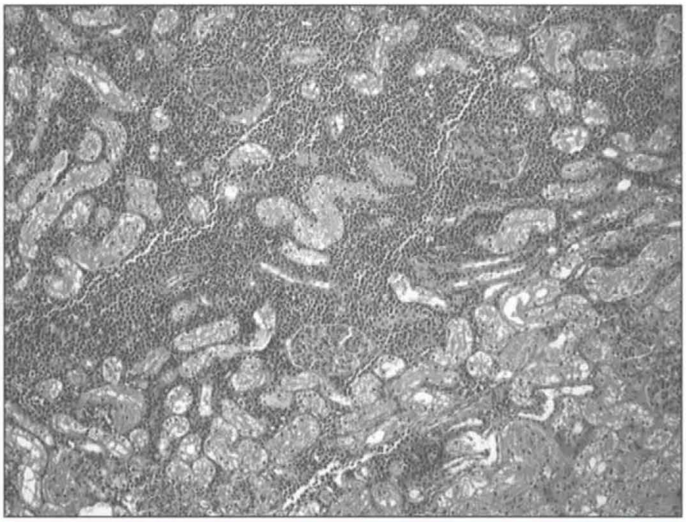

Figure 4.85 Diffuse infiltration and disruption of renal parenchyma by **lymphosarcoma**.

Metastatic tumors are common in the kidneys, and disseminated neoplasms of any type are likely to localize there, typically with bilateral involvement of the cortices. Many such metastases are of microscopic size and of hematogenous origin. Retrograde lymphatic invasion along the renal lymphatics may occur from carcinomas in adjacent organs.

In dogs, primary **pulmonary adenocarcinoma** with renal metastases may be difficult or impossible to distinguish from primary renal carcinoma with pulmonary metastases, since their microscopic appearance is quite similar.

Renal involvement in **lymphosarcoma** is common in those species in which the neoplasm is common. This is the most common renal neoplasm in cats, but is more often a metastatic rather than a primary lesion. The involvement may be diffuse or nodular. When the nodular lesions are grossly visible, they are numerous, poorly defined, fatty in appearance and project hemispherically above the surface. The capsule is not adherent. When lymphomatous involvement is diffuse (Fig. 4.85), the organ is enlarged and has a uniform white fatty appearance. The differentiation of lymphomatous metastases from interstitial nephritis often requires microscopic examination and, indeed, metastases may sometimes only be discovered, especially in cats, by microscopic examination. Polycystic kidney disease has been found concurrently with renal lymphosarcoma in a cat. Peripelvic and periureteral infiltrates, which cause hydronephrosis, are common in cattle.

Lower urinary tract

GENERAL CONSIDERATIONS

The lower urinary tract consists of **ureters, urinary bladder**, and **urethra**. The ureters and bladder, and also the renal pelvis, are lined by transitional (nonkeratinizing) stratified epithelium – the **urothelium**. The ureters are of uniform diameter throughout, and usually course directly to the bladder, although they may be tortuous and dilated distally in baby pigs. The ureters enter the bladder wall obliquely and are covered by a mucosal flap. Histologically, the ureteral mucosa is present in longitudinal folds; there are poorly defined internal and external longitudinal muscle layers, a prominent middle circular layer, and either adventitia or peritoneal serosa. Thus, peritonitis may involve the ureters and interfere with their peristalsis. Ureters and the renal pelvis of horses have simple branched tubuloalveolar mucous glands in the propria-submucosa. Histologically, the bladder is an expanded ureter, lined by stratified transitional epithelium ranging from 3 to 14 cells thick depending on the species and degree of distension. Superficial cells, which contain tubulovesicular compartments, supply additional membrane to allow for bladder distension. The basolateral plasma membrane of the superficial cells and the plasma membrane of the intermediate layer of transitional cells interdigitate and are attached by desmosomes that provide structural stability and elasticity during distension and relaxation. Lymphoid nodules are commonly found in the lamina propria of all domestic animals. Theliolymphocytes are common in ruminants. Eosinophilic intracytoplasmic inclusion bodies of canine distemper seen in urinary bladder epithelial cells must be differentiated from similar nonspecific inclusions.

The function of the ureter is to propel urine from the kidney to the bladder by peristalsis. In this it is assisted by the renal pelvis. Ureteral peristalsis is controlled by one or more pacemakers, which are located in the recesses of the renal pelvis, and by the activity of the ureteropelvic junction, which determines whether a pacemaker stimulus initiates a peristaltic wave. The regulation of nerve impulses for smooth-muscle contraction is mediated by tachykinin activation of neurokinin-2 receptors. At low urine production rates, peristalsis may occur with every fifth pacemaker stimulus, but during diuresis, every stimulus initiates a peristaltic wave. The ureters pass obliquely through the muscular wall of the bladder at the ureterovesical junction. *The segment of ureter in the bladder wall, the intravesical ureter, forms the basis of the* **vesicoureteral valve**, *which prevents reflux of urine from bladder to ureter.* When the length of the intravesical ureter is short, as is often the case in puppies, reflux frequently occurs. Thus, the angle of the ureteral entry and the thickness of the bladder wall influence the competence of the valve. The urinary bladder stores urine and, in concert with the urethra, expels it. During continence, the bladder is relatively flaccid and the urethra acts as a valve. During micturition, contraction of the *detrusor muscle* – the urinary bladder musculature – pumps urine through the relaxed urethra. Sphincter mechanism incompetence or detrusor instability can lead to incontinence, seen most commonly in bitches.

Embryologically, the ureters are formed by buds from the mesonephric ducts, which develop craniad to their entrance into the cloaca. The cloaca is divided into a dorsal rectum and ventral urogenital sinus by the urorectal fold in such a way that the urogenital sinus is continuous with the allantois. The allantois originates as an evagination of the hindgut. At this stage of development, the mesonephric duct and ureteral bud form a Y shape – one arm of the Y is the ureteral bud and the other arm plus the stem of the Y are formed by the mesonephric duct. As the allantois and urogenital sinus develop, the stem of the Y is absorbed and the mesonephric duct and ureteral bud enter the urogenital sinus independently. In females, the entire urethra, plus the vaginal vestibule, is derived from the urogenital sinus, but in males only the prostatic urethra is so derived. The penile urethra forms by closure of a groove, the urethral groove, on the caudal face of the penis. The bladder, which is formed from the cranial part of the urogenital sinus and the caudal part of the allantoic diverticulum, communicates with the allantois via the urachus, which forms from the cranial part of the intraembryonic allantoic diverticulum. The communication is severed at birth and the urachus closes but remains as the umbilical ligament of the bladder.

Most ailments of the lower urinary tract are associated with obstruction and infection, which are often concomitant. Unlike the gastrointestinal tract, which has a normal microbial flora throughout its length, only the most distal part of the male urethra, and the female vagina, normally host microorganisms. The operation of sphincter-like mechanisms in the urethra and vesicoureteral valves, and the intermittent pulsatile flow of urine from the kidneys and bladder, normally prevents the movement of organisms higher up the tract. The susceptibility of the urinary bladder of the female to severe infections is undoubtedly related to its short distensible urethra and its proximity to the external environment and especially the rectal flora. On the other hand, the anatomy of male urethras, with their flexures, ossa, and appendages, make them prone to obstruction, particularly by calculi. Specific factors concerned in the establishment and maintenance of infections in the urinary bladder and their spread to the kidney are discussed in the sections on Cystitis and Pyelonephritis. The causes and effects of obstruction are considered in the sections on Urolithiasis and Hydronephrosis.

The **urothelium** of the renal pelvis, ureter, and perhaps the trigone of the bladder originate from mesoderm, whereas in the rest of the bladder it has an endodermal origin. Thus, urothelium responds to chronic irritation from infections, calculi, and excreted chemicals by proliferation and/or metaplasia, both of which are regarded as premalignant changes. Downwards proliferation of urothelium, a common reactive change, results in groups of proliferating cells isolated in the submucosa, known as **Brunn nests**. If the center of the nest undergoes liquefaction, *cystitis cystica, ureteritis cystica,* or *pyelitis cystica* results. *Pyelitis, ureteritis, or cystitis glandularis* develops if the epithelium lining the cyst undergoes mucous metaplasia. Metaplasia of squamous or mucous types is often superimposed on predominantly proliferative lesions. The male urethra has a thin lining of transitional epithelium; that of the female is similar but has stratified squamous epithelium at its termination. Most of the adenomas and adenocarcinomas of the lower urinary tract develop in areas of mucous metaplasia. A few may arise in submucosal glands or mesonephric and urachal remnants. Urothelium that is not exposed to urine has a tendency to undergo metaplasia to an intestinal-type epithelium – such is the fate of some cystic urachal remnants, which are normally lined by transitional epithelium.

Urine may be obtained for urinalysis or culture by cystocentesis at autopsy. The bladder may be dilated in downer animals, even in states of dehydration, due either to the absence of the correct posture needed for urination or to decreased medullary tonicity due to hypoproteinemia (low urea production) that has led to polyuria. Dog bladders are often constricted at necropsy and hence have a thick wall. If the bladder can be dilated by pulling it between the fingers, the thickening is not pathologic. Horse urine normally contains mucus and crystals.

ANOMALIES OF THE LOWER URINARY TRACT

Ureters

Agenesis of the ureters is due to failure of the ureteral bud to form, and may be unilateral or bilateral. In dogs, it is often accompanied by renal agenesis (see section on Anomalies of development, above). **Duplication** of a ureter is caused by the formation of two ureteral diverticula from the mesonephric duct. The caudal ureter drains the caudal part of the kidney and the cranial one drains the cranial part. Usually the caudal ureter empties normally while the other is ectopic. Duplication is rare but occurs in dogs and pigs (Fig. 4.86). **Ureteral dysplasia** occurs in association with renal dysplasia. **Ureteral valves** are occasionally seen in dogs.

Ectopic ureter *is the most important ureteral anomaly*. Rather than terminating at the trigone of the bladder, the affected ureter may empty into the vas deferens, vesicular gland, or urethra of the male, or the bladder neck, urethra, or vagina of the female. In bitches, the ectopic ureter usually terminates in the vagina or urethra, whereas in cats urethral termination is most common. There are two possible causes: either the ureteral bud arises too far craniad to be incorporated into the urogenital sinus, or the differential growth of the sinus is abnormal and the ureter fails to migrate to its usual location. Ectopic ureters occasionally empty into the rectum because of anomalous cloacal division by the urorectal fold. Very rarely they empty into the cervix, uterus, or uterine tube, possibly as a result of aberrant origin from the paramesonephric (Müllerian) duct. Even more rarely, an ectopic ureter may be blind-ended cranially in cases with accompanying renal agenesis.

Ectopic ureter is most common in dogs and is diagnosed up to 20 times more frequently in females than in males. However, this sex difference may be apparent or exaggerated since affected females are usually incontinent from birth, whereas affected males may not be. Termination of the ectopic ureter proximal to the external urethral sphincter in males leads to retrograde filling of the bladder rather than to incontinence. Ectopia can be unilateral or bilateral and is often associated with other urinary tract abnormalities, including bladder agenesis or hypoplasia, renal agenesis or hypoplasia, ureteral or bladder duplication, and branching of the terminal ureter. In the USA, certain dog breeds have a high risk for the defect, including the Siberian Husky, Bulldog, Newfoundland, Labrador Retriever, West Highland White Terrier, Fox Terrier, and Miniature and Toy Poodles. The breed predilection in the UK includes the Golden

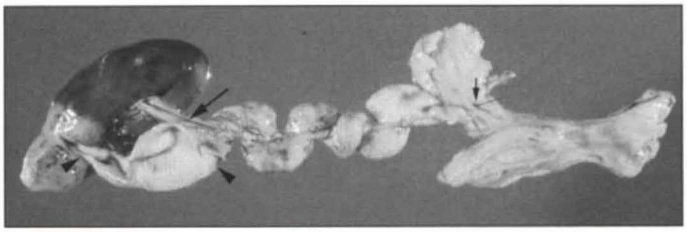

Figure 4.86 Renal dysplasia and **ureteral duplication** in a pig. The ureter draining the dysplastic cranial part of the kidney (between arrowheads) is markedly dilated and tortuous; the ureter draining the caudal part (between arrows) is traced by a wire from kidney to bladder trigone.

Retriever, Labrador Retriever, Skye Terrier, Border Terrier, Briard, Bulldog, and the Griffon. The defect is familial in Siberian Huskies and Labrador Retrievers. Ectopic ureter also occurs in White Shorthorn bulls and tends to involve the region of the seminal vesicles. It is a rare anomaly in horses.

A **ureterocele** is a congenital abnormality that is defined as *a focal submucosal dilation of the distal ureter,* especially involving that portion that lies within the urinary bladder wall. It may be associated with normal anatomic emptying (orthotopic or intravesical ureterocele), or an ectopic location (ectopic ureterocele). A proposed grading scheme is as follows: grade 1 has no concurrent ureteral or renal disease, grade 2 has unilateral hydroureter, hydronephrosis, or chronic renal disease, and grade 3 is similar to grade 2 but with bilateral hydroureter and a consistently worse prognosis.

Ureteral anomalies often predispose to hydronephrosis/hydroureter and urinary tract infection that may culminate in pyelonephritis. **Ureteral diverticula** result from transitional cell hyperplasia, mucinous metaplasia, and submucosal urothelial proliferation with the formation of small cysts. Neoplastic transformation may occur more readily in such sites.

Urinary bladder

Duplication of the urinary bladder occurs in dogs and causes dysuria, incontinence, and, less frequently, abdominal distension and cryptorchidism. The extra bladder originates dorsally between the urinary tract and uterus or rectum. Cystic remnants of the urorectal fold may be responsible for this defect.

Patent or **pervious urachus** is the *most common malformation of the urinary bladder* and is seen more often in foals than in other animals. Animals with this defect dribble urine from the umbilicus because the urachal lumen fails to close and remains as an open channel between the apex of the bladder and the umbilicus; a patent urachus is susceptible to infection and abscessation. Rupture of the urachus causes uroperitoneum. The condition must be differentiated from perinatal rupture of the bladder. Occasionally, urachal obliteration is partial, and rests of epithelium remain intact to develop into **urachal cysts** at any point between the umbilicus and the bladder. These cysts may become quite large but usually are small and multiple and are attached to the midline of the bladder. Occasionally they adhere to the intestinal serosa. The urachus is normally lined by transitional epithelium, but metaplasia to squamous or mucus-secreting columnar epithelium is common in urachal cysts and sinuses. Urachal remnants in the bladder wall may give origin to neoplasms.

Diverticula of the bladder may be primary or acquired secondary to partial obstruction to the outflow of urine, or as the result of pressure changes exerted during normal contractions. Diverticula are usually seen at the vertex, where they represent incomplete closure of the urachus (vesicourachal diverticulum) with an area of discontinuity in the muscle but also occur less commonly in the trigone region in association with a malformation of the bladder muscle wall. Contraction of the bladder tends to distend the diverticulum, but rupture does not occur. Additionally, stasis of urine in the diverticulum eventually leads to persistent infection and inflammation. Calculi may form in the diverticulum. If the distal urachus remains patent to the exterior through the umbilical opening, a **urachal sinus** results.

Urethra

Urethral **agenesis**, **duplicated** urethra, **ectopic** urethra, and **imperforate** urethra occur rarely in dogs. Recently, the first case of bovine urethral duplication was reported in a Swiss Braunvieh heifer with other urogenital malformations, as is often the case. This animal had cytogenetic confirmation of reciprocal autosomal translocation between chromosomes 20 and 22, suggesting that genetic anomalies could be responsible for this condition. Hypospadias is described with male genitalia. *The most common urethral anomaly is* **urethrorectal** or **rectovaginal fistula**, which is caused by incomplete division of the cloaca into rectum and urogenital sinus by the urorectal fold. In males, the communication involves the pelvic urethra and affected dogs urinate from the rectum. In females, the opening is in the vagina and may be associated with imperforate anus. These defects are reported in dogs, cats, pigs, rabbits, alpacas, and foals, often as one of several congenital anomalies. These changes usually predispose to urogenital tract infections but sometimes are incidental autopsy findings. An uncommon occurrence of this lesion as a single anomaly has been documented in a mature gelding.

In male ruminants and swine, a **urethral recess** is normally present near the ischial arch and is not anomalous, but is an impediment to catheterization. Dilation of the urethral recess can cause midline perineal swelling in ruminants. A case of **congenital megalourethra** in a calf was characterized by dilation of the penile urethra, with a poor urine stream and a lower urinary tract infection.

Urethral atresia and **urethral hypoplasia** have been noted in newborn freemartin intersex calves with uroperitoneum following rupture of the urethra or urinary bladder. **Urethral strictures** have been documented in intersex ruminants, a llama, and a Nubian goat.

Acquired anatomic variations

Displacements of ureters and urethra are sometimes caused by local inflammatory and neoplastic swelling. Their main significance to the urinary system is related to obstruction of urine flow. Ureteral and urethral displacements may also occur with variations of position of the bladder. **Torsion** of the bladder is uncommon; it may be partial or complete about the long axis of the organ. Presence of part of the bladder within the pelvis in dogs, so-called "*pelvic bladder,*" is thought to be a normal variation, dependent on the degree of distension of the bladder, and is not a cause of incontinence.

Dorsal **retroflexion** occurs in male dogs with tenesmus in response to prostatic enlargement or constipation. The normal position is assumed following emptying. A more serious form occurs with prolapse of the vagina in cows, sows, and bitches and occasionally in perineal hernia of older male dogs. In these cases, the bladder may be present in the hernial sac and, because of the retroflexion, there is obstructive kinking of the neck of the bladder and sometimes of the urethra and ureters. If the ureters are patent, the accumulation of urine in the bladder contributes to the size of the hernia. Hydronephrosis or rupture of the bladder may occur if the condition is not corrected.

Eversion of the bladder (*invagination into and through the urethra*) occurs in females and is permitted by the short, wide urethra in this sex. The bladder may arrive in the vagina. This can occur in any of the larger species and is perhaps most common in mares. Eversion is predisposed to by circumstances in which increased intra-abdominal pressure or straining occurs, often after parturition. Hypocalcemia in periparturient dairy cows may contribute by resulting in decreased bladder tone prior to eversion. The everted bladder may allow for herniation of intestine. Rarely, *umbilical eversion* of the bladder can occur in foals that experience traumatic tearing of the umbilical cord and urachus during birthing. Eversion of the bladder is to be distinguished from **prolapse** of the bladder; in eversion, the mucosal surface protrudes from the vulva, whereas *in prolapse the bladder has been displaced through a rent in the vagina and the serosal surface appears.*

Hydroureter, or *dilation of a ureter*, may be due to obstruction by calculi, neoplasms, or inflammatory debris, or due to accidental ligation during surgery, e.g., ovariohysterectomy, or following post-surgical scarring, and will lead to hydronephrosis. Dilation without physical obstruction occurs in association with peritonitis and may be due to loss of muscle tone. Dilation of ureters is often present in neonatal pigs with enteric infections. Congenital hydroureter and hydronephrosis often occur in piglets in association with epitheliogenesis imperfecta.

Ureters may **rupture** as a consequence of blunt physical trauma and only rarely in association with parturition. Ureters may also be accidentally **transected** during surgery, e.g., ovariohysterectomy. Leakage of urine from a traumatized ureter is the most common cause of a **urinoma** – a retroperitoneal accumulation of urine sometimes referred to as a *paraureteral or uriniferous pseudocyst* due to its fibrous connective tissue wall and absence of an epithelial lining. Urethral obstruction and urine leakage from a rent in the renal capsule are also documented causes. **Perinephric pseudocysts** resemble urinomas but surround the kidney and are thought to be associated with chronic renal failure in cats. Foals experience **ureteral tears** that are thought to be the result of blunt nonpenetrating trauma. The common bilateral nature suggests a possible congenital predisposition in this species.

Dilation of the bladder may be of local obstructive or neuroparalytic origin. The wall is thin and almost transparent, and the distended organ may extend almost to the liver. Brief periods of distension may allow quick return of normal contractibility, but severe or prolonged distension may result in loss of tone, which is not restored before bacterial complications terminate the condition. The *causes of obstruction* include calculi, prostatic enlargement in dogs, accumulated inflammatory detritus or blood clots in the urethra, urethral strictures, and tumors of the neck of the bladder or urethra. Detrusor atony of the bladder may follow prolonged dystocia in the dog.

Neurogenic disorders of micturition may be the result of abnormalities of the sphincter or of the bladder and may result from failure to store urine, failure to void urine, or a combination of both. Neurogenic distension follows spinal injury with loss of tonic parasympathetic outflow from the sacral plexus. Spinal myelitis, as in canine distemper and rabies, may also cause paralysis of the bladder. Perhaps it most commonly follows herniation of intervertebral disks in the dog. Cystitis and, less commonly, fundic necrosis secondary to compression of vessels within the distended urinary bladder wall, are the usual complications. In horses in particular, bladder paralysis and distension can lead to sabulous urolithiasis. Descriptions of *detrusor-urethral dyssynergia* in dogs are sparse and most have been documented in young and middle-aged large-breed dogs. This condition resembles urinary obstruction by uroliths but it is a functional disorder of the voiding phase of micturition. This condition occurs with involuntary contraction of the external urethral sphincter in the postprostatic urethra or with contraction of the smooth muscle of the neck of the bladder or prostatic urethra (internal sphincter). Typically, these animals have dysuria with interrupted spurting of urine and a large residual urine volume.

Sphincter mechanism incompetence *is the most common cause of urinary incontinence in middle-aged, spayed bitches*, but the prevalence is also higher in animals with body weights over 30 kg, docked breeds (Doberman Pinschers, Old English Sheepdogs, and Rottweilers, as well as in Weimaraners and Setters). In females, an intrapelvic bladder neck, a short urethra, reduced urethral tone and neutering before first estrus predispose. Restoration of normal anatomic location of urethra/urinary bladder by surgical procedures is often curative. Bladder neck position (i.e., intrapelvic), breed, prostate size, and castration status are significant risk factors for incontinence in male dogs. Congenital urethral sphincter mechanism incompetence in cats has been associated with genitourinary dysplasia (urethral hypoplasia and vaginal and/or uterine hypoplasia/aplasia).

Distension of the bladder occurs when calves fed indigestible milk-replacer starve to death. They are usually recumbent for several hours before death but this is probably due to weakness rather than nervous disease. Renal concentrating ability is depressed by starvation because of lack of urea and a partial insensitivity to antidiuretic hormone and mineralocorticoids. The bladder distension is possibly caused by overproduction of dilute urine.

Hypertrophy of the bladder is fairly common in dogs and less so in other species. It is a response to long-standing partial obstruction to the outflow of urine.

Rupture of the bladder (cystorrhexis) often occurs following urethral obstruction, such as occurs in urolithiasis, but rarely following pelvic trauma or dystocia; traumatic rupture of the bladder can occur during parturition in mares and cows. The interval between obstruction and rupture depends somewhat on the competence of the vesicoureteral valve and whether hydronephrosis develops. Rupture of the bladder occurs in newborn foals, with an incidence of 0.2–2.5%, affecting either the dorsal or ventral aspect of the viscus; males are most often affected. Some ruptures are congenital and most are probably caused by birth trauma. Twists in the amniotic portion of the umbilical cord may compress the urachus, causing distension of both bladder and urachus and predisposing to rupture. Only rarely is the urinary bladder rupture secondary to atrophy of circular smooth-muscle fibers in the dorsal bladder wall.

Urine in the peritoneal cavity, or **uroperitoneum**, follows leakage from the kidneys, ureter, bladder, or urethra. Diagnosis of uroperitoneum is supported by the finding of peritoneal-to-serum ratios for potassium, phosphate, and creatinine greater than 2:1. Calcium carbonate crystals are occasionally seen in the peritoneal fluid. Uroperitoneum has been seen increasingly in foals in association with positive sepsis scores (45%) in one recent study, and was a negative prognostic indicator. *Escherichia coli*, *Actinobacillus equuli* and, less commonly, *Clostridium perfringens* are implicated in associated sepsis or urachal infections. Abdominal trauma is the most common cause related to urine leakage from the bladder in dogs and cats; catheterization and bladder expression are the most common causes of urethral leakage in cats. Urinary calculi and obstruction by transitional cell carcinoma are also causes.

Although uncommon in domestic swine, **urethral polyps** have been reported in Vietnamese pot-bellied pigs. It seems most likely that these lesions arise secondary to trauma to the mucosal folds of the urethral recess associated with repeated catheterization. **Urethral caruncles** have been described in humans and dogs and form as a result of chronic inflammation of the urethral mucosa. Glandular structures are intermixed with a granulomatous infiltrate, often producing an obstructive mass lesion.

CIRCULATORY DISTURBANCES

Hemorrhages *are the most important and most common indicator of circulatory disturbances.* In the ureters and urethra, they are associated with obstructive calculi, and ureteral hemorrhage is part of acute ascending infections. Urethral hematomas following pelvic trauma may predispose to urinary bladder rupture. In the bladder, hemorrhages are typically located in the propria mucosa and may occur in any septicemia. Small hemorrhages with the shape of tiny hematomas are common and considered diagnostically significant in classical swine fever, African swine fever, porcine salmonellosis, and equine purpura hemorrhagica. Larger hemorrhages are present in bracken fern poisoning of cattle. Hemorrhage occurs with acute cystitis and neoplastic diseases, and hemorrhage with hematoma formation is seen following rupture of the bladder.

UROLITHIASIS

Urolithiasis is the presence of calculi (uroliths or stones) in the urinary passages. Calculi are grossly visible aggregations of precipitated urinary solutes, urinary proteins, and proteinaceous debris; minerals predominate in **calculi**, whereas matrix usually predominates in **urethral plugs**. *Calculi typically have a central nidus, surrounded by concentric laminae ("stone"), an outer shell, and surface crystals.* Many calculi are hard spheres or ovoids with a small amount of organic matrix impregnated with inorganic salts. *Urethral plugs are masses of sandy sludge with a much higher organic component* whose form is largely determined by the shape of the cavity they fill. Even densely mineralized calculi of the same type may have quite a different appearance depending on whether they are located in renal pelvis or urinary bladder. Many calculi contain significant quantities of "contaminants" such as calcium oxalates in "silica" calculi; a few are relatively pure.

The diseases caused by uroliths are among the most important urinary tract problems of domesticated animals. Several factors are important in predisposing to calculus formation and several are important in precipitating disease. These are not the same for all conditions. Obviously, calculogenic material must occur in urine in quantities sufficient to be precipitated. Sometimes this concentration is achieved because a substance is metabolized in an unusual way, as is uric acid in Dalmatian dogs; or it may be processed abnormally by the kidney, as is cystine in cystine stone-formers; or abnormally high levels of a substance in the diet, such as silicic acid in native pastures, may produce potentially dangerous urinary levels. Regardless of the type of calculus, certain factors are more or less important; these are **urinary pH**, in terms of its optimum for solute precipitation, and **reduced water intake**, in relation to the degree of urine concentration. Other predisposing conditions include **infection** (see section on Struvite calculi, below), obstruction, structural abnormalities, foreign bodies, and drug-induced changes in urine composition, e.g., by sulfonamides. A foreign body, such as a suture, grass awn, catheter, or needle, can act as a nidus for urolith formation. Deficiency of vitamin A is frequently suggested as a factor predisposing to urolithiasis, but the evidence is equivocal; it may contribute in exceptional circumstances by producing metaplastic changes in the urinary epithelium.

Urine is often supersaturated with respect to the components of stone-forming salts, and this **supersaturation** is the essential precursor to initiation of urolith formation (nucleation). Supersaturation may be in the **unstable** region where spontaneous precipitation occurs (homogeneous nucleation, the precipitation-crystallization theory of urolith initiation), or in the **metastable** range where precipitation occurs by epitaxy or heterogeneous nucleation (one type of crystal grows on the surface of another type). Although formerly it was thought that urinary proteins such as uromucoid, which make up 5–20% or more of some calculi, were pre-eminent initiators of crystal formation in the metastable range (*the matrix-nucleation theory of urolith initiation*), it is now believed that in many cases either co-precipitation of proteins and minerals occurs or that proteins are adsorbed on to formed crystals. It is possible that crystals of one salt, for which urine is supersaturated in the unstable range, cause epitactic induction of crystals of another salt, for which supersaturation is metastable. Crystals are much more common in urine than are calculi. Even though equine urine, for example, is normally supersaturated with calcium carbonate and crystalluria is normal, horses experience a low prevalence of calculi. The factors that promote crystal growth and crystal aggregation or, more importantly, prevent them in some animals, are poorly understood. Experimentally, high levels of urinary inorganic pyrophosphate and magnesium are important inhibitors of calcium phosphate and calcium oxalate crystallization, and pyrophosphate also inhibits aggregation of calcium phosphate crystals. Certain urinary macromolecules, probably glycosaminoglycans, are also strong inhibitors of crystal aggregation in experimental systems. Deficiency of inhibitors of crystallization may be important in calcium oxalate and calcium phosphate calculogenesis (*crystallization-inhibition theory of urolith initiation*). It is not known why calculi stay in the renal pelvis and urinary bladder until they are large enough to cause disease.

The important types of urinary calculi are given below according to species (Table 4.5). Although one mineral may predominate in a urolith, *many uroliths are of mixed composition*. Overlap in the gross appearance of uroliths usually precludes specific gross diagnosis of mineral type. The division indicated in Table 4.5 is arbitrary. Obviously, silica calculi are only important where ruminants are pastured, and clover stones are only important where subterranean

Table 4.5 Composition and importance of urinary calculi

Species	Common types	Uncommon types
Dog	Struvite Oxalate Purines (urate, uric acid, xanthine)	Silica Cystine Calcium phosphate
Cat	Struvite Oxalate	Urate Cystine
Ox	Silica Struvite Carbonate	Xanthine
Sheep	Silica Struvite Oxalate "Clover stones" Carbonate	Xanthine
Horse	Carbonate	
Pig		Urate

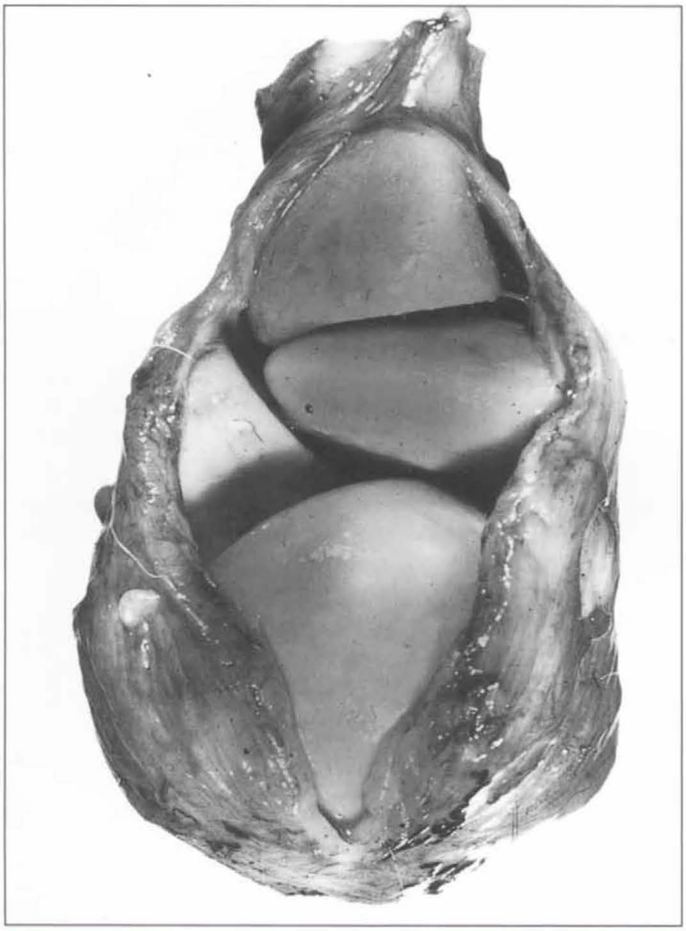

Figure 4.87 Faceted **calculi** filling the urinary bladder of a dog.

clover grows. *In general, calculi are important in cattle, sheep, dogs, and cats, less important in horses, and unimportant in pigs.* In *pigs*, uroliths are occasionally found in the renal pelvis of old animals and, more often, in the pelvis of dehydrated sucklings (see Fig. 4.2; and see section on Renal disease, renal failure, and uremia, above). In *horses*, they occur sometimes as single or several, spherical or faceted carbonate stones in the bladder; urethral obstructions are rare. In *dogs*, several breeds are predisposed to formation of calculi, namely Dachshunds, Dalmatians, Cocker Spaniels, Pekingese, Basset Hounds, Poodles, Schnauzers, and small terriers.

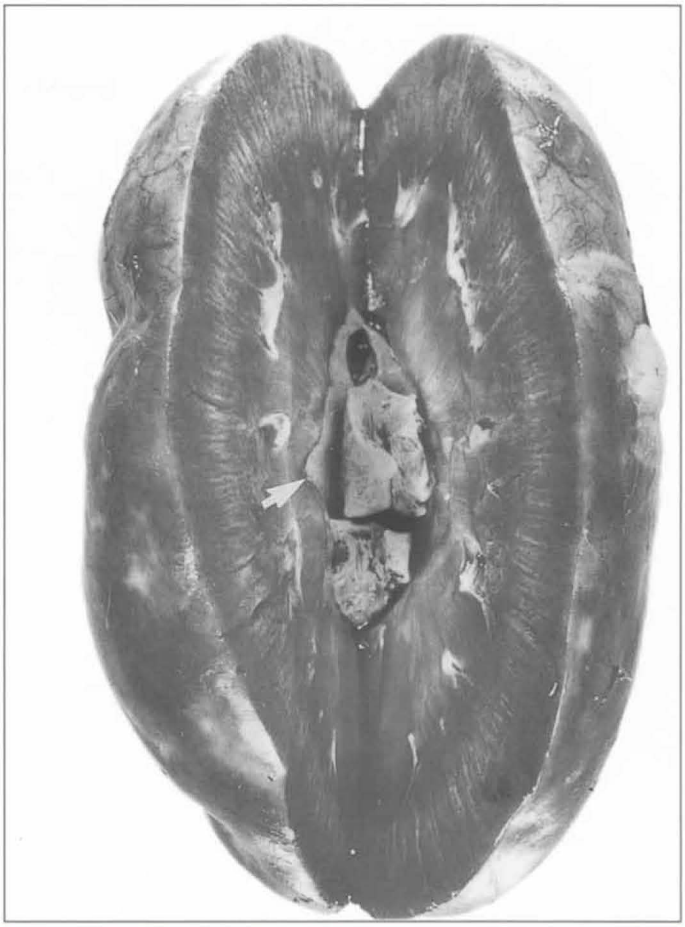

Figure 4.88 Calculus in the renal pelvis of a dog. The renal crest is ulcerated (arrow), and the cortex is irregularly scarred.

Calculi may form in any part of the urinary duct system, from the renal pelvis to the urethra. Some uroliths clearly originate in the lower urinary tract, but the point for development of most is not known (Fig. 4.87). In experimental urolithiasis produced by oxalates or calcium phosphate in laboratory animals, the calculi, initially microscopic, form in the collecting tubules and encrust on the renal papilla. They may grow large enough to make voidance impossible (Fig. 4.88). It is not known whether this is a general phenomenon. Tubular microlithiasis may simply represent crystallization in the highly concentrated urine of the medulla, or, alternatively, it may indicate the production there of an abnormal or excessive matricial substance. Obstructive nephroliths and ureteroliths occasionally develop in horses and cause secondary chronic tubulointerstitial nephritis; the suggested pathogenesis is renal medullary crest necrosis resulting from the use of nonsteroidal anti-inflammatory drugs in dehydrated horses, with subsequent mineralization of the sloughed necrotic renal crest material. Nephroliths are uncommon forms of uroliths in most species (1–4% of canine uroliths).

Small calculi may be voided in the urine, but *impaction in the urethra is common in males.* The common sites of urethral impaction are

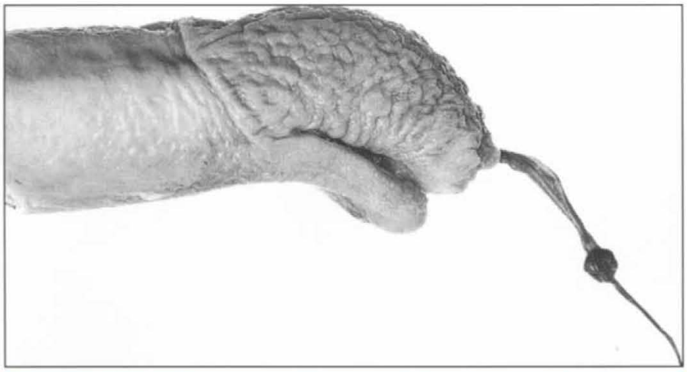

Figure 4.89 Calculus impacted in vermiform appendage of a ram.

the ischial arch, the sigmoid flexure of ruminants, the vermiform appendage of rams (Fig. 4.89), the proximal end of the os penis in dogs, and anywhere along the urethra of male cats. At the point of impaction, there is local pressure necrosis with ulceration of the mucosa and, because the urinary stasis favors bacterial growth, acute hemorrhagic urethritis develops and often ascends to the bladder and even to the kidney. Hydronephrosis is not a prominent development with urethral calculi, because rupture of the urethra with leakage of urine into the surrounding tissues, often associated with infection and acute cellulitis, terminates the condition fairly quickly.

Because of the development of numerous stone analysis centers, large numbers of companion animal uroliths have been studied and knowledge is expanding on the prevalence of mineral composition, breed predilections, geographical region prevalence, and the association with urinary tract infections.

Silica calculi

In **ruminants** these calculi are hard, white to dark-brown, radiopaque, often laminated, and up to 1 cm across. In the bladder of ruminants they are spherical, ovoid, or mulberry-shaped and have smooth surfaces, but in the kidney they are angular and irregular, having the shape of the minor calyces where they are located almost exclusively.

"Pure" silica stones contain about 75% silica as silica dioxide. Mixed calculi contain some calcium oxalate or carbonate. Silica calculi contain about 20% organic matter. Most have a friable core, which is high in amorphous silica and low in organic matter. The core is surrounded by a layer of organic matter, which separates it from the outer concentric laminations, which are high in silica.

Silica calculi are very common in pastured ruminants and are a major cause of urinary tract obstruction. They occur with increasing prevalence in dogs and rarely in horses. Silica calculi are present in over 50% of steers on native (unimproved) range in western Canada; fewer than 5% develop urethral obstruction. The singularity of adjacent laminae in the calculi is consistent with intermittent deposition as urine composition changes. Certain grasses contain 4–5% or more of silica; the level increases through the growing season. Most of it is relatively insoluble but that in the cell sap is relatively soluble, unpolymerized silicic acid. Rumen fluid becomes saturated with respect to silicic acid. After absorption, some is returned to the gut in digestive secretions; less than 1% of dietary silica is excreted in urine and up to 60% is resorbed from the filtrate. However, when urine production is very low, either because of the nature of the diet or because of high insensible fluid losses in hot climates, the concentration of silicic acid in urine may reach five times the saturation level. Even so, precipitation from solution requires other substances, probably proteins of renal or serum origin, in the urine. Calculus formation is reduced to subclinical levels by adding salt to the ration, thereby ensuring high water consumption. Acid-forming effects of the diet and a reduction in the dietary calcium-to-phosphorus ratio also reduce silica urolith formation.

Silica calculi in **dogs** are primarily detected in males, are located in the bladder and urethra, and often cause urinary obstruction. Male German Shepherd Dogs and Old English Sheepdogs are at increased risk for formation of these calculi. Unlike cystic silica calculi in ruminants, bladder stones in dogs have very irregular shapes with surface protrusions; many silica uroliths have a "jackstone" configuration. Silica uroliths in dogs may be multi-layered or single-layered, and may contain calcium oxalate and struvite. Large quantities of plant-derived ingredients, particularly corn gluten feed, rice hulls, and soybean hulls, in dry dog food are implicated as risk factors for development of silica uroliths. Some cases are associated with lower urinary tract infections, often with *Staphylococcus* species. Silica uroliths are likely less soluble in acid than in alkaline urine.

Struvite calculi

Struvite stones are white or gray, radiopaque, chalky, usually smooth, and easily broken. They may be pure struvite but usually contain other compounds such as calcium phosphate (which may form a shell around a struvite), ammonium urate, oxalate, or carbonate. They may be single and large, or numerous and sand-like. Struvite is *magnesium ammonium phosphate hexahydrate* ($MgNH_4PO_4.6H_2O$); formerly it was called "triple phosphate," a misnomer.

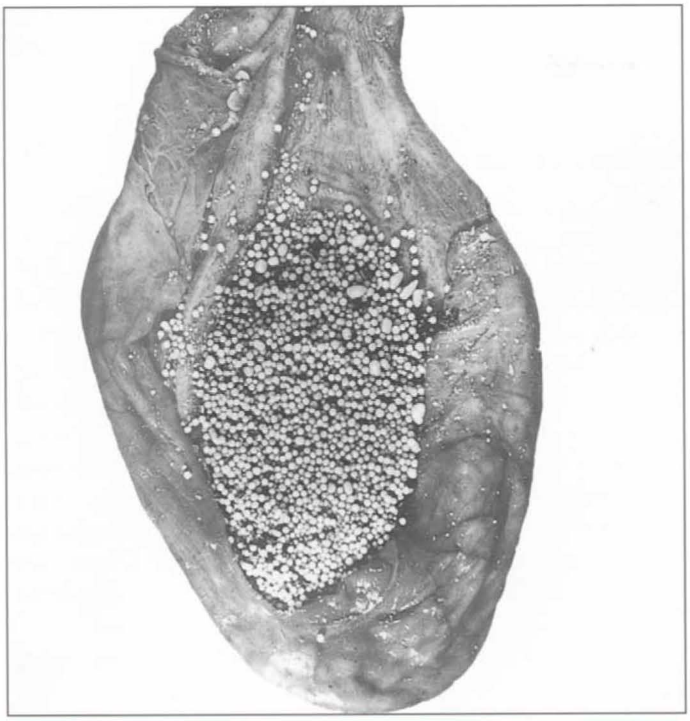

Figure 4.90 Struvite calculi in urinary bladder of a cow.

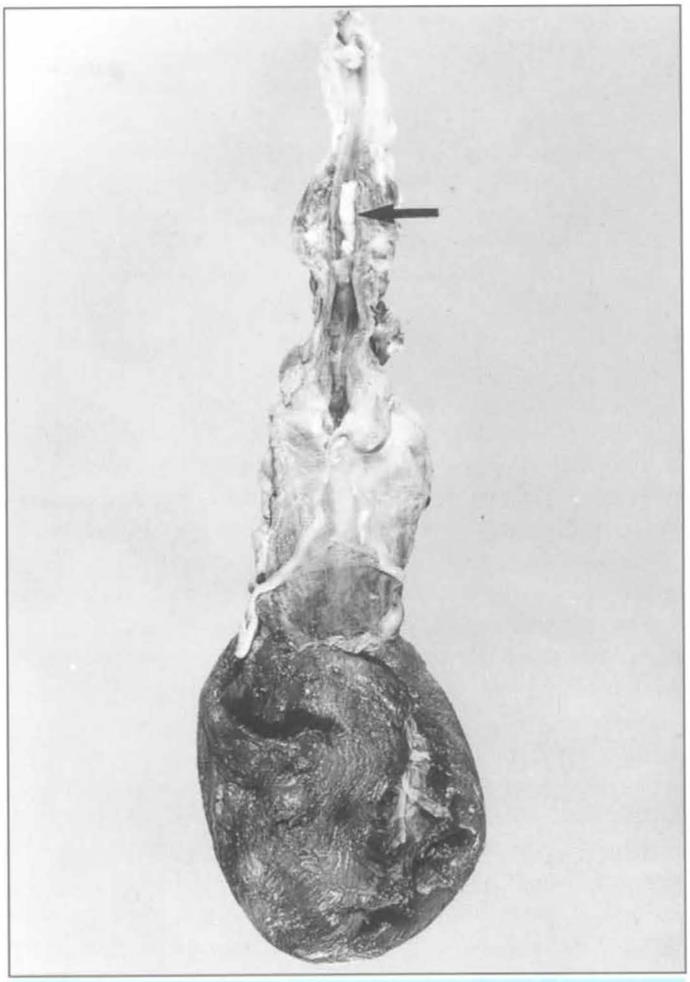

Figure 4.91 Plug of struvite crystals in urethra (arrow) and hemorrhagic cystitis in a cat with feline lower urinary tract disease.

Struvite calculi are important in dogs, cats, and ruminants (Fig. 4.90). In **dogs**, they are the most common types; females are particularly susceptible, perhaps because they develop bladder infections more often than males. Struvite calculi are often single, rapidly forming masses which mold to the shape of the cavity they occupy. They are called *infection calculi* in recognition of their common association with infection. Bacterial ureases from staphylococci and *Proteus* induce supersaturation of urine with struvite by increasing urine pH and ammonium ions. Alkaline urine decreases struvite solubility and increases ionization of trivalent phosphate, both of which favor calculus formation. Factors other than urease production, which are associated with infection, are probably important in the genesis of struvite stones. A high incidence of struvite calculi in Miniature Schnauzers may be related to a familial susceptibility to urinary tract infections. The reason for *sterile* struvite urolithiasis in three related English Cocker Spaniels and in an inbred line of Beagles is not known, but familial risk factors and dietary factors are postulated. The somewhat refractory response of struvite calculi to medical or dietary manipulations in dogs is thought to be due to the presence of associated hydroxyl apatite and concentric laminations, which have a low porosity.

In **cats**, most cases of the heterogeneous group of disorders referred to as *feline lower urinary tract disease* (FLUTD) are idiopathic, and are discussed below in the section on *Cystitis*. One manifestation of FLUTD is urolithiasis, in which discrete calculi develop in the urinary bladder of young to middle-aged cats (increased risk for cats between 4 and 10 years of age). Additional risk factors are associated with Russian Blue, Himalayan, or Persian breed, and castrated male or spayed female status. Intact females had a reduced risk. Struvite crystalluria is often seen in cats with and without calculi; the reasons for aggregation of crystals into sterile calculi are obscure. The prevalence of struvite uroliths and struvite urethral plugs has declined since the mid-1980s when cat foods were reformulated; there has been a concomitant increase in calcium oxalate urolithiasis in cats. Formation of struvite uroliths can be induced in previously normal cats fed calculogenic diets containing 0.15–1.0% dry weight magnesium. Primary pores in struvite calculi are an important feature and may allow dietary and medicinal manipulations successfully to dissolve these uroliths. Coagulase-positive staphylococci and other bacteria may be cultured from the urine or calculi of some affected cats, and the formation of infection-induced struvite calculi is similar to that mentioned above for dogs; these calculi are much less common than are sterile struvite uroliths.

Of considerably more importance than discrete calculi are the amorphous accumulations of protein, cellular debris, and struvite crystals that form sabulous (matrix-crystalline) urethral plugs in male cats, with castrated males being at a higher risk and spayed females at the lowest risk. Animals between 2 and 7 years of age are predisposed. This condition has been known as "feline urologic syndrome," a term no longer favored; it results from concomitant occurrence of urinary tract inflammation and the presence of various types of urine crystals. It is characterized by dysuria, hematuria, and urethral obstruction. If unrelieved, the obstruction can lead to bladder distension, hemorrhagic cystitis, azotemia, and death (Fig. 4.91). *The obstructive material, which becomes molded to the shape of the urethra in male cats, may be either* *struvite "sand" or rubber-like protein matrix, or a mixture of the two*; the matrix contains Tamm–Horsfall mucoprotein, albumin, globulins, cells, and cellular debris. The inflammatory component of plugs may be the product of infection with viruses, bacteria, or fungi. Various viruses, including feline cell-associated herpesvirus (a strain of *Bovine herpesvirus 4*), feline syncytia-forming virus, and *Feline calicivirus*, have been implicated as potential urinary pathogens in cats. There is no concrete evidence for *Mycoplasma* or *Ureaplasma* being urinary pathogens in FLUTD. Addition of magnesium and phosphate to the diet causes disease in some, presumably predisposed, cats and, conversely, reduction of dietary magnesium reduces the incidence. Alkaline urine pH is likely of more significance in the formation of struvite crystals than is magnesium intake. The apparent increased incidence during cold winter months may be due to decreased fluid consumption or increased intervals between urinations. The incidence of urethral plugs has decreased as more cats have been fed magnesium-restricted/pH-controlling diets (total mineral <6% dry matter (DM), Mg 0.05–0.10% DM, Mg <20 mg/100 kcal dose equivalent, maintain an average resting urine pH of 6.5 or less and an average postprandial peak pH not to exceed 7.0).

In **ruminants**, struvite calculi usually occur in feedlot cattle or sheep on high grain rations and obstruction may develop in up to 10% of steers. As in cats, *calculi usually form a gritty sludge with a high proportion of matrix*. Inhibition of urethral growth by early castration predisposes to obstruction, and increased water consumption tends to prevent obstruction. Animals with crystalluria often have crystals adhering to preputial hairs. Diets high in phosphate can cause a very high incidence of calculi in sheep; a calcium-to-phosphorus ratio of 1:2 or wider appears to be the critical factor, but the form in which they are fed and the balance of other constituents such as magnesium, sodium, and potassium are probably also important. Additional potassium tends to promote phosphate urolithiasis. Magnesium deficiency leads to renal mineralization and tubular microlithiasis, at least in laboratory species, and both sodium and magnesium are competitive with calcium, and increase the solubility of calcium salts in urine. There may also be a genetic effect on urolithiasis in sheep; urolithiasis is more likely to develop in sheep that excrete phosphorus mainly in urine than in those that excrete phosphorus mainly in feces.

Oxalate calculi

Oxalate calculi are hard, heavy, white, or yellow, and typically covered with jagged spines, though some are smooth. They tend to be large and solitary in the bladder.

Oxalate calculi occur as the calcium oxalates, *whewellite (calcium oxalate monohydrate)* and *weddellite (calcium oxalate dihydrate)*. Their development is not well understood, but obviously *hypercalciuria and hyperoxaluria are involved*. There are several causes of hypercalciuria (see section on Hypercalcemic nephropathy, above). Oxalic acid is synthesized from glyoxylic and ascorbic acid and may be ingested in certain foods. Hyperuricosuria may be involved in oxalate precipitation, since sodium hydrogen urate may act as a heterogeneous nucleator. Dietary magnesium and citrate inhibit the formation of calcium oxalate uroliths by forming soluble complexes with oxalate and calcium respectively.

Oxalate (and silica) calculi may be important in **sheep** grazing grain stubble but the source of the oxalate is not known. Oxalate-containing plants are not apparently a source since oxalate is metabolized in the rumen; nonetheless, occasional exceptions to this general rule do seem to occur. Feeding a low-calcium diet (0.3% Ca) has produced oxalate urolithiasis in steers, possibly because of increased bone resorption resulting in increased plasma concentrations of hydroxyproline, an oxalate precursor. High magnesium intakes inhibit formation of oxalate calculi while low levels induce formation in some species.

In **dogs**, oxalate calculi are second to struvite calculi in prevalence and are of increasing importance, but little is known of their origins. Calcium oxalate and calcium phosphate (hydroxyapatite or calcium apatite) calculi occur in dogs with primary hyperparathyroidism, hypercalcemia, hyperadrenocorticism, or following exogenous steroid administration. Canine dietary factors such as high protein, fat, Ca, P, Mg, Na, K, Cl, and use of canned foods are thought to decrease the risk of development of these stones. Males are more frequently affected than females, and they are seen more commonly in older animals. The Miniature Schnauzer, Bichon Frise, Lhasa Apso, Yorkshire Terrier, Shih Tzu, and Miniature Poodle are breeds at increased risk. In Miniature Schnauzers predisposed to development of calcium oxalate uroliths, hypercalciuria, decreased urinary oxalate, normal urinary citrate, increased brushite urinary relative supersaturation, lower urine volume, and elevated excreted uric acid levels are consistent findings.

The prevalence of oxalate uroliths in **cats** has increased markedly from the early 1980s through the 1990s. This increase has been accompanied by a marked decline in the prevalence of struvite uroliths. The underlying cause for oxalate uroliths in cats is usually unknown, but likely related to diet. Several dietary factors can contribute to calciuria, including high animal-source protein, low magnesium, high sodium chloride, and diets formulated to acidify urine. Risk factors also include use of a single brand of cat food without additional supplementation, and maintaining cats in an indoor environment only. Persian, Himalayan, and several other breeds are at increased risk; cats with calcium oxalate uroliths tend to be older than cats with struvite uroliths. Additionally, male and neutered cats are at higher risk for the development of oxalate calculi. Oxalate uroliths in cats have been associated with parathyroid neoplasia, as in dogs.

Uric acid and urate calculi

These *purine calculi* are usually multiple, hard, concentrically laminated, brown-green, and moderately radiodense. In the bladder, they are frequently spherical and less than 5 mm across. Most contain ammonium urate with some uric acid and phosphate; in others, sodium urate is the predominant salt.

Urate stones are most common in dogs, especially Dalmatians, but also occur in pigs (see section on Renal disease, renal failure, and uremia, above) and rarely in cats. Neonatal piglets in a negative energy balance produce increased purine catabolites, which predispose to urate urolithiasis. Dalmatians excrete high levels of uric acid in their urine. This is due to defective hepatocellular uptake of uric acid, which results in incomplete conversion of uric acid to allantoin, a more soluble product of purine metabolism; this defect is an inherited autosomal recessive trait. Hepatic uricase levels are normal. Additionally, the defective transport system involves renal tubules and prevents reabsorption of uric acid from glomerular filtrate. Active tubular secretion also contributes. Predisposing factors for urolith formation include hyperuricemia, hyperammonemia, hyperuricosuria, hyperammonuria, aciduria, and a genetic predisposition. Male Dalmatians are predisposed. Other dog breeds with a higher incidence of urate urolithiasis include English Bulldogs, Miniature Schnauzers, Shih Tzus, and Yorkshire Terriers. Dogs with portosystemic shunts have ammonium biurate crystals in their urine, and may have urate-containing calculi in kidneys and bladder.

Urates exist in supersaturated urine as lyophobic colloids, which are flocculated (coalesced and precipitated) by high levels of ammonium ion and, to a lesser extent, by low pH. Urea-splitting organisms may be important in the development of urate calculi since production of ammonium ion favors calculus formation. Also, although higher pH inhibits precipitation of uric acid, it favors precipitation of ammonium urate, as well as phosphates, which are often found in urate calculi.

Xanthine calculi

Xanthine stones are yellow to brown-red, often concentrically laminated, friable, and irregularly shaped. They are radiolucent. *Xanthine is a metabolite of purines*, which seldom appears in urine because it is normally degraded by xanthine oxidase to uric acid.

Xanthine calculi occur occasionally in dogs and are reported in sheep, calves, and a cat. A high incidence in sheep was circumstantially related to deficiency of molybdenum in unimproved pasture; molybdenum is a component of xanthine oxidase. Several cases in calves in Japan were also associated with deficiency of xanthine oxidase. Xanthine precipitates in acid urine. Calculi usually form in the collecting ducts and calyces of the kidney, and may cause hydronephrosis.

Two forms exist in dogs, as in humans. The *primary form* is inherited as an autosomal recessive, and is due to an inborn enzyme defect in xanthine oxidase. This hepatic enzyme catalyzes two sequential steps in degradation of purines, namely conversion of hypoxanthine to xanthine, and then xanthine to uric acid. This form has been noted most often in Dachshunds and recently in a family of Cavalier King Charles Spaniels. The *secondary form* (iatrogenic) is the more common in dogs, especially Dalmatians, and is usually the result of previous treatment with allopurinol, which binds to and inhibits the action of xanthine oxidase.

Cystine calculi

Cystine calculi are small and irregular, soft and friable, waxy, and light yellow to red-brown, turning to green on exposure to daylight. Many cystine calculi consist of pure cystine; others may also contain calcium oxalate, struvite, brushite (calcium hydrogen phosphate dihydrate), and complex urates.

Cystine stones occur in dogs and rarely in cats. They comprise about 1–3% of canine calculi in North America, but 20–30% in some European centers, being second to struvite calculi in incidence. Cystinuria occurs in both males and females, but cystine calculi and urinary obstruction occur almost exclusively in males. They are primarily found in the urinary bladder, but nephroliths are common in Newfoundlands. Other predisposed breeds include Dachshunds, Bulldogs, Mastiffs, Bassett Hounds, and Tibetan Spaniels. Although blood cystine levels are normal, an *inborn error of metabolism in affected dogs* results in high levels of urinary cystine because of defective proximal tubular reabsorption from glomerular filtrate. Many dogs with cystinuria also have high levels of other amino acids in their urine, but these are more soluble than cystine. Cystine precipitates in acid urine, but factors other than urinary pH are probably important in the genesis of cystine stones since dogs with crystalluria do not always form them. The incidence of recurrent urolithiasis is enhanced in those dogs with higher excretions of urinary cystine. The mode of inheritance of cytinuria is unknown in most breeds of dogs, but it is transmitted as a simple autosomal recessive trait in Newfoundlands. In some dogs the severity of cystinuria may decrease with age.

Clover stones

Sheep grazing estrogenic pastures, particularly subterranean clover, or those *injected or implanted with estrogens*, may have an incidence of fatal urinary obstruction as high as 10%. There are probably three *separate developmental patterns* and, in each, the obstructing material is soft or pulpy and scantily mineralized. Probably the most common pattern is urethral obstruction by desquamated cells and secretions of accessory glands originating in the pelvic urethra under the influence of estrogen. The second type, the so-called "clover stone," is usually found in the renal pelvis as a yellow, soft material, which eventually leads to fibrosis and shrinkage of the kidney. It affects both sexes equally. These calculi contain benzocoumarins, which may be metabolites of phytoestrogens. Third, sudden and serious mortalities may occur in male sheep grazing subterranean clover during its period of rapid maturation. The urethral process becomes impacted with soft white paste consisting mainly of calcium carbonate and an unidentified organic material probably related to isoflavones.

Other types of calculi

Several other types of calculi develop in animals; they may be important locally or simply be curiosities. **Tetracycline**, **sulfonamide**, and **barium** stones, iatrogenic and rare, fall into the latter category. Other chemical compounds are more common but often constitute a minor part of certain uroliths. Stones with a high **carbonate** content are associated with very alkaline urines and are seen in ruminants consuming high oxalate plants or clover-dominated pastures.

In horses, calcium carbonate crystals are seen commonly in normal urine. Calculi are much less frequent, but are most commonly composed of **calcium carbonate**, usually in the crystalline form of calcite, and substituted vaterite (the Ca of $CaCO_3$ is replaced in various amounts by Mg, K, and Mn); weddellite (calcium oxalate dihydrate) may also be present. Alkaline pH and dietary factors are implicated in their formation.

Fewer than 3% of canine stone patients have uroliths composed of **calcium phosphate**. Factors that decrease calcium phosphate solubility and hence predispose to urolith formation include: alkaline urine, hypercalciuria (hyperparathyroidism and other hypercalcemic disorders), reduced concentrations of crystallization inhibitors (inorganic pyrophosphates, citrate, magnesium ions, nephrocalcin), or increased concentrations of crystallization promoters (epitactic induction by calcium oxalate and monosodium urate crystals).

INFLAMMATION OF THE LOWER URINARY TRACT

Inflammation of the lower urinary tract centers on involvement of the urinary bladder, i.e., **cystitis**. **Ureteritis** is rare in the absence of cystitis, and clinical **urethritis** in animals is usually associated with obstruction by a calculus from the bladder. Under normal circumstances, the bladder is resistant to infection, and bacteria are quickly eliminated by the normal flow of normal urine. *Predisposition to urinary tract infection* (UTI) occurs when there is stagnation of urine due to obstruction, incomplete voiding at micturition, or urothelial trauma. *Other risk factors for UTI* include catheterization, vaginoscopy, urinary incontinence, vaginitis, or administration of antibiotics or corticosteroids within the last 60 days. Of itself, normal voiding is not sufficient to prevent or eliminate bladder infection. Indeed, complete voidance does not occur but residual urine is rapidly diluted or added to by continuing excretion. *Defense mechanisms* in the bladder and urethra, which prevent bacterial adhesion to mucosal surfaces, are essential if bacteria are to be removed by urine flow. Tamm–Horsfall mucoprotein, produced in the kidneys, may bind to bacterial adhesins and prevent adherence. Local production of immunoglobulin A and a surface glycosaminoglycan layer is probably important in preventing attachment of organisms to the normal urothelium, and immunoglobulin G may have similar activity in specific UTIs. Urinary oligosaccharides may be able to detach adherent bacteria. Voiding of sloughed urothelial cells with attached bacteria aids their clearance. Incomplete voiding at micturition may be a result of diverticula of the urinary bladder or vesicoureteral reflux. The presence of residual urine can maintain a bladder infection, allowing organisms to take advantage of any opportunity to invade the urothelium.

Unlike human urine, which tends to be a good medium for bacterial growth, animal urines, especially those of dogs and cats, usually have antibacterial activity. This activity is related to urine pH and particularly to urine osmolality. In general, the further the pH is from the optimum range of 6–7, the less likely it is to support bacterial growth. The antibacterial effect of acid urines is related to their concentration of undissociated organic acids. High concentrations of urea and other solutes increase urine osmolality and contribute significantly to its bacteriostatic effect.

In order to infect the urinary tract, uropathogens must compete with the normal bacterial flora of the distal urethra, vulva, or prepuce. *The usual causes of cystitis are* **bacteria** *from the urethra, the origin of which are almost always the rectal flora.* Cystitis is common in young animals with patent urachus, and the bacterial flora is mixed. When bacteria breach the surface defenses of the urothelium and attach to the epithelial cells, the cells are desquamated through a rapid apoptosis-like mechanism involving caspase activation and host DNA fragmentation. When the urothelium is penetrated, clearance is prevented and neutrophils and macrophages in the submucosa respond. Leukocytes in urine are not usually phagocytic.

A variety of bacteria may be involved in bladder infections (see section on Pyelonephritis, above) and these include in all hosts *Escherichia coli, Proteus vulgaris*, streptococci, and staphylococci. In a large compilation of canine urinary tract infection culture data, the six most common isolates included, in decreasing prevalence: *E. coli* 44.1%, *Staphylococcus* spp. 11.6%, *Proteus* spp. 9.3%, *Klebsiella* spp. 9.1%, *Enterococcus* spp. 8.0%, and *Streptococcus* spp. 5.4%. Infection with a single organism was seen in >72 % of infections, and there was a predisposition for females. The *Corynebacterium renale* group (*C. renale, C. pilosum, C. cystitidis)* is important in cows, and less so in other species, where it is usually part of a mixed infection. *C. urealyticum* can cause an "encrusted cystitis" in dogs because of the deposition of struvite (magnesium ammonium phosphate) along the bladder mucosa secondary to ammonia release by these urease-producing bacteria. *Actinobaculum (Eubacterium) suis* is the primary cause of cystitis and pyelonephritis in swine and a leading cause of death in sows; *A. suis* infections typically produce macrohematuria and alkaline urine.

Mycoplasmas are uncommon causes of UTI in dogs and cattle. Urogenital infections causing prostatitis, orchitis, nephritis, and cystitis may occur in canine **blastomycosis**. *Aspergillus, Candida*, and *Nocardia* are unusual causes of cystitis in dogs and cats. *Candida* infections can be seen more commonly with predisposing factors such as diabetes mellitus, prolonged antibiotic or glucocorticoid usage, aciduria, indwelling catheters, or an immunocompromised state. *Borrelia burgdorferi* has been detected by nested flagellin PCR in the urine of dogs with cystitis or prostatitis, suggesting that urinary signs can be associated with Lyme disease in dogs.

Bacterial pathogens of the urinary tract, such as *Escherichia coli*, can express a formidable array of *virulence factors*, including fimbriae or pili adhesins (P fimbriae, type 1 fimbriae), nonfimbrial adhesins, aerobactin (an iron chelator), hemolysin, capsular polysaccharide (K antigen), and anticomplementary serum resistance. The most urovirulent strains often express multiple virulence factors simultaneously to produce a synergistic or additive effect. Certain virulence factors, such as adhesins, specifically favor the development of pyelonephritis, while others favor cystitis. In humans, *E. coli* with P fimbriae bind to renal pelvic urothelium and are thought to be responsible for pyelonephritis. Type 1 fimbriae (pili) are of most importance in bladder colonization. Type 1 pilus tips interact with membrane glycoproteins known as uroplakins. Attachment results in exfoliation of bladder epithelial cells as part of an innate host defense system. In contrast, gram-positive bacteria utilize extracellular polysaccharides for adhesion.

Cystitis

Cystitis does occur without obvious predispositions of the types described above. There is a higher incidence in females, which is probably associated with the shorter urethra. Pathological urine may be a better medium for bacterial growth than normal urine. Although the glucosuria of diabetes mellitus promotes bacterial growth, the influence of other reducing substances and of even slight levels of proteinuria may be significant in the development of cystitis with this disease. Decreased leukocyte efficiency may also be involved. Diabetic animals with associated Cushing's disease, pyometra, or progesterone-somatotrophin-induced diabetes mellitus are at increased risk for developing urinary tract infections with *E. coli. Emphysematous cystitis* develops in some dogs and cats with diabetes mellitus, and is thought to be a result of fermentation of sugar by glucose-fermenting bacteria. Emphysematous cystitis is less commonly detected in nondiabetic animals (Fig. 4.92). Hormone-induced changes as occur in hyperestrogenism may also affect the functional integrity of the urethral and vesicular epithelium, and the role of hormones in the production of glycosaminoglycans in the urogenital tract may also change the susceptibility to UTIs. During estrus in sows, estrogen causes the urine pH to rise, producing an alkaline environment suitable for the growth of *Eubacterium suis.*

As well as the opportunistic bacterial UTIs that develop in all species, there are a few diseases of which inflammation of the lower urinary tract is often a part. Hemorrhagic cystitis sometimes occurs in *malignant catarrhal fever* in cattle and deer, and occasionally is the dominant gross feature in the disease. Linear granulomas occur in the renal pelvis, ureter, and bladder of cattle with *Schistosoma mattheei* infections. Cystitis in horses and cattle (but not sheep) grazing *Sorghum* sp. is associated with ataxia caused by degenerative encephalomyelopathy; the bladder lesions are almost certainly

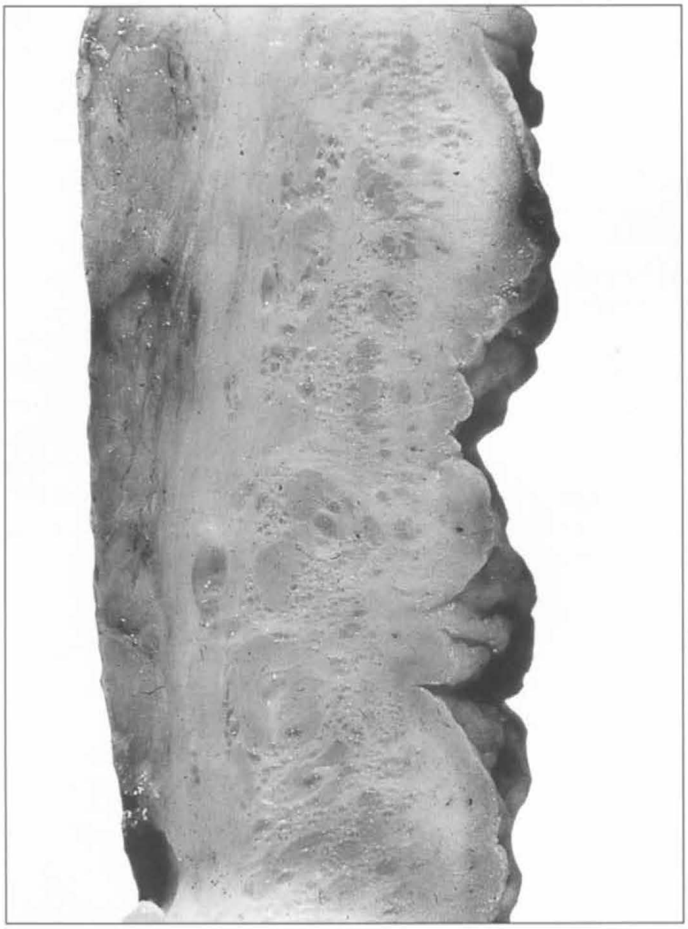

Figure 4.92 Emphysematous cystitis in a dog. Not associated with diabetes mellitus.

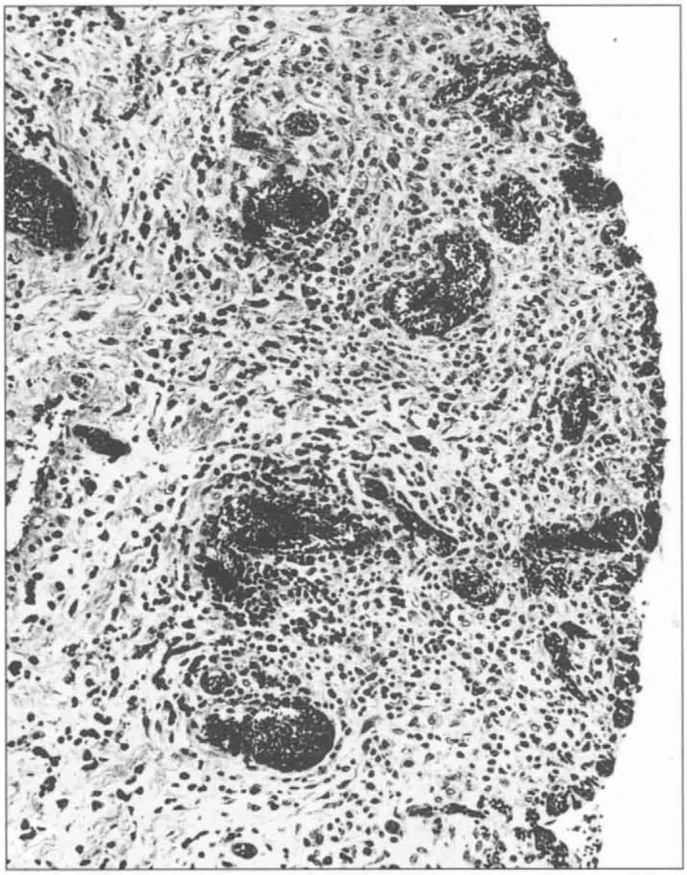

Figure 4.93 Acute hemorrhagic cystitis with complete loss of epithelium, bovine.

neurogenic in origin. The cause of a similar *epizootic cystitis of horses* in Australia is not known.

Lower urinary tract disease (LUTD) in cats may result from UTI of viral, bacterial, or fungal origin; uroliths; urethral plugs; congenital or acquired anatomic defects of the bladder or urethra; or iatrogenic causes. Abyssinian cats, cats greater than 10 years of age, and spayed females are predisposed to bacterial UTI. Novel feline caliciviruses have been isolated from LUTD cases; further studies are required to determine if these are uropathogens and/or causative agents. Many cases of LUTD remain noninfectious and idiopathic (iLUTD). Feline iLUTD bears considerable resemblance to the somewhat obscure condition in humans called "interstitial cystitis." **Feline interstitial cystitis** is characterized by chronic irritative voiding signs (dysuria, hematuria, pollakiuria, and/or inappropriate urination), sterile and cytologically negative urine, and cystoscopically visible submucosal petechial hemorrhages ("glomerulations"). This common feline condition may result from decreased urinary excretion of glycosaminoglycans, increased bladder permeability, and neurogenic inflammation. Increased sympathetic activity is confirmed in feline interstitial cystitis cases and this affects bladder function locally. Nonspecific histologic changes in the bladders of affected cats include submucosal edema, dilated submucosal vessels with margination of neutrophils, and submucosal hemorrhage; there may also be increased numbers of submucosal mast cells. Cats between 4 and 10 years of age are predisposed.

Sterile hemorrhagic cystitis may occur in dogs and cats treated for neoplastic or immunologic diseases with *cyclophosphamide*. Activated metabolites of the drug cause mucosal ulceration, hemorrhage, and edema. Signs of cystitis occasionally follow an 8-week course of therapy but have also been noted within 24 hours of administration of the first therapeutic dose. Concurrent treatment with other drugs, degree of diuresis, and pre-existing cystitis may influence the prevalence of cyclophosphamide-induced lesions. Fibrosis and mineralization of the bladder may result in persistent hematuria and incontinence. Transitional cell carcinoma may develop in the bladder of dogs in association with prolonged cyclophosphamide therapy.

Eosinophilic cystitis is an uncommon form of cystitis seen in older dogs with a history of urolithiasis and characterized by the predominance of eosinophils in a proliferative fibroblastic mass.

Cystitis is differentiated into acute and chronic forms, but there is considerable overlap in both the lesions and the causes. In simple **acute** catarrhal inflammation, there is moderate hyperemia and submucosal edema and the surface is covered with a layer of tenacious catarrhal exudate. The urine is cloudy. Histologically, there is degeneration and desquamation of the epithelium and prominent leukocytic infiltration. Submucosal vessels are dilated and cuffed by leukocytes. In somewhat more severe grades of inflammation, leukocytes may infiltrate all layers of the bladder wall, and hemorrhage from the dilated vessels may be severe enough to produce large clots in the bladder. These hemorrhagic complications are common in cystitis (Fig. 4.93) following urethral obstruction, especially in cats and cattle. When the

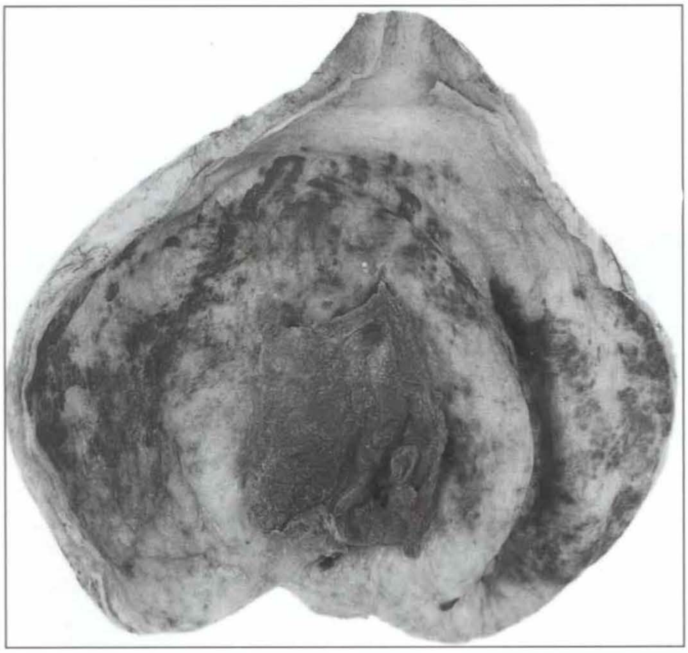

Figure 4.94 Acute fibrinous cystitis in a dog.

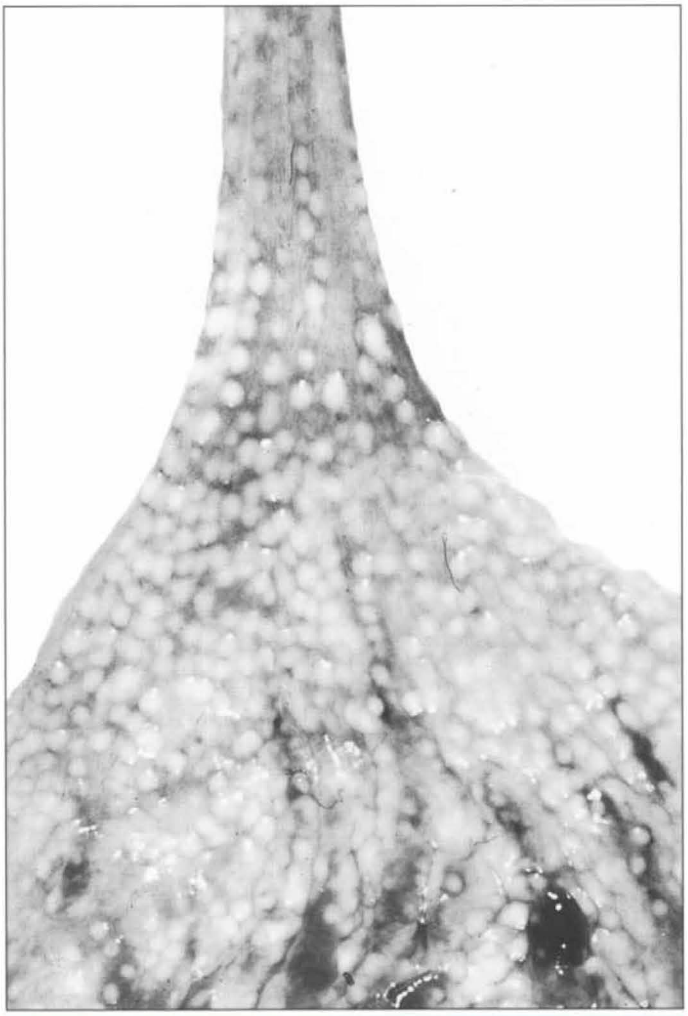

Figure 4.95 Follicular cystitis in a dog.

inflammatory process is severe, the cystitis may be of superficial fibrinous or deep diptheritic type (Fig. 4.94). In both, there is a thick, dirty-yellow friable surface encrustation, which may peel with difficulty. A large portion of the mucosa may become necrotic in addition to deeper layers of the bladder wall. Ulcerations may penetrate the wall to the serosa or predispose to rupture.

Chronic cystitis may also take a number of anatomic forms. The simplest occurs in association with vesical calculi. The mucosa is irregularly reddened and usually thickened. There is some epithelial desquamation and the submucosa is heavily infiltrated with mononuclear inflammatory cells; there are few neutrophils. In addition, there is often connective tissue thickening of the submucosa and hypertrophy of the muscularis.

There are also some special anatomic forms of chronic cystitis. In **follicular cystitis**, which is common in dogs, the mucosa is studded with gray-white nodules about 1 mm across (Fig. 4.95) which may be confluent or surrounded by a zone of hyperemia. Histologically, the nodules are aggregates of proliferating lymphocytic cells. These are immediately beneath the epithelium, which may be normal or ulcerated.

Chronic polypoid cystitis is common in any species (Fig. 4.96). In this, the mucosa is thrown into many folds or villus-like sessile projections. The polyps are covered by epithelium over a core of proliferated connective tissue densely infiltrated with mononuclear leukocytes. The polyps often undergo mucoid degeneration in cattle, or the epithelium may undergo metaplasia to a mucus-secreting, glandular type, often resembling colonic epithelium. Such polyps may break down and cause intermittent hematuria. Obstructive uropathy is another sequela. Biopsy is required to differentiate them from neoplasms.

Enzootic hematuria

Enzootic hematuria is a syndrome in mature cattle characterized by persistent hematuria and anemia, and is associated with hemorrhages or neoplasms in the lower urinary tract. In over 90% of cases, the hematuria originates from tumors of the urinary bladder. Outbreaks of the disease are reported in sheep.

Enzootic hematuria occurs on all continents but is restricted to particular locations. In endemic areas, up to 90% of adult cattle may be affected. *The syndrome is attributed to chronic ingestion of* **bracken fern** and is reproducible experimentally. The extent and persistence with which toxic ferns are grazed probably influences the incidence of bladder lesions. There are two subspecies of bracken fern: *Pteridium aquilinum* subsp. *aquilinum*, containing eight varieties, and *P. aquilinum* subsp. *caudatum*, containing four varieties, and it is not known whether all varieties are toxic. *P. revolutum*, a species of bracken fern common in south Asia, and *P. esculentum*, a bracken fern of Australia, also produce enzootic hematuria. In areas where bracken does not grow, other ferns, such as *Cheilanthes sieberi* (mulga or rock fern from Australia), are capable of producing enzootic hematuria.

Bracken fern is one of the most common plants on the planet, and is said to be the only plant that causes naturally occurring tumors in animals. *It contains several toxic substances,* including a thiaminase, a variety of carcinogens (quercetin, shikimic acid, prunasin, ptaquiloside (braxin C), ptaquiloside Z, aquilide A, and others), and a "bleeding factor" of unknown structure. Following administration of ptaquiloside to guinea pigs, hemorrhagic cystitis results, suggesting that this is one of the toxic principles in bracken fern hematuria. There is a strong link between bracken fern and Bovine papillomavirus 2 (BPV-2) in the development of bladder neoplasms in animals with enzootic hematuria; the relationship of oncogenic viruses to bracken is discussed in Vol. 2, Alimentary system.

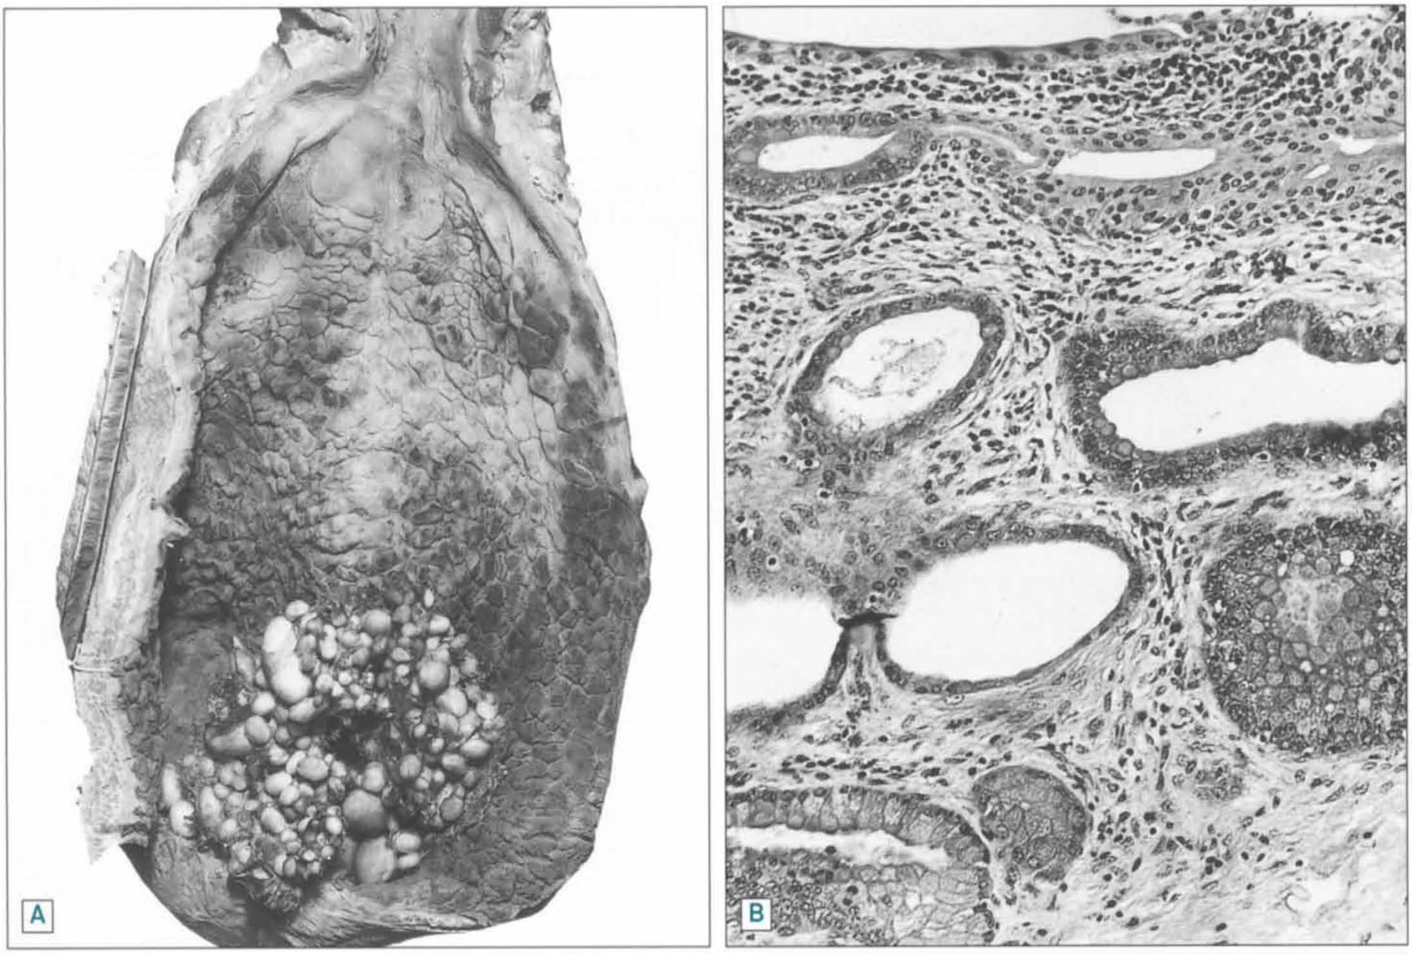

Figure 4.97 Enzootic hematuria in a cow. **A.** Dark **angiomatoid lesions** and confluent **nodular tumors** involving most of the bladder mucosa. **B. Mucous adenocarcinoma** of urinary bladder. There is ulceration and inflammation of the bladder surface (above, right).

Cattle fed low levels of bracken fern develop microscopic, followed by macroscopic, hematuria. Microhematuria is usually associated with petechial, ecchymotic, or suffusive hemorrhages in the urothelium of the renal calyces, pelvis, ureter, and bladder. These lesions appear to be a manifestation of the hemorrhagic syndrome characteristic of acute bracken fern poisoning (see Vol. 3, Hematopoietic system). In some cases, microscopic hematuria occurs before gross lesions are visible. Diffuse or patchy areas of pink discoloration develop in the bladder mucosa and, microscopically, ectasia and engorgement of capillaries are present. These altered vessels are prone to hemorrhage into the bladder wall or lumen and nodular hemangiomatous lesions develop in affected areas. In a few animals, macroscopic hematuria is solely associated with these non-neoplastic changes, but it is usually caused by the development of tumors, which ulcerate and bleed into the lumen (Fig. 4.97). Occasionally tumors also develop in the renal pelvis and ureter, and hepatic hemangiomas accompany bladder tumors in a few animals. Most neoplasms are located on the ventral and lateral walls of the bladder, where constant contact with urine is provided.

Several types of epithelial and mesenchymal neoplasms may develop, including transitional cell and squamous cell carcinoma, papilloma, adenoma, hemangioma, hemangiosarcoma, leiomyosarcoma, fibroma, and fibrosarcoma. Multiple tumors of more than one type may be present, and in over 50% of affected cattle mixed epithelial–mesenchymal neoplasms develop. *Papillomas, fibromas, and hemangiomas with carcinomas are the most common types.* Malignant types may invade locally and about 10% of epithelial malignancies metastasize to iliac nodes or lungs. Chronic cystitis usually accompanies the neoplastic changes. The gross and microscopic appearance of the inflammatory and neoplastic lesions is conventional; Brunn nests may develop in the mucosa. Epithelial neoplasms appear to develop from the hyperplastic and metaplastic (squamous and mucous) changes in the urothelium that often accompany the vascular lesions described above. A pagetoid variant of urothelial carcinoma in situ has been reported in a cow that also had enzootic hematuria and concurrent BPV-2 infection; fragile histidine triad (Fhit) protein, expressed by the tumor suppressor gene *FHIT*, was found to be absent in some of the pagetoid cells, correlating with late-stage neoplastic progression. Uroplakins are urothelial cell differentiation products that form a major portion of the asymmetric unit membrane and are more consistently expressed in the superficial transitional epithelium. A decrease has been noted in superficial positive immunohistochemical uroplakin staining in increasingly malignant urothelial tumors in cattle with chronic enzootic hematuria. Although not necessarily of use in prognosticating tumors, staining for uroplakins may assist the identification of metastatic urothelial cell clusters and further characterize transitional cell differentiation in neoplasia.

NEOPLASMS OF THE LOWER URINARY TRACT

Neoplasia of the lower urinary tract is uncommon but most often occurs in dogs, cats, and cattle (Figs 4.97A and 4.98) (see section on Enzootic hematuria, above). There are few data for other animals, thus the following discussion concerns mainly these species; almost all bovine tumors are part of enzootic hematuria. Tumors of the urinary bladder account for fewer than 1% of all canine neoplasms, and a lower prevalence in cats. They occur somewhat more often in female than male dogs in some studies, but in other studies they are more frequent in male dogs, as they are in human males. The Scottish Terrier, Shetland Sheepdog, Beagle, and Collie seem to be at greater risk than other breeds. The greater susceptibility of the urinary bladder than of other parts of the tract to neoplasia may be due to more prolonged exposure of the bladder mucosa to urinary carcinogens. *In general, urinary bladder tumors are slow-growing and late to metastasize.* With the exception of rhabdomyosarcoma, neoplasia of the lower urinary tract usually occurs in old animals.

Bladder neoplasia may be caused by a variety of *industrial chemicals* (2-naphthylamine, benzidine), tryptophan metabolites (ortho-aminophenol), chronic irritation, foreign bodies (sutures), viruses, bracken fern, and cyclophosphamide. The greater concentration of *tryptophan* metabolites in dog urine than in cat urine may account for the higher prevalence of bladder tumors in dogs. *Grading of urinary tract neoplasms according to tumor invasiveness, lymph node involvement, and presence of metastases (the TNM system)* can assist with prognostication and selection of therapy; the use of biological markers (antigens, tumor products) shows promise of improving clinical staging of urinary tumors in human medicine.

Secondary tumors are rare; those of the bladder comprise ~5% of tumors of this organ. These originate in pelvic organs or as peritoneal implants.

Epithelial tumors

Epithelial tumors comprise ~80% of the lower urinary tract neoplasms. They occur as adenomas, papillomas, and carcinomas, and most of them develop in the bladder of old animals.

Adenomas are rare in all species; they originate from areas of mucous metaplasia of the urothelium and may be single or multiple with a papilliform or pedunculated appearance. Microscopically, they form glandular structures, some of which contain mucin. **Papillomas** constitute ~17% of primary tumors of the urinary bladder. They tend to be multiple and may be pedunculated or sessile, occasionally involving most of the mucosa. They are covered by well-differentiated transitional epithelium, which is demarcated by basement membrane from a delicate supporting stroma. Squamous metaplasia of the epithelium may develop. Papillomas are susceptible to superficial necrosis, which results in hematuria. In dogs, some papillomas undergo malignant transformation to form transitional-cell (TCC) or adenocarcinomas. *Papillary hyperplasia*, to be differentiated from the much rarer papilloma, occurs in the urinary bladder of cattle and can cause urinary obstruction and hydronephrosis.

Carcinomas of the lower urinary tract are of four histologic types: (1) TCC; (2) squamous cell; (3) adenocarcinoma; and (4) undifferentiated carcinoma. Together they make up ~60% of primary bladder tumors in dogs and cats; the majority of these are TCCs. Carcinomas may be solitary or multiple and usually do not reach a large size before they cause hematuria or death from urinary complications. Epithelial metaplasia and squamous and glandular hyperplasia are often present in the urothelium adjacent to epithelial neoplasms; Brunn nests are most often found in association with adenocarcinomas.

TCCs may be papillary, polypoid or sessile. Occasionally they are not visible on the vesical mucosa, even though the bladder wall is infiltrated diffusely; the tumors may be present in any part of the bladder, but are often in the bladder neck or trigone. Tumors originating in the prostatic urethra are easily overlooked at gross necropsy. Features of tumors that tend to be localized include papillary architecture, in situ tumor, low tumor grade, and a strong lymphoid response. Metastatic disease is seen with infiltrative and nonpapillary growths, increasing tumor grade, deeper invasion, vascular invasion, and peritumoral fibrosis (Fig. 4.99). Occasionally, transitional cells can induce fibroblasts from the desmoplastic areas surrounding metastases to produce heterotopic bone. A few TCCs contain areas of squamous metaplasia. *About 50% of TCCs metastasize*, sometimes in a rampant or unpredictable manner. The usual pattern is for late metastasis to regional lymph nodes and lungs, but

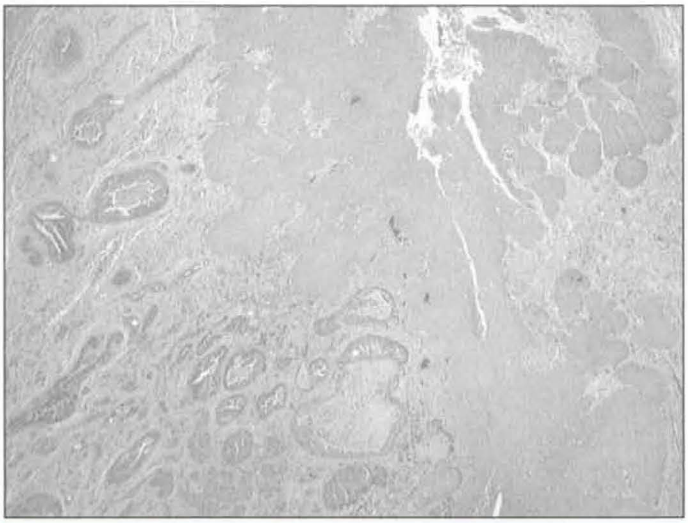

Figure 4.99 Transitional-cell carcinoma from the ureter of a dog, present transmurally and inducing marked desmoplasia.

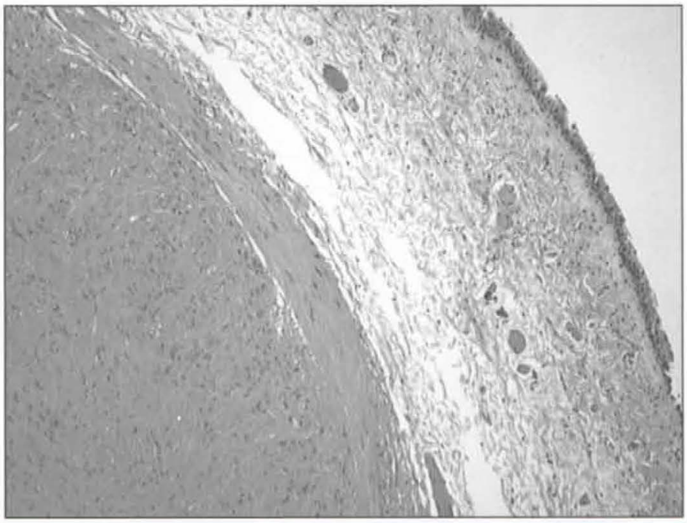

Figure 4.100 Leiomyoma, growing expansively in the wall of the urinary baldder of a dog.

peritoneal implantation or retrograde lymphatic spread to the soft tissue and bones of the hindlimbs or vertebrae is common. Occasionally solitary metastasis to bone occurs. Immunohistochemically, canine TCCs often stain for antigens similar to tumor-associated glycoprotein 72 (TAG-72), a high-molecular-mass glycoprotein used in the diagnosis of carcinomas originating in numerous human tissues. Recently, uroplakin III has been determined to be a specific and sensitive marked for canine transitional cell neoplasms. The presence of uroplakin III was not noted to correlate with tumor grade. Expression of cyclooxygenase-2 in neoplastic urinary bladder epithelium, but not in normal epithelium, suggests this may be a useful marker for neoplastic transformation and growth and can be targeted for therapeutic effects. *In order to assist clinical management of TCC, pathology descriptions should include tumor architecture, tumor grade, and depth of invasion based on sampling of multiple sites.*

Squamous cell carcinomas and **adenocarcinomas** are usually nonpapillary infiltrative growths, which are grossly nodular or sessile and often ulcerated. They develop in areas of squamous or mucous metaplasia. Histologically they are "pure," without transitional-cell areas (Fig. 4.97B). Squamous cell carcinomas and adenocarcinomas occur in dogs, cattle, and cats, and are the most common urinary bladder neoplasm in horses. Squamous cell carcinomas occur most often in bitches in the urethra, the distal two-thirds of which is lined by stratified squamous epithelium. Apparently these are less likely to metastasize than are transitional-cell tumors. **Undifferentiated carcinomas** are those very rare primary neoplasms that do not conform to one of the histologic types mentioned above.

Mesenchymal tumors

Mesenchymal tumors comprise fewer than 20% of tumors of the lower urinary tract. Neoplasms causing enzootic hematuria in cattle are about 10% mesenchymal and 55% mixed, with most of the nonepithelial tumors in these mixtures being hemangiomas. A few vascular tumors also occur in the bladder and about the urethra of dogs, but most mesenchymal tumors in dogs are leiomyomas or fibromas. **Leiomyomas** originate in the smooth-muscle coats of the urinary bladder (Fig. 4.100) and form well-defined projecting spherical white nodules. The nodules may be multiple and seem to have a predilection for the neck of the bladder, where they may interfere with urinary outflow. **Leiomyosarcomas** are very rare and generally do not metastasize; immunohistochemical staining for smooth-muscle actin and desmin are expected. **Fibromas** probably arise from subepithelial connective tissue, are usually solitary, and have a typical gross and microscopic appearance. **Fibrosarcomas** are rare; they are likely to metastasize, often widely.

Rhabdomyosarcoma is a rare tumor in any location (see Vol. 1, Muscle and tendon). **Botryoid** (shaped like a bunch of grapes) **rhabdomyosarcoma** occurs in the urinary bladder and occasionally the urethra of young dogs; large breeds, particularly the St. Bernard, seem to be overrepresented. This tumor has been reported in a Maltese bitch, two Poodles, and a filly. The youthfulness of the affected animals (less than 2 years old in most cases) raises the possibility that these tumors arise in rests of embryonic myoblasts. Grossly the tumors usually occur at the trigone and project into the bladder as botryoid masses. They infiltrate the wall and may metastasize, but are usually identified because of urinary obstruction before this occurs. This tumor has been associated with hypertrophic osteopathy in a dog. Microscopically, there is usually a mixture of fusiform and pleomorphic cells with some strap cells and multinucleated cells. Cytoplasmic cross-striations are sometimes present (Fig. 4.101). Immunoperoxidase staining of the intermediate filament desmin may aid in the diagnosis of this tumor.

Involvement of the urinary bladder in primary **lymphosarcoma** has been reported only rarely in domestic animals; primary canine epitheliotropic T-cell lymphoma involving the urinary bladder is even more rare.

ACKNOWLEDGMENT

The authors acknowledge the late Dr. Donald Dungworth for his contributions to the field of comparative respiratory pathobiology. He contributed extensively to advancing our understanding of the response of the lung to injury, especially after inhalation of toxicants, and acted as a mentor to numerous prominent scientists in and out of veterinary pathology. His previous efforts as the author of this chapter provided a sound framework for the current edition. These, and his many other contributions to veterinary medicine, are greatly appreciated and duly acknowledged.

GENERAL CONSIDERATIONS

Of all the organ systems, *the respiratory tract may be unique in its vulnerability to injurious agents*. The involuntary nature of ventilation, necessitated by aerobic respiration and the need for oxygen, actively pulls large volumes of air into the lungs (estimated at 5400 L/day in dogs and 11 400 L/day in horses). Along with this air there are a variety of potentially injurious materials. In addition, the flow of the entire cardiac output passing through the extensive and delicate vascular bed of the gas exchange region of the lungs provides a separate avenue for the delivery of potentially harmful substances to the respiratory tract. The dual exposure routes are particularly important in determining the expression of disease in the lung, with *distinct patterns of lesions depending upon whether the route of entry is airborne (aerogenous) or vascular (hematogenous)*. The array of potentially injurious agents includes airborne microorganisms, toxic particulates, and gases in ambient air, and a wide variety of infectious agents and extrinsic or intrinsic toxins delivered via the pulmonary circulation. The patterns of pulmonary disease, as well as mechanisms to prevent respiratory injury, are covered later in this chapter.

In order to understand the response of the respiratory system to injury, it is necessary to review the general anatomic features of the respiratory system and biology of the major cellular constituents therein. There has been a rapid increase in our understanding of the complexity of the biology of the lung, elucidating, for example, the role of the recruitment of bone marrow-derived stem cells during lung injury. While many of the features to be discussed are common to other taxa, our overview is based upon the *mammalian respiratory tract*; excellent reviews covering the respiratory biology of birds, reptiles, amphibians, and fish are available in the literature.

The upper airway

The **nasal airways**, except for the external nares, are noncollapsible structures encased in bone. The passages for air contain *osseous and cartilaginous turbinates* (conchae), and are divided by a cartilaginous *nasal septum*. The respiratory turbinates subdivide the nasal cavity into distinct air passages, which direct airflow into the lower respiratory tract and to sites of olfaction. The presence of respiratory turbinates is restricted to mammals and birds, and is assumed to be important in the evolution of endothermy and the high levels of oxygen consumption associated with metabolism in these species; similar structures are not present within ectothermic animals.

Functionally, the *respiratory turbinates are important in warming and humidifying the inspired air* to prevent desiccation of the lower respiratory tract, and in reclaiming moisture and heat from the saturated vapor leaving the lungs. The nasal submucosa is richly supplied with a complex vascular plexus, nerves, and submucosal glands. In addition to the air-warming functions, most species have vascular shunts between the respiratory turbinates and the brain vasculature, suggesting a role in *cooling the brain* during periods of intense activity in mammals and birds. Stimulation of the parasympathetic innervation in the nasal cavity leads to increased vascular permeability and submucosal gland secretion, which occlude the nasal airways and increase resistance to airflow. This is countered by the sympathetic nerve fibers, which favor vasoconstriction and decreased vascular permeability.

The mucosa of the nasal cavity has four distinct epithelial types: (1) *stratified squamous;* (2) *transitional;* (3) *ciliated respiratory; and* (4) *olfactory*. The relative distribution and extent of each of these cell types vary among species. Stratified squamous epithelium is confined to the nasal vestibule at the entrance to the nasal cavity. Separating the squamous epithelium from the more caudal respiratory epithelium is a zone of nonciliated cuboidal to columnar cells, the transitional epithelium. Most of the epithelium lining the nasal mucosa is comprised of respiratory epithelium. This is a complex epithelium that includes pseudostratified ciliated, mucous, nonciliated columnar, cuboidal, and basal cells. *Olfactory epithelium is located in the caudal and caudodorsal nasal cavity*, lining the osseous and cartilaginous ethmoturbinates. This epithelium is the most phylogenetically conserved of the nasal epithelium, reflecting the ancient origins of olfaction. The epithelium is composed of olfactory sensory cells, sustentacular cells, and basal cells. *Olfactory epithelium is rich in cytochrome P450-dependent monooxygenase enzyme activity* and, therefore, is capable of bioactivating a variety of chemicals into potentially toxic intermediate forms. Hence, olfactory epithelium is susceptible to many of the chemicals toxic to the nonciliated bronchiolar epithelial cells and type II pneumocytes in the lung, as has been reported after exposure to 3-methylindole in horses.

The **nasopharynx** is lined by ciliated pseudostratified epithelium with zones of stratified squamous epithelium. *Lymphoid nodules* are abundant throughout the submucosa, and are one of the components of Waldeyer's ring, a collection of lymphoid tissues that encircle the oropharynx and nasopharynx. *The auditory (eustachian) tubes* extend from the nasopharynx to the middle ears. In horses, diverticula in each auditory tube form the *guttural pouches*, which are located dorsocaudal to the caudal pharynx. The function of the guttural pouches is not completely understood, but they may play a role in cooling blood destined for the brain during periods of intense activity and respiration. This respiratory-based cooling mechanism is facilitated by the anatomy of the internal carotid artery as it courses in a crease along the caudal wall up to the dorsal surface of the pouches. As with the pharynx and auditory tube, the mucosa of the guttural pouches is lined by pseudostratified ciliated epithelium.

The **larynx** is comprised of a complex of cartilage plates lined by stratified squamous epithelium as well as pseudostratified ciliated respiratory epithelium. The larynx is at the boundary between the respiratory system and the oropharynx, and communicates directly with the oropharynx. The cartilage of the larynx is important in vocalization in animals, and also resists deformation and obstruction from ingesta or external pressure. There is considerable variability in the anatomy of the larynx between domestic species, reflecting both interspecies variability as well as changes brought about through selective breeding; this is particularly true for the brachycephalic breeds of dogs, where the anatomy of the upper airways is associated with significant clinical disease.

The **trachea** extends from the terminus of the larynx to the *carina*, the branch point for the primary bronchi leading into the right and left lungs. With its relatively simple gross anatomy, and seemingly simple function serving as the conduit for air traveling to and from the lungs, the trachea is often overlooked in routine pathology examinations.

Organization of the lung

The organization and subdivision of the lower respiratory tract arise as a function of the development of the organ, and vary considerably by species (lung development is reviewed later in the chapter). Many of these gross features are important in the pathogenesis of disease and the susceptibility of individual species to a variety of insults, including infectious agents and inhaled toxins and particulate matter. Additionally, proper usage of terminology is important in the gross description of lesions at the time of necropsy.

The divisions of the lungs, from largest to smallest, include lobes, bronchopulmonary segment, and terminal acinus. In all of the domestic species, the lung is divided into a right and left lung, each of which is served by a single **primary bronchus** (mainstem bronchi) arising at the tracheal bifurcation. Each of the two lungs is further subdivided into individual lobes. The **lung lobe** represents the largest subdivision of the right and left lungs. *The lobe is defined as the gas exchange region ventilated through the* **lobar (secondary) bronchus**. The numbers and distribution of lung lobes vary by species. All domestic species except the horse have two lobes in the left lung (cranial and caudal) and four lobes in the right lung (cranial, middle, caudal, and accessory); the horse lacks a right middle lung lobe. The cranial lobe of the left lung is subdivided into a cranial and caudal part in all species except the horse, and the right cranial lobe of domestic ruminants is similarly divided into a cranial and caudal part. Interestingly, the lobar bronchus (**tracheal bronchus**) of the right cranial lung lobe of ruminants and pigs arises from the trachea before the primary bronchi bifurcate from the trachea to the right and left lungs. This location proximal to the primary bronchi predisposes the right cranial lung lobe to inhalation of foreign materials, especially liquids, as well as accumulation of inflammatory exudates from the more distal lung fields as they are cleared by the mucociliary apparatus. It is therefore not uncommon to find this lung lobe extensively involved in instances of inhalation pneumonia or with severe bacterial bronchopneumonia.

Depending upon the species, further subdivisions into individual **lobules** by connective tissue septa may or may not be grossly visible; when present, these interlobular septa are contiguous with the surface pleura. *In humans, pigs, and cattle, lobulation is highly developed, with individual lobules readily seen on the pleural surface of the lung. Equine, ovine, and caprine lungs are intermediate in lobulation; canine and feline lung are essentially devoid of septation and lobule formation.* A **bronchopulmonary segment** is the area served by a tertiary bronchus that arises from the lobar (secondary) bronchi. Well-developed interlobular septa that nearly completely surround individual bronchopulmonary segments, as in the pig and cow, limit collateral ventilation as well as the movement of cells and molecules between adjacent segments. Functionally, this is important in these species in limiting the extension of inflammation between lobules. Well-developed connective tissue septa can effectively sequester inflammation in affected lobules, leading to the characteristic gross pathology especially common in bacterial bronchopneumonia, with severely affected lobules adjacent to less affected lung lobules. The lack of collateral ventilation is also largely responsible for the common, incidental, interlobular emphysema found in cattle lungs at the time of necropsy. This emphysema occurs antemortem with preterminal labored breathing, and reflects the accumulation and tracking of pulmonary gasses along the path of least resistance within the septa, rather than extending through the septa to adjacent lobules.

Organizationally, the next smallest discernible functional unit within the lung distal to the bronchopulmonary segment is the **terminal acinus**, *which is comprised of one terminal bronchiole and its associated gas exchange region of the lung.* The anatomy of the terminal acinus varies among domestic species, especially the length between the terminal bronchiole and the alveoli. This junction is comprised of respiratory bronchioles and/or alveolar ducts; depending upon the species, it may be entirely one or the other, or a combination thereof. **Respiratory bronchioles** are bronchioles with variable lengths of their architecture interrupted by periodic alveolar outpocketings before transitioning into the gas exchange region. **Alveolar ducts**, in contrast, are cylindrical airways, circumferentially surrounded by alveoli, and invested with spiral smooth muscle. The anatomy of these distal airways is of more than just academic interest; this junction with the gas exchange region is a common site for initiation of viral and bacterial infections, for injury from insoluble toxic gases, and for the deposition of small particulate matter such as asbestos fibers.

Vascular supply to the lung

The vascular supply to the lung is dual, arriving through both the pulmonary and bronchial circulation. This unique system of perfusing the lung with blood has important implications in the pathogenesis of pulmonary disease. The *pulmonary arterial circulation* receives the entire output of the right ventricle and is characterized as a high-flow, low-pressure system; in contrast the *bronchial arterial circulation*, being a part of the systemic arterial blood vasculature, is a low-flow, high-pressure system. The bronchial circulation supplies nutrition to the large bronchi and blood vessels, the pleura, and much of the interstitium associated with these structures. The bronchial arteries can arise from a variety of sites, including the aorta, intercostal arteries, and subclavian arteries. The pulmonary circulation nourishes the alveolar parenchyma and distal bronchioles and, in the alveolar capillary bed, is the site of gas exchange. A *dual venous drainage* is also maintained: *pulmonary veins* drain the capillaries served by the pulmonary arteries, and *azygous veins* drain those supplied by the bronchial arteries.

The morphology of the two vascular systems in most species is readily apparent. Muscular pulmonary arteries have an internal and external elastic lamina, whereas the external elastic lamina is indistinct or absent in bronchial arteries. There is much variability in the histomorphology of the pulmonary arteries in the domestic species. At the pulmonary trunk, the arteries of most species have considerable numbers of elastic fibers interspersed with the smooth muscle. The more distal arteries and arterioles do not have elastic fibers. The smaller branches of pulmonary arteries vary considerably between species in their morphology, especially the thickness of the tunica media. *Cats, pigs, and cattle have the thickest pulmonary arteries of the domestic species*, and in domestic cats the medial hypertrophy/hyperplasia can be quite pronounced, though usually incidental. Because of the presence of smooth muscle in the small pulmonary arterioles of many domestic species, care needs to be taken in diagnosing pulmonary arterial hypertension based simply upon arteriolar histology. Pulmonary veins follow the bronchial tree in most domestic species, and have a thin fibrous wall in all of the species except for cattle and pigs, where there is interspersed smooth muscle.

While the primary function of the pulmonary vascular system is oxygenation of venous blood for delivery to the systemic arterial circulatory system, the arterial and venous systems have other important functions. Of particular importance is the *proper maintenance of tissue fluid balance within the lung*. Under normal circumstances there is a fine balance between fluid movement into the alveolar lumen, and reuptake into the interstitium and alveolar capillaries to prevent interstitial and alveolar edema. As with other tissues, vascular hydrostatic pressure and interstitial colloid oncotic pressure favor filtration of fluid into the pulmonary interstitium, while plasma colloidal oncotic pressure and interstitial hydrostatic pressure keep fluid from moving into the alveolar space. The capillary endothelial cells play a variety of roles in this balancing act. Normal pulmonary capillary endothelial cells transport albumin into the alveolar interstitium through caveolae-dependent transcytosis to maintain the correct interstitial oncotic pressure. Under inflammatory conditions, cytokines such as tumor necrosis factor-α induce the formation of intercellular gaps between endothelial cells, allowing less restrictive movement of albumin and other macromolecules into the interstitium, and subsequently into the alveolar lumen, where it forms the eosinophilic alveolar edema seen histologically.

The pulmonary vasculature is a dynamic tissue, capable of remarkable physiologic and morphologic adaptations given the proper stimuli. Remodeling of the architecture of the pulmonary vasculature can occur under a variety of disease states, and the relative contributions of both the pulmonary and bronchial systems vary with the disease in question. *Angiogenesis* (formation of new blood vessels from pre-existing vasculature) is primarily a feature of the bronchial circulation; the pulmonary arterial system has limited angiogenic capacity. Angiogenesis is particularly important in primary lung neoplasms, where the continued nutrition, and therefore survival, of the tumor is dependent upon this process. Both the pulmonary arterial and bronchial circulation can play a role in providing nutrition to pulmonary metastatic neoplasms. Angiogenesis, as a response to inflammation within the respiratory tract, can be a prominent feature of remodeled airways; such newly formed blood vessels are prominent within the lamina propria and submucosa in chronic bronchitis, and may be increased in asthmatic airways. Experimentally, *Mycoplasma pulmonis* infection in mice leads to increased numbers of blood vessels within the trachea. Regardless of the inciting stimuli, these newly formed vessels are prone to protein leakage and can contribute to local edema formation, and even hemoptysis.

Cellular architecture and cell biology of the lung

Before considering select cellular constituents of the lower respiratory tract, it is important to be mindful of the functional interdependence of the cellular constituents of the respiratory system in relation to organ development, homeostasis, and response to injury. This interdependence has its origins in the embryologic development of the lung, specifically the close association of the endodermal and mesodermal components (see section on Lung development and growth, below). In the adult lung, this anatomic and functional relationship has been termed the *epithelial–mesenchymal trophic unit*. Conceptually, this unit considers the epithelial and mesenchymal components in the respiratory tract together; disparate tissue constituents, such as airway epithelial cells, smooth-muscle cells, extracellular matrix proteins, and inflammatory cells communicate and direct the organ response during development, health, and disease. The relationship between these various components likely extends the length of the lower respiratory tract, and possibly the upper respiratory tract, determining whether there is restoration of the injured tissue or replacement with permanently remodeled tissue, with consequent changes in organ function.

In all domestic species, the **trachea and bronchi** *are surrounded by rings of hyaline cartilage*. These rings resist physical deformation, thereby helping to maintain the patency of the upper airways. In spite of their greater diameter, relative to the bronchioles, approximately 80% of the resistance to pulmonary airflow resides within the first 4–7 generations of the conducting airways. Partly because of this, any process that results in significant narrowing of the bronchi can result in clinically detectable changes at an earlier stage than a similar process involving the bronchioles.

Bronchioles, in contrast to bronchi, *have no cartilage in their walls to prevent airway collapse*. Bronchiolar airway patency is dependent on the attachment of alveolar septa to the thin connective tissue layer in the bronchiolar wall. The one exception to this rule is marine mammals, both cetaceans and pinnepeds, which possess well-developed cartilage rings around even the smallest bronchiole that prevent airway collapse in the face of supra-atmospheric pressures found at depth within the oceans. In terrestrial mammals, the radially arranged alveolar septa are tethered to and pull on the bronchiolar wall to maximize the luminal diameter during peak lung volume during inspiration. During expiration, as the forces from the interalveolar septa decrease, the bronchiolar lumen decreases in diameter. Because of their smaller diameter, collapsibility and thin-walled structure, bronchioles are much more susceptible to disease processes occurring in the surrounding alveolar parenchyma than are bronchi, and they individually have a higher resistance to airflow than individual bronchi. In spite of this, there is less resistance to airflow in the distal airways because of the higher number of bronchioles. Therefore, a large percentage of bronchioles must be affected before clinical evidence of disease is detected (e.g., hypoxemia due to ventilation/perfusion abnormalities or dyspnea due to small-airway obstruction).

Histologically, there is great cellular diversity within the mucosal epithelium of the conducting airways, the cell populations changing depending upon the species and airway generation under consideration. This complexity is difficult to appreciate in routine two-dimensional histologic sections. The trachea, bronchi, and proximal bronchioles are lined by pseudostratified epithelium composed of a mix of ciliated, mucous, and nonciliated cells. In general, the numbers of ciliated and mucous cells decrease within the distal airways, with a greater proportion of nonciliated (Clara) cells present within the bronchioles. These distribution factors can play an important role in the region-specific susceptibility of the airway epithelium to specific forms of injury, especially infectious agents, particulate matter, and toxins (either inhaled or within the systemic circulation).

Proximal generations of bronchioles are lined by epithelium that is shorter but otherwise indistinguishable from the pseudostratified epithelium found in the distal bronchi. More distally, the small bronchioles are lined by a simple columnar to cuboidal epithelial lining, composed almost entirely of ciliated cells and nonciliated bronchiolar (Clara) cells; in many species, Clara cells are the predominant cell type.

While the principal function of the ciliated cell – movement of airway-lining fluid – is well known, the biology of the **Clara cell** is not as well appreciated. This nonciliated nonmucus-secreting cell functions as a *progenitor cell* for epithelial repair within the airway mucosa, as it has the capacity to divide and differentiate into ciliated cells or other nonciliated cells. In addition, Clara cells of many species have abundant smooth endoplasmic reticulum within the apical cytoplasm, which possesses high concentrations of cytochrome P450-monooxygenase enzymes. Indeed, on a per-cell basis, Clara cells of some species have greater metabolic capacity than even hepatocytes. Therefore, *Clara cells are extremely sensitive to a variety of xenobiotics and natural toxins*; metabolism of these compounds can generate intermediate metabolites that form adducts with macromolecules within the cell, and lead to Clara cell injury. Finally, Clara cell secretory protein (CC10), secreted by these cells in response to adrenergic stimuli, may dampen the inflammatory response by inhibition of phospholipase A_2.

Smooth-muscle cells are located around the circumference of the bronchi and bronchioles, and extend to the ostia of alveolar outpocketings in the respiratory bronchioles, and into the alveolar ducts of some species. Historically, the *airway smooth-muscle cell* (ASMC) was considered to be a relatively static cell population, contributing little to the structure of the remodeling lung beyond its ability to undergo hypertrophy in response to chronic airway inflammation as in asthma and chronic bronchitis. Their importance was primarily seen as the transducer of bronchoconstriction and bronchodilation. Smooth-muscle cells can undergo hyperplasia in response to paracrine signals arising from the airway epithelium in inflammatory diseases, and this doubtless contributes to the accentuation of smooth muscle found histologically in chronic bronchitis and asthma.

There is considerable evidence that smooth-muscle cells are important members of the epithelial–mesenchymal trophic unit. *They produce a wide array of cytokines, chemokines, growth factors, and extracellular matrix metalloproteases*, allowing them to modify the interstitial matrix directly around smooth-muscle bundles. *ASMCs also secrete matrix proteins*, including fibronectin, elastin, and a variety of laminins and collagens. The matrix produced by ASMC can then modulate the proliferation, migration, and apoptosis of smooth-muscle cells. Transforming growth factor-β is a potent profibrogenic cytokine produced by ASMC; in bovine trachealis smooth-muscle cells, plasmin can stimulate release of active TGF-β from the cells, which in turn results in collagen upregulation by the ASMC. This paradigm may partly explain the increased extracellular matrix found around smooth-muscle bundles in chronically inflamed airways.

The **alveolar parenchyma** is the site of the only essential function of the lung, that being *gas exchange to support cellular aerobic respiration*. Regardless of the media for gas exchange (water or air), the essential design of the gas exchange membrane in animals is remarkably similar, consisting of an epithelial layer exposed to the exchange media, in close apposition to blood-filled capillaries. This relatively simple arrangement belies the complexity of the biology of the region. In mammals, there are five major cell types associated with the alveolar parenchyma: (1) *type I and type II pneumocytes*, (2) *capillary endothelial cells*; (3) *interstitial fibroblasts*; and (4) *alveolar macrophages*.

Type I pneumocytes *are large, flat, squamous epithelial cells that line ~93% of the alveolar surface*. Type I pneumocytes are terminally differentiated, thus they do not contribute to the resolution of alveolar injury through regeneration of new epithelial cells. They are particularly vulnerable to oxidant injury in part because of their large membrane surface area and low levels of important antioxidants, especially reduced glutathione. Irreversible injury to type I cells is quickly followed by sloughing of the cells from the alveolar basement membrane, which triggers a rapid regenerative response orchestrated by the type II pneumocytes. This description of type I cells suggests a passive role in the lung, facilitating gas exchange across the plasma membrane, and poised for injury and loss following any number of insults. While this is true, they also play a critical part in maintaining normal lung fluid composition, providing a structural basis for preventing movement of fluid into the alveolus, and clearing fluid and protein from the alveolus during pulmonary edema.

Type II pneumocytes *are the primary cuboidal cell lining the alveolus*; the brush cell or type III pneumocyte is also cuboidal, but much less numerous. Histologically, they are found most commonly at the intersection of two alveolar septa, the so-called "corners" of the alveoli. The ultrastructure of the type II pneumocyte is similar among mammals, with apical microvilli, and characteristic cytoplasmic osmiophilic lamellar inclusions, which are the site of surfactant storage. The primary functions of type II pneumocytes are to *synthesize pulmonary surfactant*, to serve as *progenitor cells* for replacement and turnover of alveolar epithelium, and to *metabolize xenobiotics*.

Pulmonary surfactant (name derived from its behavior as a *surface active agent*) is a complex mixture of phospholipids and small amounts of protein synthesized by type II epithelial cells and bronchiolar Clara cells. Surfactant is approximately 80% phospholipids, 10% neutral lipids, and 10% surfactant proteins (SP-A, SP-B, SP-C, SP-D), and is found at the air–liquid interface along the epithelial surfaces of both the conducting airways and alveoli. Interestingly, there are differences in the composition and presumed function of surfactant in these two locations. The main function of surfactant in the alveoli is to *lower surface tension in the alveolar space during expiration to prevent alveolar collapse during respiration*. Beyond its role in regulating alveolar surface tension, the surfactant phospholipids and proteins also have important immunoregulatory and pulmonary defense functions (see section on Lung defenses, below).

The proliferative capacity of type II pneumocytes is important in alveolar development and postnatal lung growth; the lungs of most species are not fully developed, undergoing continued maturation after birth (see section on Lung development and growth, below). Type II cells can rapidly proliferate to repopulate denuded basement membrane following injury to type I pneumocytes. This process follows a general pattern, consisting of rapid migration to cover the basement membrane, followed by proliferation, and re-differentiation to the dominant alveolar epithelium. The process is dependent upon the ability of the type II pneumocyte to modify the extracellular matrix to facilitate this process. Type II cells synthesize a variety of matrix components, including fibronectin, type IV collagen, and proteoglycans, as well as matrix-degrading enzymes such as metalloproteases.

The **brush cell**, sometimes known as the *type III pneumocyte*, is a poorly understood epithelial cell of the respiratory tract. Although known as the type III pneumocyte in the lung, their distribution is not restricted to the alveolus, and similar cells are also found in the nasal cavity, trachea, and conducting airways, as well as within the gastrointestinal tract and gallbladder. The function of brush cells is not completely understood, but most evidence suggests that they *act as chemoreceptors*. In the alveolus, they may sense hypoxia and regulate capillary perfusion accordingly. The presence of brush cells has been documented within the respiratory tract of rats and humans, and it is assumed that similar cells are present in domestic animals.

Fibroblasts are found within the alveolar wall associated with a network of normal extracellular matrix proteins, including collagen and elastin. This network is not uniformly distributed within the membrane; this leads to regions of the wall that are "thick" and "thin," with gas exchange only occurring where this network is absent. The fibroblasts of the lung are heterogeneous in terms of morphology, functionality, and expression of surface markers. This heterogeneity is particularly well documented in experimental and human cases of pulmonary fibrosis. The surface glycoprotein Thy-1 is an example of a marker of fibroblast heterogeneity in the lung. The presence or absence of Thy-1 on lung fibroblasts is associated with variation in fibroblast adhesion to extracellular matrix, production of cytokines, and ability to produce extracellular matrix proteins including collagen. The array of matrix proteins potentially produced by lung fibroblasts is extensive, and includes collagen types I, III, IV, V, and VI, elastin, laminin, fibronectin, glycosaminoglycans, and proteoglycans.

Pulmonary macrophages are an important class of lung cells, and are found in a variety of compartments within the organ. Five separate populations of macrophages in the lung have been recognized: (1) *alveolar macrophages*; (2) *interstitial macrophages*; (3) *pulmonary intravascular macrophages*; (4) *dendritic cells*; and (5) *pleural macrophages*. As with other organ systems, pulmonary macrophages are *derived from circulating monocytes*; their further differentiation is partly determined by the specific tissue microenvironment within which they reside.

Alveolar macrophages are integral to maintaining pulmonary homeostasis and the sterility of the alveolar parenchyma. The role that pulmonary macrophages play in pulmonary defense is discussed subsequently (see section on Lung defenses, below). Less appreciated is the role of alveolar macrophages in preventing the accumulation of native proteins, especially surfactant, within the alveolus. *Alveolar proteinosis*, a condition of alveolar accumulation of surfactant components, can be caused by local deficiency of granulocyte–macrophage colony-stimulating factor; this impairs the ability of the alveolar macrophage to clear surfactant, leading to its accumulation in the alveolus.

Alveolar macrophages function as *important regulatory cells* in the lung, controlling inflammatory, immune, and repair processes through the release of a wide array of cytokines and other regulatory molecules. Inflammation and immunity are promoted by macrophage synthesis and release of cytokines such as interleukin-1 (IL-1), tumor necrosis factor-α and interferon-γ, as well as by release of inflammatory mediators that include leukotriene B_4, C_4, platelet-activating factor, and thromboxane A_2. Repair processes are generally promoted or otherwise regulated by release of cytokines that include transforming growth factor-β and -α, fibroblast growth factor, insulin-like growth factor, and platelet-derived growth factor.

Dendritic cells (DC) are *ubiquitous immunoregulatory cells*, found in all tissues. Derived from bone marrow, the DC are motile cells involved in surveillance for antigens at the epithelial surfaces of the respiratory tract. Their location extends from the mucosa of the nasal cavity, to the epithelia of the conducting airways, the pulmonary interstitium, and pleura. Various subpopulations of DC can be distinguished by means of morphologic characteristics, primary location, and unique surface marker proteins.

Morphologically, DC have numerous long processes, and function as antigen-presenting cells, priming naive T cells and driving the cells into T-helper type 1 (Th-1) or Th-2 effector cells. The ability of DC to present antigen to T cells requires that the DC themselves mature; this occurs within regional lymph nodes under the influence of appropriate proinflammatory signals. The numbers of DC can increase markedly in the respiratory tract under the proper stimuli, and they play an important role in allergic airway disease and asthma.

Interstitial macrophages are the least well-understood class of pulmonary macrophages. Because of their location within the interstitium of the conducting airways and alveolar parenchyma, they are more difficult to isolate and characterize than other macrophage populations. Interstitial macrophages may be a precursor cell for alveolar macrophages, but they also have unique functions. In mice, interstitial macrophages have less phagocytic activity than alveolar macrophages, and instead are primarily immunomodulatory cells, expressing more major histocompatibility complex class II molecules and producing more cytokines, such as IL-1 and IL-6, than the alveolar macrophage.

Pulmonary intravascular macrophages (PIMs) are unique mononuclear phagocytes found within the alveolar capillaries of select species, including cattle, sheep, goats, horses, pigs, cats, and cetaceans. PIMs may be recruited into the lungs of rats and humans during inflammatory lung diseases. PIMs form membrane-adhesive complexes with the capillary endothelium, which *keeps them localized to the vascular bed*. These cells are highly phagocytic and play an important role in the clearance of circulating bacteria and particulates in the pulmonary circulation. PIMs release an array of proinflammatory mediators following interaction with particulates and bacterial endotoxin. Because of their proinflammatory properties, they can contribute to the lung injury coincident with acute lung inflammation. Depletion of PIMs can attenuate lung injury following experimental bacterial infections or exposure to endotoxin.

Stems cells and the lung

The biology of stem cells, and their place in maintaining tissue integrity in health and disease, are recognized. Stem cells are considered to have nearly unlimited self-renewal and are divided into embryonic and adult stem cells. *Embryonic stem cells* reside within the inner cell mass of blastocysts and are pluripotent, capable of generating cells representative of all three embryologic germ layers (endoderm, mesoderm, and ectoderm). *Adult stem cells*, on the other hand, are multipotent, and capable of differentiating into a limited range of site-appropriate cell lines. Unipotent stem cells can only contribute to a single cell line; the differentiation of type II pneumocytes into type I pneumocytes is an example. Adult stem cells are found within fully differentiated tissues, and are involved in maintaining tissue homeostasis, replacing cell loss from apoptosis, and participating in tissue repair after injury.

In the lower respiratory system, there appear to be reservoirs of adult stem cells in each of the major anatomic localities; thus, in the trachea, cells with stem cell characteristics have been identified within the submucosal glands and with a Clara-like cell associated with neuroepithelial bodies. The basal cell of the trachea and bronchi is important in maintaining the attachment of the respiratory epithelium to the basal lamina, and there is evidence that they are a central stem cell involved in replenishing the epithelium of the proximal airways following injury. Clara cells are the primary stem cell of the bronchioles, and can readily replace both themselves and ciliated cells. Interestingly, when Clara cells are selectively removed from the airways using the Clara cell-specific toxicant naphthalene, there is morphologic evidence of the ciliated cell participating in reconstitution of the airway epithelium. The ciliated cell is traditionally considered to be terminally differentiated, so this information suggests that there is more plasticity to the airway epithelium than previously considered.

Finally, brief mention should be made of colonization of the lung with *bone marrow-derived stem cells.* A growing body of literature suggests that circulating stem cells can engraft within the lung and differentiate into both epithelial and mesenchymal cells. This process has been particularly well documented in experimental models of lung injury, and has important implications in understanding the pathogenesis of lung disease, and potential novel therapeutic avenues.

Lung defenses

The necessary function of gas exchange requires that the lung remain exposed to the environment. Thus, the sterility of the lung is continuously challenged by immense quantities of microorganisms and foreign material in inhaled air, and by opportunistic pathogens within droplets that are aspirated from the nonsterile upper respiratory tract. Despite this constant challenge, the lung must remain sterile or at least minimally contaminated, because excessive numbers of bacteria induce inflammation, which impedes gas exchange in the lung. Additionally, because of the tremendous blood flow through the lung, contamination of the lung by bacteria carries a significant risk of bacteremia. Thus, *the lung requires a multi-layered system of defense against infectious agents.* The objective is to maintain the sterility of the lung without inducing inflammation, as inflammation is detrimental to gas exchange. This is accomplished by the following:

- The *mucus* that lines the airways entraps particles and microbes, and is propelled by coughing or by ciliary beating to the pharynx, where it is swallowed.
- *Antibody and innate defense proteins* kill microbes directly, prevent them from colonizing mucosal surfaces, and/or opsonize the microbes to make them more easily ingested by phagocytes.
- *Alveolar macrophages* and *newly recruited neutrophils* that recognize foreign invaders, particularly in the presence of opsonins, engulf and kill these microbes without inducing inflammation.

If the infection cannot be contained by these mechanisms, inflammation is triggered in an attempt to control the threat. In these situations, alveolar macrophages and airway or alveolar epithelial cells produce cytokines and other mediators that recruit neutrophils and more monocytes–macrophages to the site of invasion. Inflammatory mediators also induce the production of antibacterial proteins by epithelial cells of the airway surface and submucosal glands. But this response has the potential to do harm: *inflammatory exudates impair gas exchange, leukocyte-derived enzymes and oxygen radicals cause injury to lung tissue, and repair processes may result in organization of alveolar exudates or fibrosis of alveolar septa that permanently decreases lung compliance and thickens the blood–gas barrier.* The significance of these sequelae depends on the extent of lung involvement. The tremendous reserve capacity of the lung means that many animals have localized areas of pneumonia that are of no clinical significance, yet mild changes present throughout the lung can seriously compromise pulmonary function.

The inspired air may carry a variety of particulates, including infectious agents, allergens, and inert particles. *The site of* **particle deposition** *in the respiratory tract depends on their size, density, and charge.* Particles larger than about 10 μm diameter are almost completely removed in the nasal cavity, mainly by impaction at sites in the nasal turbinates where the airflow changes direction. Particles that are 3–10 μm diameter are more likely to impact the mucosa of the trachea and bronchi, where they can be cleared by the mucociliary apparatus. In general, particles less than 5 μm have the greatest potential to reach the deep lung (terminal bronchioles and alveoli), although this is most common with smaller particles (1–2 μm). The velocity of airflow declines precipitously in the terminal airways because the total cross-sectional area increases; as a result, particle deposition in the bronchioles and alveoli results from sedimentation, diffusion, and electrostatic charge.

Coughing and mucociliary clearance *are the major mechanisms for clearing of particles that become entrapped in the airways.* Mucociliary clearance of particles from distal airways requires 2–6 hours, and the presence of innate defense proteins within the airway mucus, described in more detail below, probably serves to limit bacterial growth during this time. Mucociliary clearance may be as rapid as 10 mm/min in the trachea, but is much less rapid in the bronchioles. The airways are covered by a *lower periciliary liquid layer* (formerly known as the sol or hypophase) and a superficial mucous layer. The mucous layer contains abundant glycoproteins that are sticky and tend to trap a wide variety of particles that impact on the airway surfaces. The quality of the periciliary liquid layer is also critical for clearance of entrapped particulates, because the low viscosity of this fluid permits the cilia of the epithelial cells to beat effectively. Additionally, clearance of sputum from the larger airways by coughing requires that the periciliary liquid layer be fluid and abundant, allowing the superficial mucous layer to be easily propelled. Finally, effective ciliary function is necessary for mucociliary clearance, and requires coordinated unidirectional ciliary beating at an adequate frequency of around 15 beats per second. The regulation of this system is not well known. However, shear stress on the epithelium both increases the ciliary beating frequency and promotes epithelial secretion to maintain the quality of the liquid and mucous layer. Nitric oxide, cyclic adenosine monophosphate, and cyclic guanosine monophosphate are other regulators of ciliary beat frequency. When entrapped particles reach the nasopharynx, they have the opportunity to interact with the well-developed lymphoid tissue in the tonsils and nasopharyngeal mucosa before reaching the pharynx and being swallowed. Although this clearance of inhaled particles is normally beneficial, it is a method for the spread of agents such as *Mycobacterium bovis* and *Rhodococcus equi*, and is important in the migration of helminth eggs and larvae. Mucociliary clearance may be impaired by infection of the airway epithelium with viruses, mycoplasmas, or *Bordetella*, exposure to cold air or ammonia, squamous metaplasia due to chronic bacterial infection or toxin exposure (cigarette smoke and environmental pollutants being the best-characterized examples), inherited anomalies of ciliary structure or function, or abnormal mucus production in human cystic fibrosis.

The mucus covering the airway mucosa contains a rich spectrum of **antimicrobial factors**, which operate by several distinct mechanisms. Some cause *direct injury to pathogens*, such as the β-defensins, anionic antimicrobial peptides, cathelicidins, lactoferrin, lysozyme, the complement membrane attack complex, and lactoperoxidase. *Lactoferrin binds iron* and makes it unavailable for use by many bacteria, while neutrophil gelatinase-associated lipocalin – secreted by airway and alveolar epithelial cells in addition to neutrophils – binds bacterial siderophores that allow pathogens to scavenge ferric iron. Other components, including immunoglobulin A and polysaccharides within the mucus, *block the attachment of bacteria to mucosal surfaces*. Finally, *infectious agents may be opsonized* by immunoglobulin G, the complement component C3b, and surfactant proteins A and D. Two families of antimicrobial proteins, defensins and collectins, deserve particular mention. The *defensins* are a family of 3–5 kDa, cationic, arginine-rich peptides that are present in neutrophil granules, intestinal Paneth cells, and epithelial cells of the trachea and bronchi. Some defensins are constitutively expressed, while others are rapidly induced by proinflammatory cytokines, lipopolysaccharide, and other stimuli that activate nuclear factor-κB. The defensins are able to kill bacteria, fungi, and enveloped viruses by forming pores within microbial membranes that are rich in anionic phospholipids, and may also have roles in leukocyte chemotaxis and wound healing. The *collectins* are a family of calcium-dependent carbohydrate-binding lectin proteins that include the surfactant proteins A and D. Both of these proteins are produced by type II pneumocytes, and SP-A is also secreted by Clara cells in the bronchioles. These pulmonary collectins agglutinate and opsonize bacteria, viruses, and fungi, and also maintain surfactant homeostasis, have antioxidant activity, and bind lipopolysaccharide to regulate inflammatory responses.

Alveolar macrophages *are critical for defending the lung against particles that are deposited in alveoli, and also play a key role in recycling and removal of surfactant.* Their population is maintained by ongoing recruitment of blood monocytes. Alveolar macrophages are decorated by a variety of cell surface receptors that permit recognition of particles opsonized by antibody, complement, or collectins. In addition, CD14, Toll-like receptors, mannose receptors, and the scavenger receptor permit responses against bacteria that have not been previously encountered by the host. Alveolar macrophages phagocytose most opsonized particles within 2–4 hours, although the ingestion of inert particles such as carbon and silicates is much slower. Alveolar macrophages kill bacteria using reactive oxygen and nitrogen species and enzymes within their lysosomes. In addition, these cells are highly effective in promoting an inflammatory response by *secreting cytokines and chemotactic cytokines* that recruit and activate neutrophils and macrophages. These newly recruited phagocytes are important in the clearance of more severe bacterial infections of the lung. Alveolar macrophages are integral to the immune response by presenting antigen, secreting cytokines that modulate the response, and serving as effector cells in delayed hypersensitivity reactions. However, compared to other macrophage populations, alveolar macrophages are relatively poor antigen-presenting cells. The actual physical removal of particulates from alveoli is inefficient, in contrast to their removal when deposited on the mucociliary blanket. Most particles phagocytosed by macrophages are either inactivated or sequestered. Alveolar macrophages are mainly cleared through the bronchioles on the mucociliary blanket. As the particulate load increases, as occurs in the pneumoconioses, some particles penetrate into the pulmonary interstitium by endocytosis across the type I pneumocytes, where they enter the lymph and are phagocytosed by interstitial macrophages. Particle-laden macrophages often cluster around bronchioles and blood vessels, and some eventually find their way to the local lymph nodes. In addition to the alveolar and interstitial macrophages, *intravascular macrophages* are present in the lung of cats, horses, ruminants, and pigs. These cells serve to remove infectious agents and other particles from the blood, and thus serve an analogous role to Kupffer cells in the liver and macrophages in splenic sinusoids.

Pulmonary immune responses are initiated when inhaled antigens are taken up by *dendritic cells*, which inhabit the airway epithelium and migrate to bronchial lymph nodes where the antigen is presented to lymphocytes. Although *bronchus-associated lymphoid tissue* is often visible histologically, this structure is not present in germ-free animals of most species and may represent a consequence of inflammation and antigenic stimulation. Finally, *T lymphocytes and natural killer cells* constantly survey the pulmonary milieu, and are probably most useful in defense against viruses, intracellular bacterial pathogens, and fungi.

Thus, the lung is protected from inhaled bacteria by the filtering effect of the nasal cavity, innate and acquired humoral defenses, mucociliary clearance in the airways, alveolar macrophages, recruited neutrophils, and T lymphocytes and natural killer cells. These defenses can be considered in multiple layers, where most inhaled particles are removed in the nasal cavity or neutralized by innate defense proteins in the airway mucus prior to being cleared by the mucociliary apparatus. The small bronchioles seem to be a site of particular vulnerability, being poorly served by either mucociliary clearance or alveolar macrophages. Pathogens that reach the alveoli may be phagocytosed and killed by alveolar macrophages, particularly if the particles have been opsonized by complement or the surfactant proteins A and D, or by antibody if a previous encounter with the agent has resulted in an immune response. Still greater threats invoke a suppurative inflammatory response, which may be essential to clear bacteria from the lung but also carry the risk of compromised lung function and damage to the pulmonary tissue.

NASAL CAVITY AND SINUSES

General considerations

The responses of the respiratory tract to injury, and the resulting patterns of disease, are largely determined by the structural and functional complexity of the system. Most of the diseases of the respiratory system are caused by agents arriving by either the airborne (aerogenous) or bloodborne (hematogenous) routes, each with its own special pathogenetic considerations.

The respiratory system is under constant assault from potentially injurious agents; these include airborne microorganisms, oropharyngeal flora, toxic particulates and gases in ambient air, and a wide array of infectious agents and extrinsic or intrinsic toxins delivered via the pulmonary circulation. Pulmonary defense mechanisms are remarkably effective under most circumstances in preventing disease agents from entering or remaining in the lung and in neutralizing these agents if they penetrate initial barriers.

The *upper respiratory tract* comprises the air-conducting structures from the external nares to the trachea at the level of the thoracic inlet, including the specialized system of paranasal sinuses and the auditory (eustachian) tubes, and the guttural pouches of horses. The anatomy of the upper respiratory tract is described above. Functionally, this system conducts and conditions the air moving into and out of the lower respiratory tract during respiration. The upper airways, by virtue of their position within the respiratory tract, are constantly exposed to materials from the external environment; they play an important role in surveying the inspired air for pathogens and are exposed to a variety of potentially toxic particulates and gases. The anatomy of the upper airways is also important in the generation of species-specific vocalization in animals, and abnormal vocal sounds can be an important clinical indicator of diseases involving the upper airways.

Development of the upper airways

The development of the upper airways is complex and poorly understood in domestic animals, compared to the considerable information known in species commonly used in biomedical research. The development of the upper airways is closely tied to that of the osseous and soft tissues of the cranium, as well as the upper gastrointestinal tract. In mammals, the development of the face, including the nasal cavity, involves coordination of the development of five distinct facial primordia. The structures of the head and neck arise from the pharyngeal arches, with contributions from the ectoderm, endoderm, mesoderm, and neural crest cells. Induced or inborn errors in this complex process can result in abnormalities in the nasal cavity. Neural crest cells are particularly sensitive to potential teratogens, and may mediate many of the craniofacial defects arising from such teratogen exposure. As with the lower respiratory tract, the development of the airways of the upper respiratory tract is tightly regulated by a complex of genes, including members of the homeobox family; alterations in members of this family can result in malformation of the face, including the nasal cavity. The nasal cavity continues to develop after birth; in particular the postnatal development of the paranasal sinuses plays an important role in the development of the remaining upper airways as well as the nonrespiratory facial structures. Selective breeding for particular craniofacial features, particularly in dogs and cats, has resulted in divergent "normal" nasal anatomy, some of which can adversely affect airflow.

Congenital anomalies

Congenital anomalies of the nasal cavity and sinuses are rare but occur in all species. They are usually part of more extensive craniofacial defects accompanied by various malformations of the mouth and eyes. Animals with absent, underdeveloped, or severely distorted nasal regions are usually stillborn or die immediately after birth because of the severity of the craniofacial defects.

Choanal atresia, *in which one or usually both of the communications between the nasal cavity and nasopharynx fails to form*, occurs commonly in foals, with additional reports in dogs, sheep, and llamas. It is usually the result of persistence of the choanal membrane, which can result in partial or complete obstruction of airflow and exercise intolerance. Descriptions of the histology of the persistent tissue are limited, with pseudostratified columnar epithelium and chronic inflammation present in the resected tissue from a dog with choanal atresia. In addition to membranous blockage of the choanae, persistent osseous tissue is reported in humans with choanal atresia.

Not all developmentally related defects of the nasal cavity manifest themselves at birth. A variety of localized defects that can affect the nasal region can take time to become apparent. Defects of tooth germ origin are especially likely to be of this type. *Paranasal sinus cysts* in foals or young adult horses are cystic bony nodules filling the maxillary or frontal sinuses. The masses can distort the profile of the maxillary bone sufficiently to cause obstruction of the ipsilateral nasal passage, destruction of the nasal turbinates, distortion of the teeth, and deviation of the nasal septum. *Cystic nasal conchae* are congenital lesions that cause progressive nasal obstruction with inspiratory and expiratory noise in cattle. They are bilateral or unilateral, smooth-surfaced, bony expansions of the ventral nasal conchae, containing a mucus-filled cavity lined by epithelium. *Epidermal inclusion cysts* are described in the nasal diverticulum (false nostril) of horses.

Nasal amyloidosis

Deposits of amyloid sometimes occur in the nasal submucosa of horses. The deposition is not part of generalized amyloidosis, although there might be concurrent cutaneous amyloidosis, particularly of head, neck, and cranial thorax. The nasal vestibule and rostral portions of the septum and turbinates are mostly involved, but the deposits may extend to the larynx. The amyloid may be in nodules of various sizes or deposited diffusely. The resulting stenosis can be severe enough to cause signs of nasal obstruction. The amyloid deposits have a smooth surface and the usual waxy sheen of amyloid on cut surface. The amyloid is deposited in the walls of submucosal vessels and the basement membrane of mucosal glands as well as in the connective tissue. Macrophages and lymphocytes are usually intermingled with the interstitial amyloid deposits, and giant cells are found adjacent to nodular deposits. There may be severe ulceration of the mucosa, especially overlying large nodular masses.

Nasal amyloidosis in horses is of the *AL type*, composed of immunoglobulin light chains or light-chain fragments. AL amyloidosis is idiopathic or associated with myeloma in humans, but this association has rarely been made in horses. In other species, there are few reports of amyloid deposition in the nasal cavity. Nasal septal amyloidosis is seen as an aging change in some strains of laboratory mice. Because immunoglobulin components are integral to the formation of localized deposits of amyloid, the disease may represent a plasma cell dyscrasia, even if overt increases in plasma cell numbers are not apparent histologically. Indeed, amyloid deposition is seen periodically in extramedullary plasmacytomas, and may comprise the majority of these neoplasms, with few of the neoplastic cells apparent amongst the amyloid. This should be considered as a possibility in any animal with extensive amyloid deposition, regardless of location.

Circulatory disturbances

The ability of the nasal mucosa to regulate the temperature of inspired and expired air is facilitated by the network of blood vessels within the mucosa and submucosa. Immediately beneath the epithelium there is a complex plexus of blood vessels, in addition to highly distensible venous sinuses within the submucosa. Nasal congestion occurs when this process pools blood within the venous sinuses; the engorged vasculature causes physical obstruction to airflow. *The generous vascular endowment of the nasal vasculature, in addition to its functional activity, leads to frequent nasal hyperemia.* Congestion of the nasal mucosa is a common, nonspecific finding during postmortem examination of animals. Active hyperemia is part of the acute stage of inflammation. In the nasal and bronchial airways, plasma readily exudes from postcapillary venules into the lamina propria. While the exudation of plasma may have adverse consequences, it may play an important defensive role by delivering antibody and innate defense proteins to the nasal and bronchial mucosa.

Epistaxis *refers to hemorrhage from the nose, without regard to the source of the bleeding.* The hemorrhage may arise from the nasopharynx or from deeper within the respiratory tract. Epistaxis due to hemorrhage from the nasolacrimal duct in horses has been associated with bacterial infections of the distal lacrimal system. Examples of epistaxis originating in the lungs include exercise-induced pulmonary hemorrhage in horses, and rupture of embolic pulmonary abscesses in cattle. *Blood-stained foam* is a frequent nonspecific finding present in, and issuing from, the nose of cadavers. This finding is indicative of nasal and/or pulmonary microvascular rupture associated with terminal congestion, edema, and hemorrhage.

Epistaxis originating within the nasal region is most commonly caused by trauma, inflammation, or neoplasia. It may also be part of any of the hemorrhagic diatheses (see Vol. 3, Hematopoietic system), such as those causing thrombocytopenia. Epistaxis has been reported as a manifestation of purpura hemorrhagica, in horses that had the more characteristic findings of subcutaneous edema and mucosal hemorrhages. In most inflammatory hemorrhage, the extravasation is initially submucosal. Rhinitis with hemorrhage into the nasal lumen is a result of mucosal ulceration extending into the underlying vascular bed, as occurs in mycotic infections of the nasal mucosa or guttural pouches, or with neoplasia. Rarely, nasal hemorrhage may be the result of hypertension or vascular aneurysms.

Immunology of the upper respiratory tract

Before one considers inflammation and inflammatory diseases of the upper respiratory tract, it is important to develop an understanding of some of the basic features of the immune system of the nasal airways. As with other mucous membranes, the upper-airway mucosa has an indigenous immune system, the *nasal-associated lymphoid tissue* (NALT). NALT is considered to be a component of the broader mucosal-associated lymphoid system present in a variety of mucous membranes.

Waldeyer's ring is a collection of lymphoid tissues that encircles the oropharynx and nasopharynx of animals. The degree of organization of this lymphoid tissue varies by species. In addition, there are lymphoid follicles and loose aggregates of mononuclear cells within the lamina propria. These immune tissues induce a local immune response, and also stimulate a systemic immune reaction to nasally delivered antigens.

The organization of NALT is similar to mucosal lymphoid tissues at other sites. Specialized follicle-associated epithelium, with microfold (M) cells, covers the follicles and transfers antigen to the underlying lymphoid follicles. Within the follicles there are T-cell- and B-cell-rich regions, as well as dendritic cells and macrophages involved in antigen presentation. The formation of NALT is a postnatal event that is at least partly regulated by acquisition of commensal microbes in the nasopharynx. This resident microbial flora is often established by specific adherence of bacterial adhesins to carbohydrates on epithelial cells.

In addition to the role that nasopharyngeal commensals play in the formation of NALT, they can prevent colonization of the mucosa by more virulent organisms and modulate the immune response during infection. Experimentally, exposure of germ-free rats to the common rodent pathogen *Mycoplasma pulmonis* resulted in an exuberant immune response within the nasal mucosa when compared to conventional rats exposed to the same organism. Injury to the nasal mucosal surface can allow infection of the underlying tissues by certain of the normal flora or, more importantly, affect surface binding sites so that adherence and colonization by pathogenic microorganisms can occur. Finally, disruption of the normal nasopharyngeal flora by prolonged antibiotic therapy may result in fungal or opportunistic bacterial infections of the nasal cavity, further illustrating the role of these commensals in mucosal defense.

Rhinitis

Rhinitis, inflammation involving the nasal cavity, can be localized or a manifestation of systemic disease. Causes of nasal inflammation include viral, fungal, bacterial, and parasitic infections, allergens, inhalation of irritant gases, and particulate dusts (Table 5.1). Most cases of significant acute rhinitis begin with serous exudation, which change in the course of the disease to catarrhal and then purulent inflammation. Pseudomembranous, ulcerative, or hemorrhagic rhinitis are signs of severe damage. Chronic rhinitis is most commonly manifested by proliferative changes involving the mucosa and NALT.

During the initial **serous** stages of rhinitis, regardless of the inciting conditions, the mucosa is swollen and gray to red depending on the degree of hyperemia. Histologically, the epithelial cells are normal or show hydropic degeneration and loss of cilia. Goblet cells and submucosal glands are hyperactive. The secretion is a thin, clear seromucin, which contains a few leukocytes and epithelial cells. The underlying lamina propria is edematous and sparsely infiltrated by inflammatory cells. The swelling of the mucous membrane tends to cause mild respiratory discomfort and the familiar sneezing and snuffling.

Within hours or a few days, serous rhinitis is modified partly by changes in glandular secretion and partly by bacterial infection. The hyperemia, edema, and swelling are then aggravated and the discharge becomes *mucous, catarrhal, or purulent* because of the emigration of large numbers of leukocytes and desquamation of epithelial cells. Regenerative hyperplasia of surviving epithelium can occur, but in purulent rhinitis extensive ulceration may be evident.

Chronic rhinitis may cause progressive fibrosis of the lamina propria with atrophy of the glands, and atrophy with focal *squamous metaplasia of nasal epithelium*. With **pseudomembranous rhinitis**, fibrinous membranes can be peeled off without leaving gross underlying defects. In contrast, the deeper **fibrinonecrotic (diphtheritic) membrane** adheres firmly to the underlying tissue, leaves a raw ulcerated surface when removed, and is caused by bacteria such as *Fusobacterium necrophorum* or some viral infections. **Granulomatous rhinitis** causes diffuse or nodular lesions, and may be caused by fungi, mycobacteria, foreign material, or *Bartonella* sp. **Nasal/nasopharyngeal stenosis** or cicatrix formation occurs in cats and horses, probably as a result of previous erosive rhinitis with fibrous organization of exudates. Irregular webs of scar tissue may occlude the nasal passages, resulting in upper respiratory tract noise but only minimal discharge.

In subacute to chronic rhinitis, diffuse or localized polypoid thickenings of the mucosa develop (Fig. 5.1). The **nasal polyps** are initially sessile but can, when larger, become pedunculated. The ease with which the nasal lamina propria becomes engorged and edematous, plus the tendency of protuberances into the nasal meatus to compromise venous and lymphatic drainage because of constriction in their basal regions, are probable factors in the persistence or progression of inflammatory polyps. They occur occasionally in horses and cats, less commonly in other species. Polyps are soft, pink-gray, irregularly nodular, pedunculated or sessile masses. They have a chronically inflamed, edematous, myxomatous core, covered by variously hyperplastic, metaplastic, or ulcerated epithelium. Chronic polyps can become more fibrous, with organization and maturation of the collagenous stroma.

Idiopathic lymphoplasmacytic rhinitis is an important condition in the dog, and to a lesser extent in the cat. In dogs, the clinical disease may be either unilateral or bilateral, although histologic lesions are usually bilateral. Grossly, there is increased mucus production, mucosal inflammation, and turbinate destruction. Histologically,

Table 5.1 Major causes of nasal and sinus disease in domestic animals

Dogs
- Foreign body
- Tooth root infection
- Mycotic rhinitis
- Idiopathic lymphoplasmacytic rhinitis
- Allergic rhinitis
- Ciliary dyskinesia
- Adenocarcinoma
- Olfactory neuroblastoma
- Other considerations
    1. *Bordetella bronchiseptica*
    2. *Canine adenovirus 2*
    3. *Canine distemper virus*
    4. *Canine parainfluenza virus*
    5. *Linguatula serrata*
    6. *Pneumonyssoides caninum*
    7. *Rhinosporidium seeberi*

Cats
- *Felid herpesvirus 1*
- *Feline calicivirus*
- *Cryptococcus*
- Foreign body
- Nasopharyngeal stenosis
- Nasopharyngeal polyp
- Lymphoma
- Adenocarcinoma
- Other considerations
    1. *Bordetella bronchiseptica*
    2. *Chlamydophila* sp.
    3. *Mycoplasma* spp.
    4. Mycotic rhinitis
    5. *Rhinosporidium*

Horses
- *Equid herpesvirus*
- *Equine influenza virus*
- *Equine rhinitis virus*
- *Streptococcus equi*
- *Streptococcus zooepidemicus*
- Bacterial sinusitis
- Ethmoid hematoma
- Sinonasal polyps
- Ethmoid and sinus cysts
- Squamous cell carcinoma
- Maxillary bone tumors (fibrous dysplasia, ossifying fibroma, osteoma, fibrosarcoma)
- Other considerations
    1. Tooth root infection
    2. Nasal amyloidosis
    3. Glanders
    4. Mycotic rhinitis or sinusitis
    5. Phycomycosis
    6. *Schistosoma* spp.

Cattle
- *Bovine herpesvirus 1*
- *Bovine parainfluenza virus 3*
- Mycotic nasal granuloma
- Allergic rhinitis
- Other considerations
    1. *Limnatis* spp.
    2. *Mammomonogamus* spp.

Sheep and goats
- *Salmonella arizonae*
- *Oestrus ovis*
- Enzootic nasal tumor

Swine
- Inclusion body rhinitis
- Atrophic rhinitis

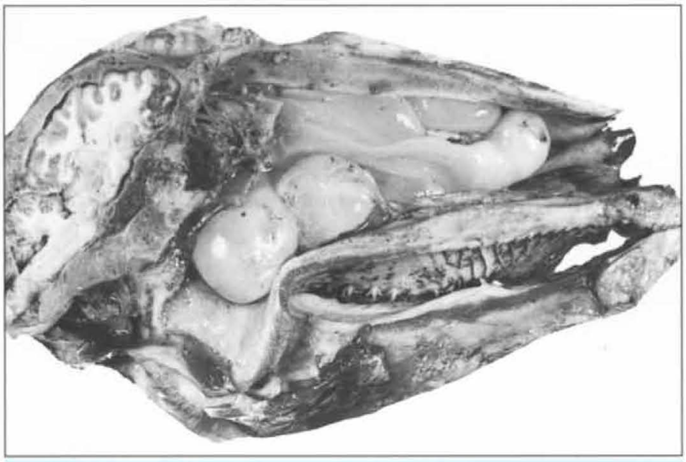

Figure 5.1 Myxomatous polyps in chronic rhinitis in a sheep.

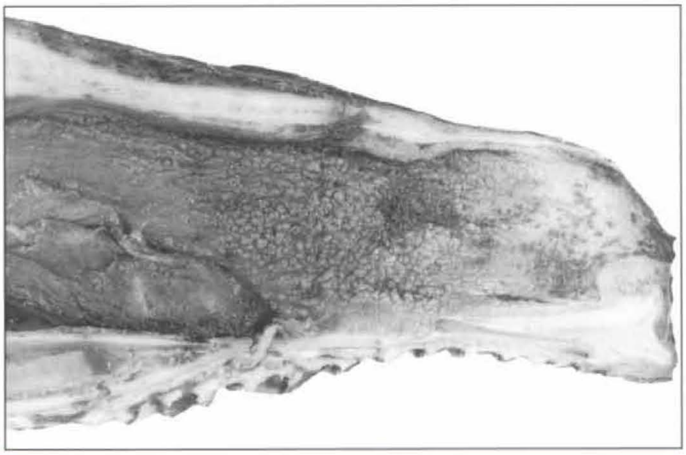

Figure 5.2 Hyperplastic mucosa of rostral nasal septum in **nasal granuloma** in a cow.

lymphocytes and plasma cells are the predominant inflammatory cell components. Chronic inflammation may lead to diffuse or polypoid thickening of the nasal mucosa and obstruction of nasal passages (Fig. 5.1). The fibrotic stroma is heavily infiltrated by lymphocytes and plasma cells, and the surface epithelium may be hyperplastic, eroded, or undergo squamous metaplasia. The cause of this disease remains unknown and the pathogenesis remains to be elucidated. It seems reasonable to consider that following an unknown initial insult there develops a self-propagating cycle that involves dysregulation of the local immune system, resulting in mucosal damage and further infection by normally nonpathogenic commensal flora and self-sustaining inflammation. Nevertheless, lymphoplasmacytic inflammation is a common reaction of the nasal mucosa to injury, and occult causes such as foreign body, bacterial or fungal infection, or neoplasia must be ruled out.

Allergic rhinitis is observed sporadically in dogs, cats, and horses. The disease in *dogs* is diagnosed on the basis of oculonasal discharge, sneezing, nose rubbing, head shaking, and perhaps epistaxis, and the *presence of eosinophils in nasal exudate.* There is no definitive information on either the pathological or immunological basis of the condition. *Cattle* and occasionally *sheep* develop a seasonal rhinitis that in its clinicopathological features is consistent with an allergic pathogenesis. Some evidence has been provided that affected cattle are allergic to pollen antigens. A familial predisposition has been reported. It occurs chiefly in the summertime when the pastures are in bloom. Affected animals have nasal discharge, lacrimation, sneezing, and evidence of nasal itching. The nasal mucosa is pale and thick from edema fluid, and mucosal erosions may be visible in the rostral nares. Eosinophils and mucus are a prominent component of the exudate. Histologically, *the surviving nasal epithelium is hyperplastic or eroded and is infiltrated by eosinophils.* The glandular epithelium can be hypertrophied and mucus is produced in excess. In more severe cases, in which there is extensive superficial diphtheresis, many of the small mucosal vessels show fibrinoid necrosis.

Nasal "granuloma" *is generally considered to be a more chronic form of allergic rhinitis.* The affected mucosa is mainly in the caudal portion of the nasal vestibule and the rostral region of the nasal septum and ventral meatus. In long-standing cases, the lesions extend further caudally to involve the caudal nasal cavity and even the larynx and proximal trachea. Grossly, *the hyperplastic epithelium is granular or has multiple nodular projections covered by intact epithelium* (Fig. 5.2). Histologically, the nodules typically consist of hyperplastic epithelium with areas of squamous metaplasia, covering a superficial edematous lamina propria with a central core of inflamed granulation tissue. Goblet-cell hyperplasia is more pronounced in the ducts of the nasal glands, at the lateral boundaries of the nodules. Eosinophils infiltrate the superficial lamina propria and epithelium, and mast cells are increased in number. Vascular proliferation, fibroplasias, and accumulation of mostly lymphocytes and plasma cells in the cores of nodules are features of chronicity. It is believed that the condition is due to an immediate (type I) hypersensitivity to plant pollens or fungal spores. Because there appears to be a familial predisposition in Jersey cattle and to a limited extent in other cattle, the existence of susceptible "atopic" animals has been proposed. The condition is therefore sometimes referred to as *atopic rhinitis.*

Mycotic nasal granulomas in cattle are less common. They also occur mostly in the rostral portion of the nasal cavity but *tend to be larger polypoid masses.* They frequently have yellow-green cores associated with massive eosinophil accumulation. Histologically, components of the lesions are similar to those previously described for the chronic allergic "granulomas," but hyphae and chlamydospores of fungi surrounded by macrophages, giant cells, and eosinophils are present. Various fungi, normally saprophytic on plants, have been isolated. It is tempting to speculate that the mycotic granulomas represent the small proportion of the more nonspecific allergic granulomas in which the causative allergen is able to vegetate. Mycotic rhinitis in canids is discussed in the section on Infectious respiratory diseases of dogs, below.

Sinusitis

Inflammation of the paranasal sinuses often goes undetected unless it has caused facial deformity or a fistula in the overlying skin. Sinusitis is of most significance in the horse because of the size and complexity of its paranasal sinuses and the compounding effects of limited drainage and tendency for periodontitis to extend to sinusitis. Sinusitis is very common in sheep as a response to larvae of *Oestrus ovis.* It also follows penetration of infection in dehorning wounds, fractures, and periodontitis. Seromucinous sinusitis may occur in viral infections of the upper respiratory tract, but it is not usually detected in routine diagnostic pathology samples. In acute catarrhal or purulent rhinitis, the mucosal swelling tends to occlude the orifices of the sinuses and impair drainage. The secretions and exudates then accumulate and render chronic purulent sinusitis almost inevitable. The histologic features of sinusitis are similar to those of rhinitis. *The accumulation of seromucinous secretion is referred to as* **mucocele**, and *the accumulation of purulent exudate is referred to as* **empyema** *of the sinus*. It is also less likely to drain and resolve spontaneously and therefore more likely to cause epithelial atrophy and metaplasia, and distort the bony walls of the sinuses by pressure or osteomyelitis.

Nonneoplastic proliferative disorders of the nasal cavity and sinuses

Polypoid thickening of the nasal mucosa can occur in cases of chronic rhinitis and sinusitis. In these chronic inflammatory lesions, mucosal and submucosal hyperplasia may become florid enough to form a discernible mass within the nasal cavity or sinuses (see Fig. 5.1). While this change is a nonspecific remodeling response in the nasal cavity, there are two specific types of polyps in domestic species whose clinical features and pathology are distinctive.

Progressive ethmoid hematomas (PEH, hemorrhagic nasal polyp) **of horses** *arise from the ethmoid turbinate region of the equine nasal cavity*. These masses usually occur in older horses, and may be more common in the Thoroughbred and Arabian breeds. PEH are unilateral hemorrhagic growths, which arise from the submucosa of the ethmoid turbinates. The cause and pathogenesis of PEH remain to be determined, although it is assumed that it represents an aberrant vasoproliferative response to submucosal hemorrhage. The lesions are progressive and may continue to enlarge until the cylindrical mass extends to the external nares. Grossly, PEH is a mottled, hemorrhagic fibrovascular mass that can fill the ipsilateral nasal meatus, or occasionally grow into the maxillary sinus. Histologically, PEH mostly consists of organizing hemorrhages of various ages with extensive siderosis and mineralization of connective tissue fibers. The inflammatory response is variable, but multinucleate giant cells are often reported within the stroma. The surface is often covered by attenuated epithelium with underlying glands, or squamous metaplasia may occur. Ulceration of the surface epithelium is common.

Nasopharyngeal polyps of cats *are nonneoplastic inflammatory masses arising within the middle ear or auditory tube.* Clinical disease is seen primarily in young cats 1–3 years of age. The signs of disease are dependent upon the location of the polyp. Extension of the mass into the pharynx is associated with dyspnea, dysphagia, and gagging; involvement of the nasal cavity may cause sneezing, nasal discharge, and protrusion through the nares; while involvement of the middle ear may result in ataxia, Horner's syndrome, and/or facial nerve paralysis. When the polyps extend into the external ear canal they are known as **aural polyps**. The cause and pathogenesis of the disease are not known, although the appearance of the lesions suggests progressive fibroproliferation in response to localized chronic inflammation. Histologically, feline nasopharyngeal polyps consist of a loose fibrovascular core covered by ciliated respiratory or squamous epithelium. Even when the surface is completely covered by squamous epithelium, ciliated cells are usually visible within nests of epithelial cells buried in the stroma. The surface of the masses is frequently ulcerated, and the stroma is infiltrated by a mixed chronic inflammatory infiltrate of lymphocytes, plasma cells, and macrophages; ulceration results in significant numbers of neutrophils infiltrating the stroma. Recurrence of the polyps is relatively common when removed by simple traction, if the base of the mass is not excised.

Neoplasms of the nasal cavity and sinuses

While *primary neoplastic disease of the nasal cavity and sinuses of domestic animals is not common*, examination of nasal biopsy specimens to rule out such disease is common. Primary nasal neoplasia is most frequent in the dog and cat, with fewer reports in horses. Endemic, retroviral-induced ethmoidal tumors in sheep and goats are an important disease in specific geographic regions and are described with the infectious diseases of these species. There is no apparent relationship between the frequency of nasal tumors and breed-specific craniofacial anatomy in dogs. Interestingly, there is some epidemiologic evidence of a link between exposure to environmental tobacco smoke and coal-burning and kerosene heat sources, and the development of nasal neoplasms in dogs.

Origin from the nasal cavity is usual in dogs and cats, whereas in horses tumors of the paranasal sinuses are most common. Because of the inflexible osseous encasement, even benign growths can be associated with significant clinical disease. In general, *most neoplasms of the nasal cavity and sinuses, regardless of species, are carcinomas*, followed in decreasing frequency by sarcomas of cartilage, fibrous tissue, or bone. Regardless of histogenesis, malignant nasal neoplasms tend to be soft, pale, and fleshy-to-friable masses. The neoplasms invade and destroy adjacent structures, including the brain, but metastasis is uncommon (Fig. 5.3).

A variety of other neoplasms are reported in the nasal cavity of domestic species. These may be primary to the nasal cavity or part of systemic neoplastic disease. Primary lymphoma of the nasal cavity is the most common of these neoplasms, likely arising from the NALT. Other neoplasms reported in the nasal cavity include transmissible venereal tumor, mast cell tumor, and histiocytic sarcoma.

Squamous cell carcinomas predominate in the cat and horse, though they may be seen in any of the domestic species. In the cat, most originate from the nasal vestibule, while in the horse the maxillary sinus is a common site. The latter may arise from the epithelium of dental alveoli. Histologically, squamous cell carcinomas in the nasal cavity and sinuses share the typical features of the neoplasm seen elsewhere in the body, although keratinization is not as prominent.

Transitional carcinomas resemble the transitional (nonciliated) nasal epithelium. These neoplasms are most common in dogs. Transitional carcinomas are so called because they assume the stratified cuboidal appearance of transitional epithelium. Because of their characteristic appearance, they are sometimes referred to as *respiratory epithelial carcinomas* and, in the literature on human nasal tumors, they are often classified as *nonkeratinizing squamous cell tumors*. Transitional carcinomas typically consist of thick stratified layers of mostly cuboidal cells with rounded nuclei, indistinct cell borders, and a distinct basement membrane beneath the layer of neoplastic cells. Large transitional carcinomas have complex infolding or pleating of the thick epithelial bands separated by delicate fibrovascular septa. Microcysts are sometimes present within the epithelial layers, and must be distinguished from the acini seen in adenocarcinomas.

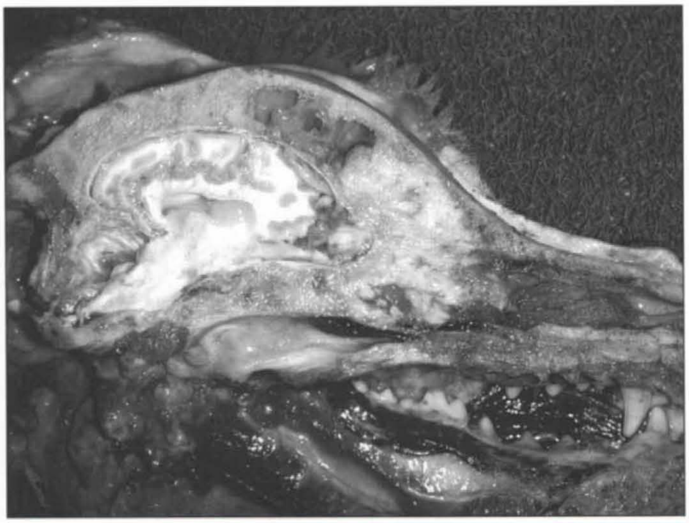

Figure 5.3 Nasal adenocarcinoma in the ethmoid region has invaded frontal sinus and through cribriform plate into the brain in a dog.

The transitional nasal epithelium in the dog is endowed with a complement of cytochrome P450 monooxygenase enzymes within the smooth endoplasmic reticulum, which may play a role in metabolizing inhaled and circulating xenobiotics in the canine nose. Metabolism of a variety of xenobiotics into reactive intermediate molecules is a well-documented mechanism of neoplastic transformation in other organs, and may play a role in canine transitional epithelial nasal carcinogenesis. This is supported by the finding that the expression of cyclooxygenase-2 is increased in the neoplastic epithelial cells.

Nasal adenocarcinomas are common in dogs and cats. They often form papillary fronds and glandular acini (Fig. 5.4). The acini are formed by a single layer of cuboidal to tall columnar cells with a basement membrane, unlike the microcysts of the transitional tumor, which are within a thick layer of tumor cells. Mucin-filled acini are a fairly common feature of adenocarcinomas.

Adenoid cystic carcinomas are rare tumors with a multilobular organization and at least some lobules with a characteristic striking cribriform pattern. These tumors possibly arise from salivary gland tissue in the soft palate rather than from nasal epithelial structures. **Adenosquamous (mucoepidermoid) carcinomas** have mucin-filled acinar components and foci with squamous differentiation. Both glandular and squamous elements must exhibit criteria for malignancy.

Undifferentiated carcinomas are mostly solid tumors in which there are large packets or nodules of round to polygonal cells with no discernible pattern. This diagnosis is usually made after examination of multiple samples fails to reveal regions with a pattern resembling the more differentiated types of carcinoma discussed above. Special methods are needed to separate these tumors from others such

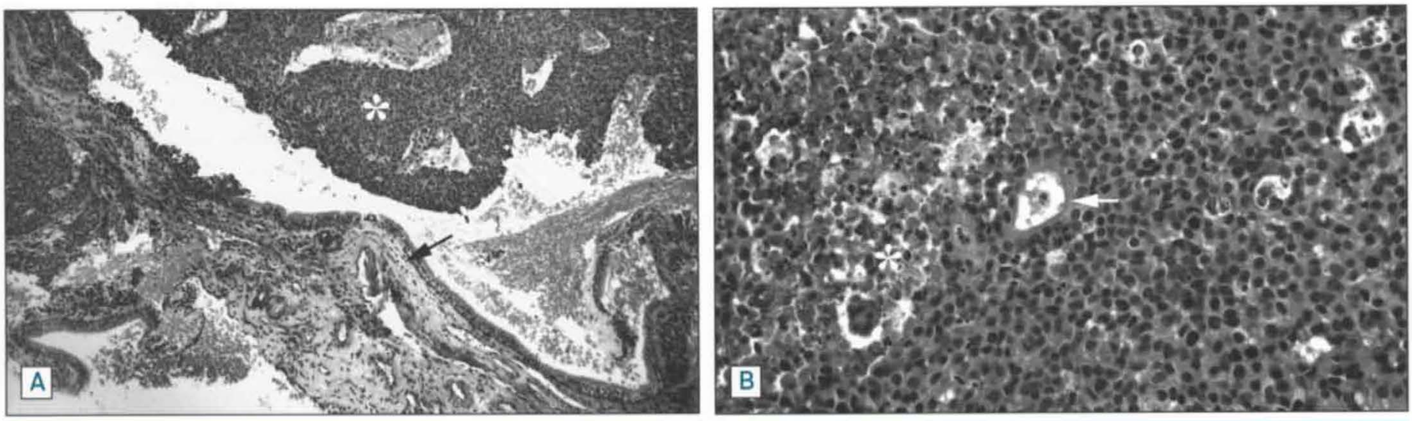

Figure 5.4 Nasal adenocarcinoma, in a dog with a chronic unilateral hemorrhagic nasal discharge; previous biopsies revealed only lymphoplasmacytic rhinitis. **A.** A densely cellular neoplasm (asterisk) contrasts with the normal adjacent nasal mucosa (arrow). **B.** The angular neoplastic cells have a predominantly solid arrangement, with occasional acini (arrow) and areas of necrosis (asterisk).

as olfactory neuroblastoma, amelanotic malignant melanoma, lymphoma, and poorly differentiated mast cell tumor. Carcinomas with mixed phenotypic expression are fairly common, especially if multiple sections are examined; for example, transitional carcinomas sometimes have scattered foci of squamous metaplasia or adenocarcinomatous regions.

Olfactory neuroblastoma (esthesioneuroblastoma, esthesioneuroepithelioma) is a rare neoplasm arising in the ethmoturbinate region of the caudal nasal cavity. Penetration through the cribriform plate and into the cerebral cortex is commonly observed. Most of the reported tumors have occurred in cats and dogs. It is unclear whether they arise from one or more of olfactory neuroepithelial cells, residual neural crest cells, or local components of the dispersed neuroendocrine system. The tumors are highly cellular and consist of a uniform population of round to elongated cells with moderately dense nuclei and small amounts of cytoplasm. *An important diagnostic feature is the presence of palisading around vessels and rosette formation*. In the absence of these features, the olfactory neuroblastoma is not distinguishable on routine examination from lymphoma or undifferentiated carcinoma. Definitive diagnosis may be facilitated by ultrastructural and immunohistochemical examinations. Limited investigation has suggested the presence of *Feline leukemia virus* in feline olfactory neuroblastomas, but it is unknown whether the association is causal.

Neuroendocrine carcinoma of the nasopharynx is formed by a *packeted* arrangement of rounded epithelial cells with indistinct borders, which express synaptophysin and neuron-specific enolase. These tumors may have invasive and metastatic behavior. **Paranasal meningioma** occurs in dogs and horses, and in dogs appears similar to intracranial meningiomas but has a more invasive behavior. **Enzootic nasal tumors** of retroviral etiology are discussed below in the section on Infectious respiratory diseases of sheep and goats. **Nasomaxillary tumors of young horses**, including fibrosarcoma, ossifying fibroma, and fibrous dysplasia, are described elsewhere (see Vol. 1, Bones and joints). Other tumors of the nasal cavity include **papilloma**, **adenoma**, **lymphoma**, **mast cell tumor**, **melanoma**, **transmissible venereal tumor**, and a variety of **sarcomas**.

PHARYNX, LARYNX, AND TRACHEA

Pharynx

The pharynx, as the site where the respiratory and alimentary systems conjoin, is exposed to both inhaled and ingested materials, some of which may have deleterious effects on the animal. Additionally, the complexity of pharyngeal organogenesis, at the junction between craniofacial development and the respiratory and alimentary systems, predisposes the region to involvement in a variety of congenital malformations. Many of these malformations arise as unintended consequences of selective breeding for desirable craniofacial features in domestic species, especially brachycephalic dogs and cats.

In **pigs**, a *caudal diverticulum of the pharynx lies immediately dorsal to the esophagus*. In young pigs, plant awns and similar foreign materials occasionally lodge in this diverticulum, causing pharyngitis and cellulitis that may lead to dysphagia and death from starvation. Iatrogenic pharyngitis, even with perforation of the caudodorsal wall of the pharynx, may occur in **cattle** during incorrect oral administration of boluses or esophageal intubation.

In young **horses**, it is not uncommon to find prominent lymphoid follicles within the pharyngeal mucosa, and in most instances this should be considered an incidental finding as these follicles are part of the normal pharyngeal mucosal immune system in the horse. **Chronic pharyngitis with lymphoid hyperplasia** is a syndrome in young racehorses that is often detected endoscopically in Thoroughbreds <5 years of age. Polypoid projections of the pharyngeal mucosa may occur in association with the hyperplastic lymphoid follicles. The cause of this syndrome is not known, though it is assumed to represent persistent, excessive local immune stimulation.

The *guttural pouches* of Equidae are ventral diverticula of the auditory tubes. They tend to become involved in inflammatory processes in analogous fashion to the paranasal sinuses. Complications differ, however, because severe guttural pouch inflammation can extend to involve nearby cranial nerves (VII, IX, X, XI, XII), vessels and the cranial sympathetic trunk, or even spread to adjacent bones, middle ear, brain, or atlanto-occipital joint. Suppurative inflammation leading to empyema occurs mostly after upper respiratory infections, particularly with *Streptococcus equi* or other streptococci. Fibrinous or fibrinonecrotic (diphtheritic) inflammation is usually associated with fungal infection, generally *Aspergillus* spp., and hence is commonly referred to as *guttural pouch mycosis*. Fibrinonecrotic inflammation is highly suggestive of, but not pathognomonic for, fungal infection. Because the fibrinonecrotic inflammation extends deeply, and fungi frequently invade vessels and other structures, severe complications are much more likely to follow than from guttural pouch empyema. Examples are thrombosis, aneurysm formation, and rupture of the internal carotid artery with epistaxis, ischemic lesions or osteitis, and fusion of stylohyoid and petrous temporal bones. Guttural pouch hemorrhage may also result from fracture of the basisphenoid bone. A less common condition is *guttural pouch tympany*. This is mostly seen in young animals, and the accumulation of air is presumed to be due to valvular action of the nasopharyngeal orifice of the eustachian tube. *Tumors of the guttural pouches* are rare, but when encountered are most likely to be squamous cell carcinomas. Pharyngeal tumors are discussed with neoplasia of the mouth (see Vol. 2, Alimentary system).

Larynx and trachea

Congenital anomalies

Congenital anomalies of the larynx are rare, while those of the trachea are relatively common in some domestic species. In dogs, and to a lesser extent cats, selective breeding for brachycephalic features has led to upper-airway obstruction that can cause clinically important respiratory signs. This spectrum of clinical disease in dogs is known as the **brachycephalic airway syndrome**. This syndrome is of lesser importance to pathologists, as tissues are not usually submitted for analysis. Insufficient pharyngeal space for the soft palate in these breeds (elongation of the soft palate) is the most significant anatomical feature contributing to the brachycephalic airway syndrome. Other common laryngeal diseases in the dog include *eversion of laryngeal saccules* and *laryngeal collapse*.

Tracheal hypoplasia is found primarily in brachycephalic canine breeds, and may or may not be accompanied by additional respiratory or cardiac disease. The hypoplasia of the trachea results in a reduction in the luminal diameter of the entire trachea; *the cartilage rings are typically entire circles*, rather than the C-shaped rings of normal trachea. There is a dearth of information regarding the histopathologic features of hypoplastic trachea vis-à-vis normal trachea in affected dogs.

Tracheal collapse, as a clinical entity, refers to *dorsoventral narrowing of the trachea* resulting in coughing and exercise intolerance. The disease is most common in middle-aged miniature breeds of dogs. The cartilage rings are abnormally shaped and form shallow arcs, and the dorsal trachealis muscle (tracheal membrane) is widened and flaccid. The membrane is thin in uncomplicated cases but becomes thickened when there is superimposed chronic inflammation. Earlier descriptions of the histologic and histochemical features associated with tracheal collapse describe foci of hypocellularity of the hyaline cartilage and areas where cartilage is replaced by fibrous and/or fibrocartilaginous tissue; reduced concentrations of chondroitin sulfate and calcium are associated with the reduction in density of chondrocytes. It remains to be determined if these changes are causative or the result of biomechanical changes associated with the tracheal collapse. Investigations into the neural network of the canine trachea reveal a multilayered nervous system that has components throughout the wall of the trachea, including within and around the trachealis muscle; this system might play a role in the physiologic changes associated with tracheal collapse.

Malformations of the cross-sectional shape of the trachea can be found as an incidental finding in nearly any species at the time of necropsy. They are most common in the dog and horse. Tracheal trauma causing fracture of the cartilage may lead to a variety of tracheal ring abnormalities. Compressive inflammatory lesions or neoplasms can also lead to focal tracheal compression with alterations in the tracheal shape.

In the **horse**, *subepiglottic cysts* are believed to arise from thyroglossal duct remnants. *Entrapment of the epiglottis* below the aryepiglottic fold is usually associated with congenital hypoplasia or acquired shortening or distortion of the epiglottis. A short epiglottis also predisposes to dorsal displacement of the soft palate and these conditions sometimes occur together. *Persistent frenulum of the epiglottis* has been reported in newborn foals, predisposing to oronasal reflux of milk after nursing and aspiration pneumonia. The persistent frenulum of the epiglottis leads to dorsal displacement of the soft palate, which can be assessed endoscopically.

Laryngeal paralysis

In domestic species, laryngeal paralysis is most commonly reported in dogs and horses. Unilateral or bilateral paralysis of the larynx is the most common cause of abnormal respiratory noise (*roaring*) in horses, while the condition in dogs is typically bilateral and results in abnormal barking and exercise intolerance. In **horses**, *the condition is almost always a left-sided hemiplegia due to idiopathic degeneration of the left recurrent laryngeal nerve*. The resulting denervation atrophy affects the intrinsic laryngeal muscles supplied by this nerve, but the atrophy is not uniform; the laryngeal adductor muscles, especially the lateral cricoarytenoid muscle, are affected first, followed by the abductor muscles. Grossly, the affected muscles are pale and atrophic, and the cricoarytenoid muscle may be reduced to only the fascial remnants. The cricothyroid muscle, which is supplied by the cranial laryngeal nerve, is the only intrinsic muscle not affected. The dorsal cricoarytenoid muscle is the main abductor of the larynx through its insertion on the muscular process of the arytenoid cartilage and, hence, is largely responsible for laryngeal opening during respiration. When denervation atrophy and dysfunction affect the dorsal cricoarytenoid muscle, the left arytenoid cartilage sags into the lumen and obstructs airflow during inspiration, particularly during intense exercise.

Microscopic examination of affected nerve fibers reveals *severe loss of myelinated fibers in middle and distal portions of the left recurrent laryngeal nerve*. Ultrastructural features indicate progressive loss of fibers in the left recurrent nerve accompanied by chronic demyelination, remyelination, and abortive regenerative attempts. Similar but milder changes can be detected ultrastructurally in the distal right recurrent nerve. The reasons for the axonal disease are still disputed. The axons in the left recurrent laryngeal nerve are much longer than those in the right recurrent nerve and this presumably makes them more susceptible to damage. The extent to which damage is caused by traumatic interruption of axoplasmic flow, neuritis by extension from guttural pouch disease, vitamin deficiency, or neurotoxins has still to be established. Idiopathic laryngeal paralysis – the most common form encountered – is typically unilateral, whereas bilateral paralysis is more typical of cases caused by hepatic encephalopathy and general anesthesia.

In **dogs**, laryngeal paralysis occurs most commonly in older, large or giant breed, males. The disease is usually bilateral. While the cause is often not identified, the relationship between recurrent laryngeal axonopathy and denervation atrophy of the laryngeal muscles is usually as described in horses. In dogs, unlike horses, laryngeal paralysis may be a single manifestation of generalized neuromuscular disease. Some breeds of dogs are predisposed to developing laryngeal paralysis, including Bouvier des Flandres and mixed Husky–Malamute puppies, where it is associated with apparent hereditary degeneration of the nucleus ambiguus; Rottweilers, as a manifestation of a polyneuropathy; and white-coated German Shepherd Dogs. Occasionally, laryngeal paralysis occurs secondary to hypothyroidism or following general anesthesia. In dogs, laryngeal paralysis may predispose to aspiration pneumonia.

Circulatory disturbances

As in the other regions of the upper airways, the mucosa of the larynx is often congested at the time of necropsy, and mucosal petechiae may be present; these findings are rarely of any significance. Laryngeal hemorrhages affecting the mucous membrane on the dorsal surface of the epiglottis occur in septicemia. They are of some diagnostic significance in salmonellosis of swine and classical swine fever.

Laryngeal edema may be part of a local or systemic inflammatory process, and can be caused by infectious laryngitis (see section on Infectious diseases of the respiratory system, below), inhalation of irritant materials, local trauma, anaphylaxis, or hyperthermia. The amount of edema varies, but is most severe in the region of the epiglottis, the aryepiglottic folds, and the ventricles.

Tracheal edema and hemorrhage syndrome of feedlot cattle, in which the lumen is partially obstructed by severe mucosal and submucosal edema of the dorsal region of the distal half of the trachea (Fig. 5.5), occasionally causes death by asphyxiation in feedlot cattle. The loud inspiratory noise made by severely affected animals has given rise to the clinical term "honker syndrome." The cause of this syndrome is not known, but the increased prevalence during hot weather and the frequent presence of concurrent bronchopneumonia suggest that hyperpnea with negative intratracheal pressures during inspiration may cause mechanical injury to the tracheal mucosa.

Laryngitis and tracheitis

The location of the larynx and trachea is such that frequently they become inflamed as part of inflammatory diseases of either the upper or lower parts of the respiratory tract. Tracheitis frequently accompanies bronchitis and bronchopneumonia. Laryngitis can, however, occur without wider involvement of the respiratory tract. Laryngitis can occur as a part of *oral necrobacillosis* (calf diphtheria) caused by *Fusobacterium necrophorum* in calves and swine or it may occur without lesions elsewhere (Fig. 5.6). *Laryngeal ulcers* occur in feedlot cattle with bronchopneumonia, and probably represent mucosal damage by the repeated trauma of laryngeal closure in dyspneic animals. *Laryngeal infarcts* with ulceration may overlie lesions of septic phlebitis in calves with *Histophilus somni* septicemia and pneumonia.

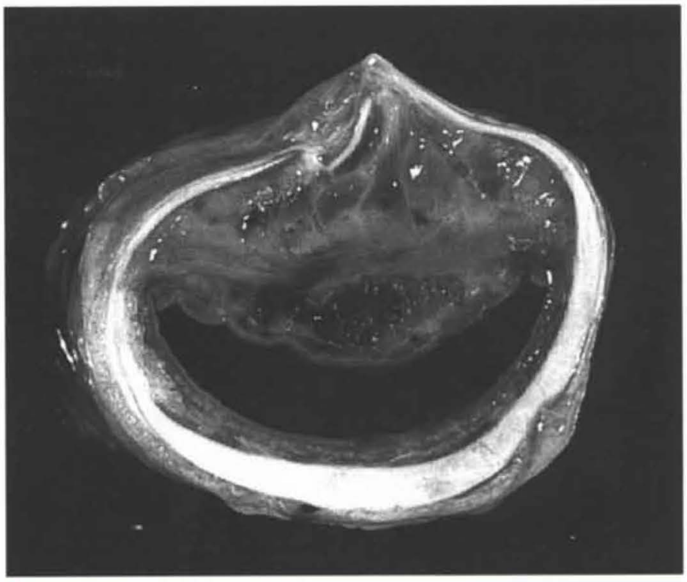

Figure 5.5 Tracheal edema and hemorrhage syndrome in a feedlot calf. Segmental thickening of the tracheal mucosa partially obstructs the lumen. (Courtesy of EG Clark.)

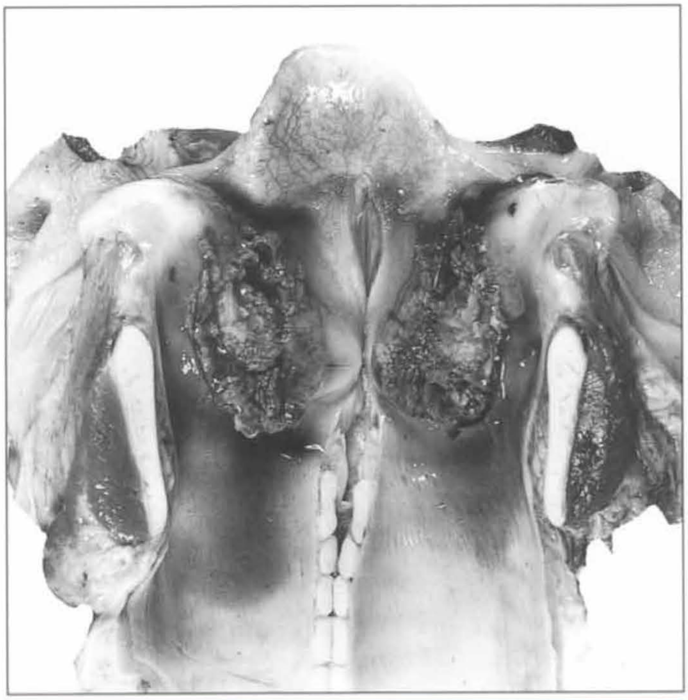

Figure 5.6 Necrotic laryngitis in a calf.

Laryngeal chondritis (*arytenoid chondropathy*) occurs in young horses, as well as sheep and calves. It is characterized by ulceration of mucosa at the rostral margin of the arytenoid cartilage, immediately caudal to the attachment of the vocal fold. The lesions are variable and may consist of a granuloma, purulent tract, or noninflammatory necrosis of the cartilage. Inflamed lesions may result in laryngeal edema that obstructs airflow. The pathogenesis is not known, but may involve mucosal trauma as the larynx closes forcefully in rapidly breathing animals.

Small foci of *mineralization*, often with accompanying granulomatous inflammation, occur in the lamina propria of the dorsal trachea and ventral turbinates of adult pigs. The cause is not known. Foci of chronic polypoid tracheitis are occasionally observed in dogs and cats. The thickening may be sufficient to cause significant stenosis and dyspnea. The cause is unknown but the various pathogenetic factors involved are probably similar to those responsible for nasal polyps. *Squamous metaplasia* of tracheal epithelium is a feature of vitamin A deficiency and severe iodide toxicosis. *Parasitic diseases* of the larynx and trachea, discussed later in the chapter, include *Mammomonogamus laryngeus* in the larynx of cattle, and *Eucoleus aerophilus, Oslerus osleri*, and *Spirocerca lupi* in the trachea of dogs.

Neoplastic diseases of larynx and trachea

Primary neoplasms of the larynx and trachea are rare in domestic species. Papillomas and squamous cell carcinomas are the most common epithelial tumor; papillomas involving the larynx are usually part of widespread papillomatosis, as may be seen in immune-compromised animals. **Tracheal chondroma and osteochondroma** is an uncommon condition of young dogs, and may represent a dysplastic cartilaginous mass rather than a true neoplasm. It forms an expansile mass of disorganized cartilage, with ossification of the central core of some lesions. Rare tumors reported to affect the larynx or trachea include adenocarcinoma, rhabdomyoma, rhabdomyosarcoma, chondroma, osteochondroma, chondrosarcoma, osteosarcoma, leiomyosarcoma, and mast cell tumor. Mucosal involvement of the larynx and trachea in lymphosarcoma or malignant mast cell tumor is an uncommon occurrence in cats and dogs; deformation or invasion of the larynx by adjacent neoplasms in the thyroid glands or lymph nodes may occur.

Laryngeal rhabdomyoma (formerly known as *oncocytoma* or *granular cell tumor*) occurs in young dogs as a solitary raised nodule in or close to the lateral ventricle of the larynx. It consists of lobular masses of angular pleomorphic cells with abundant, deeply eosinophilic, granular, or foamy cytoplasm. Diagnosis using only light microscopy is difficult and the designation as rhabdomyoma depends on demonstrating *myosin and muscle-specific actin* using immunohistochemistry. Ultrastructurally, there are numerous mitochondria and intermitochondrial glycogen granules.

LUNGS

Lung development and growth

The lungs develop early in gestation, forming from a ventral diverticulum in the foregut endoderm. The six stages of lung development and growth are the embryonic, pseudoglandular, canalicular, saccular, alveolar, and vascular maturation stages. Important development continues postnatally in most mammalian species.

During the **embryonic** stage of lung growth (30–50 days of gestation in a bovine fetus), the primordial trachea and right and left primary bronchi develop, growing into the surrounding mesenchyme. The growth of the conducting airways occurs primarily in the **pseudoglandular** stage; in most species the airways develop through a series of asymmetric dichotomous branching. Differentiation of conducting airway epithelial cells begins proximally and extends distally at this stage, with development of ciliated cells, mucous cells, basal cells, and bronchial cartilage. At the end of the pseudoglandular period, all branches of conducting airways have developed and are embedded in mesenchymal stroma. Distal airway branches are lined by cuboidal to columnar epithelial cells that contain abundant cytoplasmic glycogen. During the **canalicular** stage of growth (120–180 days of gestation), vascular "canalization" of the interstitium occurs, with capillaries growing in apposition to the airway epithelium to form the developing air–blood interface. Also during the canalicular stage, there is development of the type II pneumocytes and type I pneumocytes within the newly formed terminal airspaces. Fetal lung development to the **saccular** stage (180–240 days' gestation in the bovine fetus) is important for survival outside of the uterus. Lung volume and gas exchange surface increase markedly, and there is further reduction in mesenchyme between airspaces. The terminal branches of the conducting airways extend through the nascent parenchyma, and conditions are set for alveolar development. Small accumulations of elastic fibers, the site of secondary alveolar septal development, are deposited during this stage. During the **alveolar** stage of lung growth (240–260 days), true alveoli form by ingrowth of septa from intersaccular crests at the sites of elastic fiber deposition. These secondary septa have a doubled capillary layer separated by mesenchymal tissue. The acquisition of a mature air–blood interface, with a single capillary layer, occurs in the final stage of lung development, the stage of **microvascular maturation**. Microvascular maturation occurs after birth. The end-result is a reduction of the interstitium and maturation of the interalveolar wall. Further subdivision of alveolar septa results in continued increases in alveoli and alveolar surface area during a period of rapid postnatal growth. Airways increase in diameter and length through coordinated growth as overall lung volume and weight increase.

Movement of fetal lung fluid is important in directing normal lung development. Fetal respiration and spontaneous contraction of fetal conducting airways facilitate the movement of the fluid. Interestingly, the contraction of fetal airways will occur in lung explants without central neurologic control because of the phasic contraction of the airway smooth muscle. Neural innervation of the developing lung occurs early in development, arising from neural tissue migrating through the fetal mesenchyme. Studies in the fetal pig show that both developing nerves and ganglia are present within the fetal bronchial tree as early as the pseudoglandular stage of development. This cholinergic neural innervation coordinates the fetal airway contractions mentioned above.

The coordination of intrauterine and extrauterine lung development and growth is complex and influenced by both local tissue factors as well as influences originating beyond the developing lung. Local epithelial–mesenchymal interactions, outlined above, are necessary for directing the distal expansion of the lungs; indeed, the formation of the diverticula from the foregut endoderm, branching morphogenesis, and cell differentiation are specifically coordinated by the adjacent lung-specific mesenchyme. In each stage of lung development, a number of diffusible mediators and transcription factors direct organogenesis. Examples include the fibroblast growth factor family, transforming growth factor-β, and the sonic hedgehog-signaling pathway.

Congenital anomalies

Congenital anomalies of the lung are rare and may reflect abnormal development of the lung bud, pulmonary circulation, or both. Major malformations such as pulmonary agenesis are incompatible with life and are often accompanied by malformations in other organs.

- **Malformations of the lung bud** include pulmonary agenesis, hypoplasia, or duplication; atresia or abnormal positioning of bronchi that makes them susceptible to chronic infection, congenital lobar emphysema, bronchogenic cysts in the lung or mediastinum, congenital cystic adenomatoid malformation, epidermoid cysts, and pulmonary or cartilaginous hamartomas.
- **Vascular anomalies** include atresia of a branch of the pulmonary artery, anomalous pulmonary venous drainage, and pulmonary arteriovenous malformation.
- **Anomalies of both components** include hamartoma and accessory lung (bronchopulmonary sequestration); and the *hypogenetic, or scimitar, lung syndrome*, which is characterized by unilateral pulmonary hypoplasia, atresia or hypoplasia of the pulmonary and systemic arterial supply, and anomalous venous drainage into the vena cava.

Pulmonary hypoplasia *is defined as reduced lung weight, and hypoplastic lungs usually also have reduced numbers of alveoli*. In contrast, the airways generally develop normally. Pulmonary hypoplasia (Fig. 5.7) may accompany malformations in other organs. Its development is closely linked to the presence of lung liquid that is secreted by the pulmonary epithelium, fills the airspaces, and is required for growth of the lung mass. *Pulmonary hyperplasia* is the result of overdistension of the lung, resulting from tracheal obstruction or laryngeal paralysis. In contrast, pulmonary hypoplasia ensues if the lung volume is not maintained. Pulmonary hypoplasia is caused by conditions that compress the lung, including congenital diaphragmatic hernia,

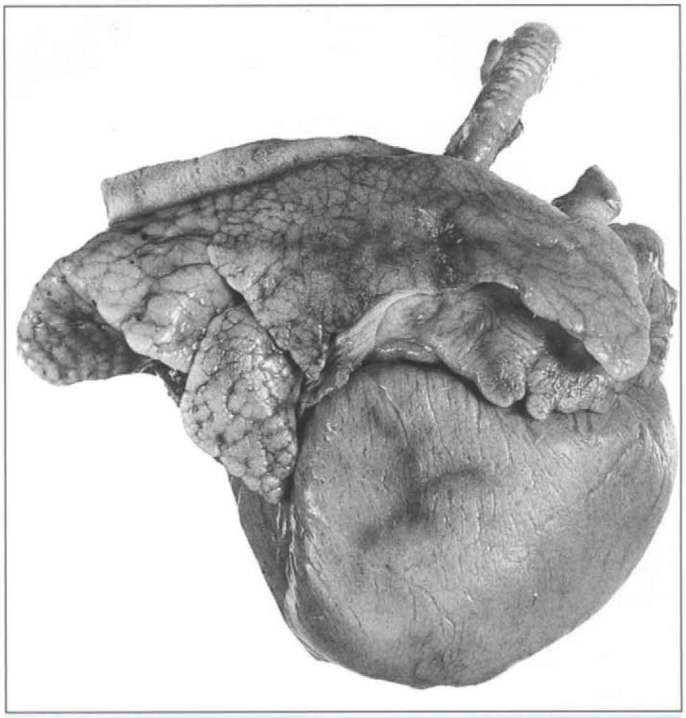

Figure 5.7 Hypoplastic lung in a calf.

intrathoracic masses, or pleural effusions; by oligohydramnios, in which the reduced uterine volume causes abnormal fetal positioning that compresses the chest and lungs; by impaired fetal breathing movements from abnormalities of the fetal nervous or musculoskeletal systems; by tracheal fistula; and perhaps by reduced fluid secretion as a result of fetal hypoxemia or high levels of epinephrine.

Adenomatoid malformation, also known as *bronchial hypoplasia or adenomatoid hamartoma*, is characterized by one or more intrapulmonary masses that are swollen, spongy or cystic, fluid- or air-filled, and lobulated. The masses are formed by adenoma-like proliferation of bronchioles that form cysts varying from microscopic to several centimeters in diameter, which are lined by pseudostratified columnar epithelium. The bronchi are hypoplastic and lack cartilage and smooth muscle in their walls. Alveoli may be normal, or airway obstruction may result in air trapping and enlargement of the alveoli (congenital lobar emphysema).

Pulmonary hamartomas *are tumor-like masses of pulmonary tissue within the lung.* They are often supplied by anomalous branches of the aorta and drained by pulmonary veins, but lack communication with the bronchi or with the pulmonary arteries. Histologically, the development of bronchi, bronchioles, alveoli, and blood vessels is variable; those formed by alveolar tissue without bronchioles have been termed microcystic hamartomas or polyalveolar lobe.

Accessory lungs *are masses of pulmonary tissue completely separated from the lung and are found in the pleural space, mediastinum, or abdominal cavity.* They may contain bronchi that connect to the upper alimentary system (congenital bronchopulmonary foregut malformation), are supplied by systemic but not pulmonary arteries, and have a pleural covering separate from the lung. The microscopic features include bronchial hypoplasia, dilation of bronchioles, and variable development of alveoli.

In **anomalous pulmonary venous drainage**, the pulmonary veins drain into the right rather than the left atrium. Completely (total) or partially anomalous forms differ in whether all of the pulmonary veins are abnormal or not.

Lung lobe torsion

Lung lobe torsion most often affects the right middle or left cranial lung lobe of dogs, presumably because of the narrow waist at the hilus. Deep-chested breeds – Afghan Hounds in particular – form the bulk of the cases. Other species and other lobes are occasionally affected. Predisposing causes are not apparent in most cases, but a minority of affected dogs have underlying causes such as neoplasia, pneumonia, or atelectasis of the affected lobe, pleural effusion, congenital dysplasia or hypoplasia of the bronchial cartilage, previous thoracic surgery, or pneumothorax. The clinical signs are variable and include respiratory distress, coughing, and hemoptysis. The affected lobe is twisted at the hilus and deeply congested. Pleural effusion is consistently present and may be transudative, chylous, exudative, or bloody. Histologic lesions vary from simple congestion in acute or partial torsions, to diffuse alveolar damage with fibrinous alveolar exudates, to pulmonary infarction with coagulative necrosis of all tissue elements.

Atelectasis

Atelectasis *refers to incomplete expansion of the lung.* Atelectatic lung is homogeneously dark-red and sunken relative to aerated lung, and the texture is fleshy or firmer and nonspongy relative to normal lung. Microscopically, simple atelectasis appears as slightly congested alveolar walls lying in close apposition with slit-like residual lumina having sharp angular ends (Fig. 5.8). Atelectasis is a common artifact in immersion-fixed lung tissue, so that each alveolar septum falsely appears to have two or more lines of erythrocyte-filled capillaries. Atelectatic alveoli often contain scant edema fluid and excess alveolar macrophages. The edema may result from hypoxic damage, hypoxic vasoconstriction, or reduced surfactant activity.

In **congenital atelectasis**, the lungs appear as in the fetus but are dark red-blue because of dilation of alveolar capillaries. They are of fleshy consistency and do not float. Alveoli are partially distended with fluid and epithelial cells are rounded. Sloughed epithelial cells (squames) from the oronasal regions and amniotic fluid are usually present in the alveolar fluid, possibly with bright yellow particles of meconium. Small numbers of "squames" can be present in the lungs of normal term fetuses but large numbers, especially if meconium is also present, indicate aspiration of amniotic fluid during the exaggerated respiratory movements of the asphyxiated fetus in utero. Patchy congenital atelectasis due to incomplete expansion is usually due to weak respiratory movements caused by asphyxia or damage to respiratory centers in the brainstem. In the neonatal period, it is often not possible to distinguish atelectasis of incomplete expansion and acquired atelectasis of briefly aerated lung.

Acquired atelectasis and **alveolar collapse** are used synonymously. **Obstructive atelectasis** *is caused by complete airway obstruction.*

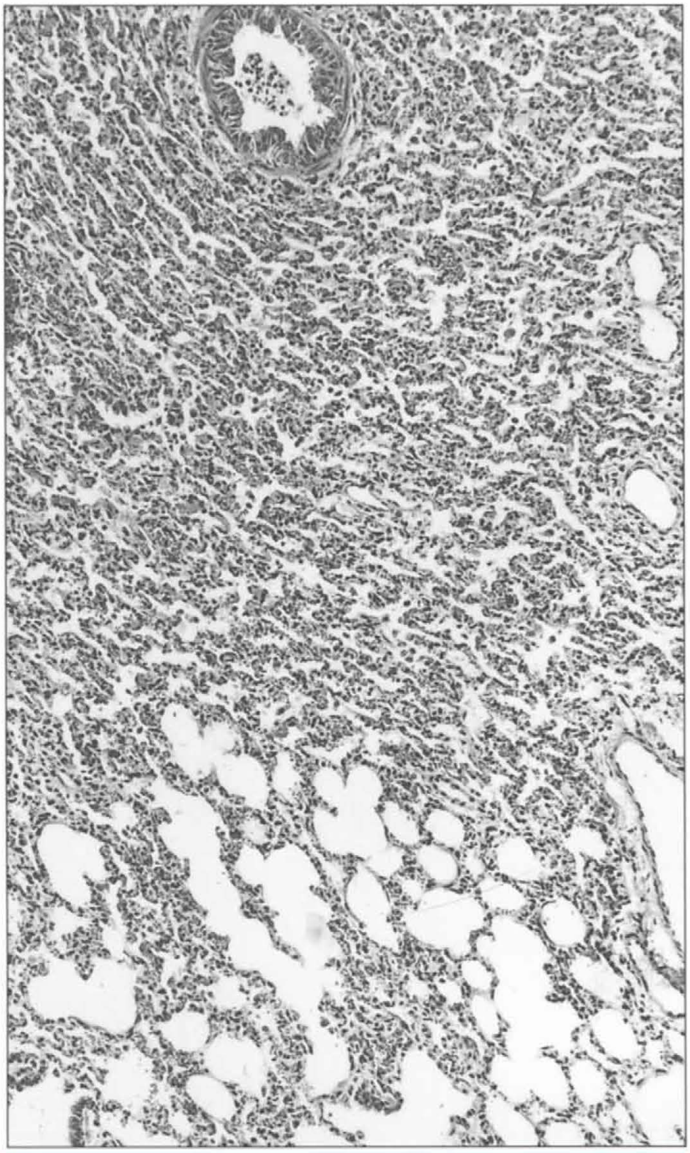

Figure 5.8 Atelectasis of the lung in a lamb.

Whether atelectasis follows obstruction depends on the size of airway obstructed and the degree of collateral ventilation. Complete blockage of lobar or segmental bronchi is necessary for atelectasis in the dog and cat where collateral ventilation is extensive. Blockage of small bronchi or even bronchioles can result in atelectasis in bovine lungs where there is insignificant collateral ventilation. Atelectasis is more likely to develop in dependent lung regions where alveoli are smallest and airways most easily compressed. Evidence of bronchial obstruction by exudate, parasites, aspirated foreign material, granulomas, or tumors can often be seen grossly, and the atelectatic lesions often follow a lobular pattern.

Compressive atelectasis *is caused by pleural or intrapulmonary space-occupying lesions.* Examples are hydrothorax, hemothorax, exudative pleuritis, and mediastinal and pulmonary tumors. In large animals, the atelectasis caused by pleural effusions often occurs below a sharply demarcated fluid line. Abdominal distension, as in severe ascites and ruminal tympany, may cause partial atelectasis, typically in the cranial regions where ventilatory movements are most easily compromised by intra-abdominal pressure. Large animals with prolonged recumbency, such as anesthesia, may develop atelectasis of the down side. The contributing factors are shallow amplitude of respiration causing impaired ventilation of dependent lung, gradual loss of surfactant activity, and pooling of secretions in the lower airways.

Massive atelectasis is mostly seen as a *sequel to pneumothorax.* What appears to be total atelectasis is seen in animals that die while breathing 80–100% oxygen during anesthesia or intensive care. Because of the speed with which the oxygen is resorbed into the tissues and the lack of nonabsorbable gas (especially nitrogen, as is present within atmospheric air), *the lungs are usually completely devoid of gas by the time they are examined after death.* Grossly, the entire lung field is markedly reduced in size; because of this, the heart will look especially prominent when the pluck is examined.

Pulmonary emphysema

Emphysema in its widest sense refers to tissue expansion by air or other gas. In the lung there are two major forms:

1. **Alveolar (vesicular) emphysema** refers to abnormal and permanent enlargement of alveoli, accompanied by destruction of their walls and an absence of obvious fibrosis. Emphysema thus differs from hyperinflation or overdistension of the alveoli, which is a reversible lesion.
2. **Interstitial emphysema** is the presence of air within interlobular, subpleural, and other major interstitial zones of the lung. *"Emphysema," unless otherwise qualified, should only be used for alveolar emphysema.*

Emphysematous lungs are grossly voluminous, pale, and puffy. When the lesion is diffuse, the lungs fill the thoracic cavity and may bear imprints of the ribs. The enlarged airspaces are often visible as small vesicles, and in severe cases coalescence of airspaces can produce large air-filled bullae. Emphysematous bullae occasionally rupture to cause fatal pneumothorax. Ruptured bullae are notoriously inconspicuous, and their detection is facilitated by submerging the lung in water or saline before inflating it with air, or by filling the trachea with saline to detect pleural leaks.

Enlargement and coalescence of airspaces are apparent histologically, and are most reliably assessed on lungs that have been infused with fixative to a volume approximating the in vivo state. Scanning electron microscopy, which dramatically reveals the moth-eaten appearance (Fig. 5.9), is best for visualization of early lesions. The emphysema may affect the terminal bronchioles and adjacent alveoli (*centrilobular or centriacinar emphysema*), or more uniformly involve the entire lobule (*panlobular or panacinar*). Less important forms are *paraseptal emphysema*, which affects distal alveoli bordering interlobular septa or pleura, and *irregular or paracicatricial emphysema*, which results from distortion of airspaces by adjacent contracted scar tissue.

Current knowledge of the **pathogenesis of emphysema** is based on investigations of the human disease and of animal models. Emphysema is an important condition in humans, where it frequently coexists with chronic obstructive pulmonary disease attributable to cigarette smoking and is the result of an imbalance between proteases and antiproteases. *Neutrophil-derived serine proteases – particularly elastase – and matrix metalloproteinases from a variety of sources are the likely culprits*, and their concentrations are enhanced by the neutrophil and macrophage activation induced by chronic bronchitis. Although

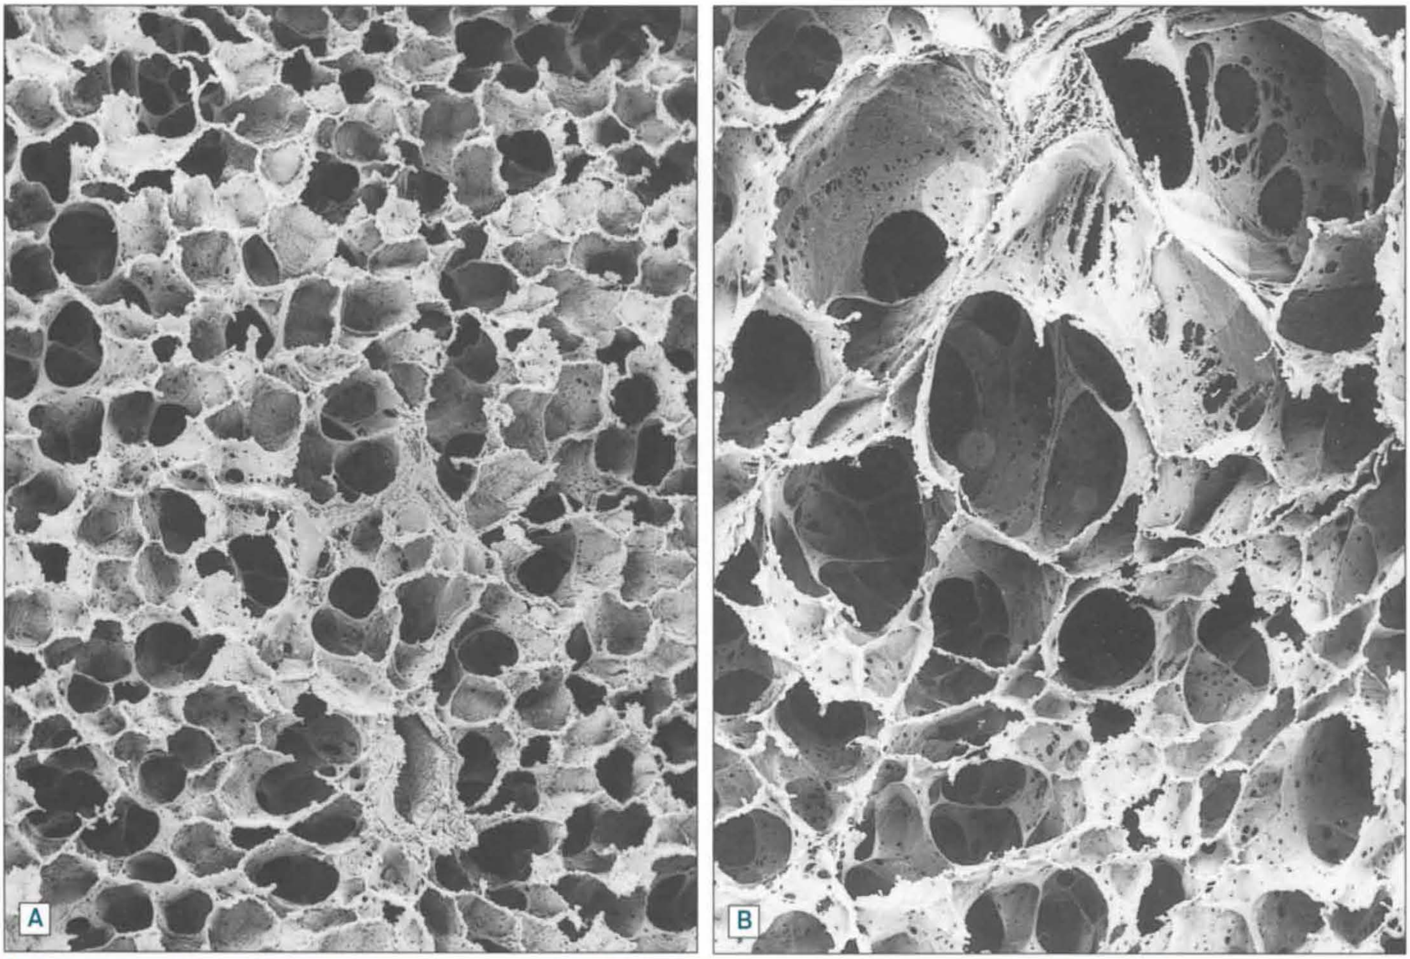

Figure 5.9 Scanning electron micrographs. **A. Normal** equine lung. **B. Emphysematous lung**. Note alveolar enlargement and alveolar wall destruction.

antiproteases – α_1-antitrypsin, secretory leukoprotease inhibitor, and tissue inhibitors of matrix metalloproteinases – protect normal lung from proteolytic damage, their function may be reduced by genetic deficiency or by oxidative stress from cigarette smoke and the resulting inflammation. Unchecked proteases degrade elastin and other matrix proteins in the interstitium, and the weakened alveolar septa are vulnerable to stress-induced failure with the tensions generated by each ventilatory cycle.

The emphysematous lung is dysfunctional. The loss of alveolar septa reduces the alveolar surface area; although the affected portion of lung may be larger than normal, gas exchange is reduced. Loss of elastic recoil caused by degradation of elastin further compromises lung function. These factors make hyperpnea necessary to maintain lung function, which may exacerbate the disease by placing additional ventilatory stresses on the damaged lung.

Emphysema is of much less clinical significance in animals. It occurs in horses with heaves. Lobar emphysema may be congenital (usually caused by hypoplasia of bronchial cartilage) or acquired (due to bronchial mucous plugs and lung lobe torsion). **Congenital lobar emphysema** is rare in dogs, and usually results from aplasia or hypoplasia of bronchial cartilage. The right middle or cranial lung lobes are greatly enlarged by alveolar and/or bullous emphysema, sometimes with bronchiectasis. Pneumomediastinum, subcutaneous edema, or pneumothorax may occur. Histologically, alveoli are expanded and the alveolar septa are thickened by fibrous tissue. Affected dogs typically have slowly progressive dyspnea and coughing, and surgical excision is usually curative. **Multifocal bullous emphysema** also occurs in dogs, and may have extensive alveolar hemorrhage with alveolar and interstitial fibrosis.

Interstitial emphysema is distinguished from alveolar emphysema by the presence of air in the connective tissues and lymphatics of the lung, including the interlobular septa, beneath the pleura, and around vessels and airways (Fig. 5.10). Positive-pressure ventilation with excessively high tidal volume is an occasional cause in all species. Interstitial emphysema without alveolar emphysema occurs frequently in cattle, presumably because of their well-developed interlobular septa and lack of collateral ventilation of the alveoli. It is an incidental finding in cattle at slaughter, and is common in recumbent ("downer") cows with periparturient paresis or toxic mastitis, where it may develop as cows forcibly exhale or grunt against a closed glottis. Thus, *the finding of interstitial emphysema in cattle does not necessarily imply primary lung disease.* Dramatic interstitial emphysema occurs in cattle with interstitial pneumonia caused by 3-methylindole toxicity, other toxicants, or pneumonia caused by *Bovine respiratory syncytial virus*. Interstitial emphysema in such cases may result from abnormally high intra-alveolar pressures caused by increased expiratory effort or bronchiolar obstruction, or perhaps from altered permeability or strength of the barrier

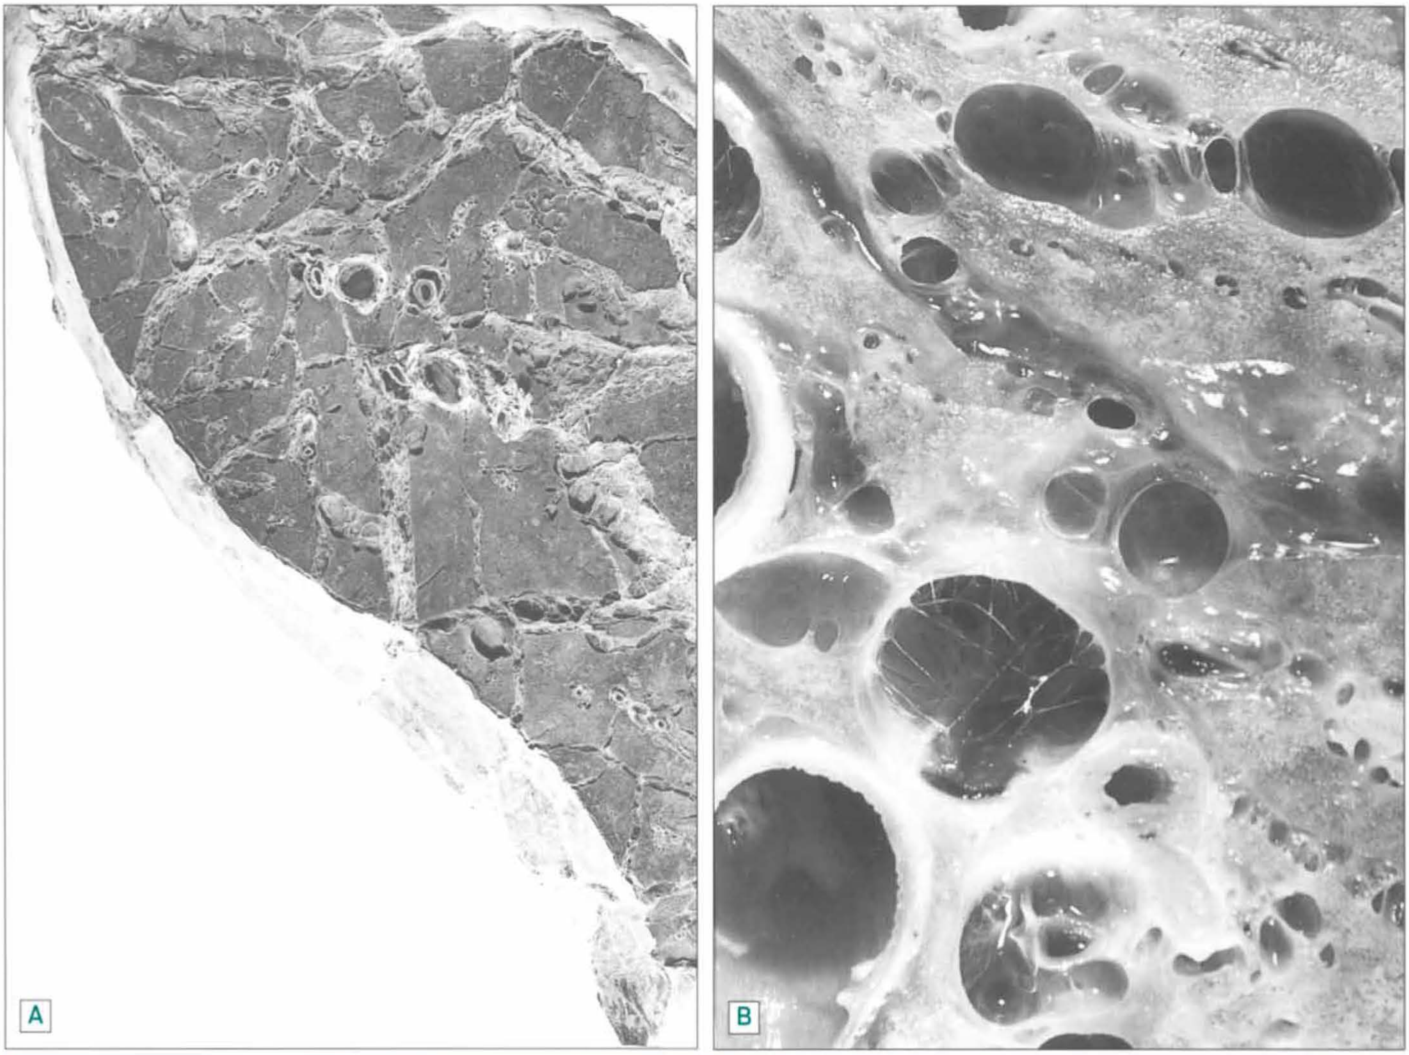

Figure 5.10 A, B. Interstitial emphysema in a calf, secondary to acute interstitial pneumonia. Note bubbles of air in interlobular septa.

between airspaces and interstitium. In animals surviving sufficient length of time with severe interstitial emphysema, the air can extend along lymphatics to the bronchial and mediastinal lymph nodes or along fascial planes of the mediastinum to beneath the skin of the back.

Overdistension of alveoli is a commonly encountered finding at necropsy, although this does not qualify as emphysema unless there is destruction of alveolar septa. These lesions mostly result from airway obstruction or spasm, with air trapping in alveoli and failure of the lung to deflate normally. Distended alveoli can be found at necropsy in the apices and along the sharp ventral border of the lungs of dogs, cats, and horses (Fig. 5.11), and along the margin of a consolidated lung.

Circulatory disturbances of the lung

Given the fact that all blood must pass through the lungs, and that perfusion is of such critical importance to pulmonary gas exchange, it is not surprising that the lung is a common target for a variety of circulatory disturbances. Active **hyperemia** is part of the acute inflammatory response and is a feature of acute pulmonary injury

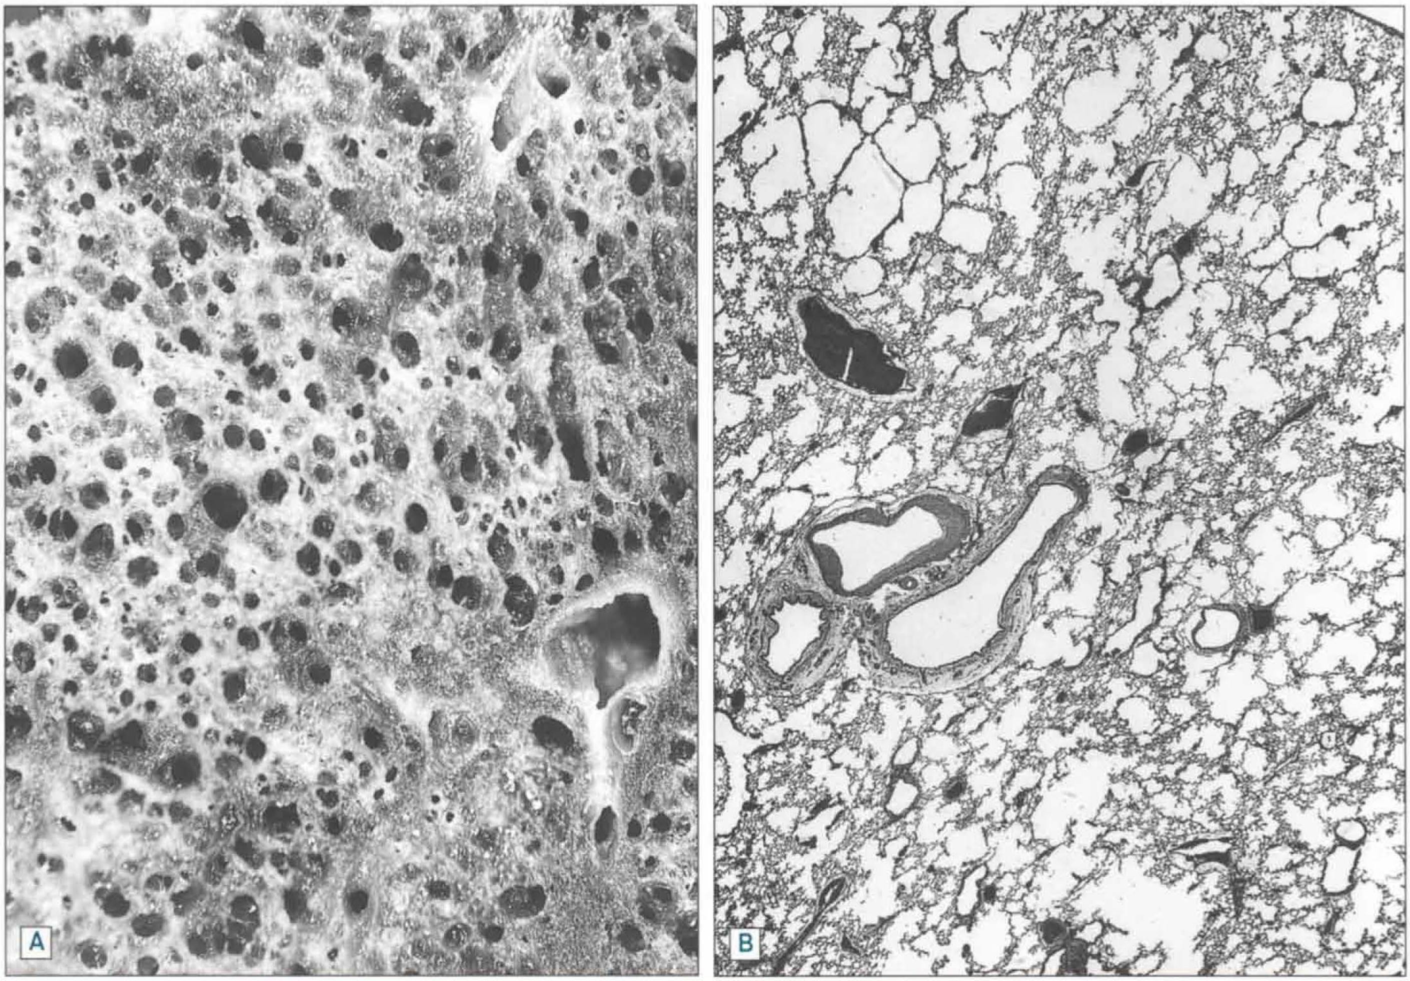

Figure 5.11 Emphysema in the lung of a dog. **A.** Subgross. **B.** Histology.

of many types. Pulmonary **congestion** is most commonly caused by left heart failure and inflammation. However, since hypostatic or diffuse pulmonary congestion is such a common incidental finding at necropsy, it should be accorded little diagnostic significance unless accompanied by edema or firmness of the tissue. *The color of lung tissue is often deceptive; increased texture is a more reliable indicator of disease.*

Histologically, the presence of *hemosiderin-laden macrophages* (**"heart failure" cells)**, which are best detected with Perls's stain for iron, or *erythrophagocytosis* are useful indicators of chronic congestive heart failure or of chronic pulmonary hemorrhage (Fig. 5.12), but their absence does not rule out acute heart failure. Additional findings in chronic heart failure include: hypertrophy of the tunica media of small pulmonary vessels due to pulmonary hypertension, vascular adventitial edema, alveolar interstitial fibrosis that often forms concentric rings around small blood vessels, or rarely diffuse alveolar damage with protein-rich edema.

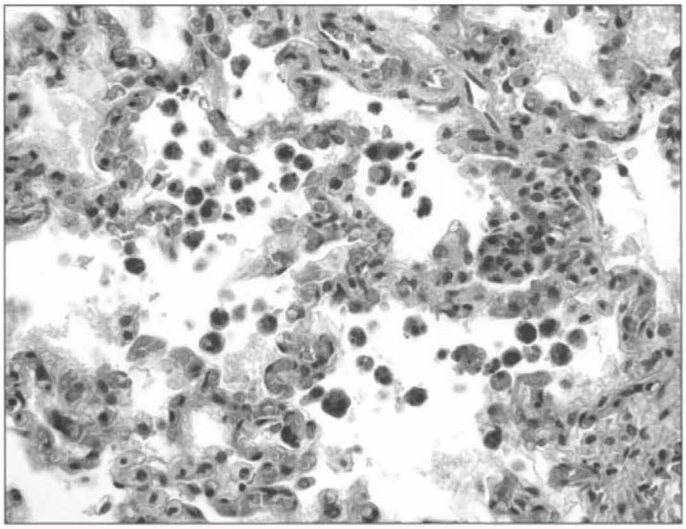

Figure 5.12 Chronic pulmonary congestion due to left heart failure in a dog. Alveoli contain increased numbers of macrophages, with hemosiderin in their cytoplasm (**heart failure cells**).

Pulmonary edema

Pulmonary edema is a frequent complication of many diseases and is therefore one of the most commonly encountered pulmonary abnormalities. If severe, pulmonary edema has a catastrophic effect on lung function by reducing pulmonary compliance, blocking ventilation of the alveoli, obstructing gas exchange across the alveolar septa, and reducing the surface area of the air–liquid interface in the alveoli. In addition, proteins present in the edema fluid interfere with surfactant function, further reducing compliance and contributing to pulmonary dysfunction. Edema of the lung is, in many respects, similar to edema of other tissues, and is governed by the permeability of the vascular wall and by Starling forces – the balance of hydrostatic and osmotic pressures between the intravascular and interstitial compartments. Distinctive aspects in the lung include the importance of type I pneumocytes as barriers to fluid movement, the role of type II pneumocytes and Clara cells in active transport of water from the alveolus, the effect of surface tension on fluid movement, and fluid exchanges between the alveolar and bronchiolar airspaces and the pulmonary interstitium. It is useful to consider separately the means by which the alveoli are kept dry, and the ways in which excessive fluid is drained from the alveoli.

The alveoli are kept dry by several related mechanisms. First, the tight junctions between alveolar type I pneumocytes are relatively impermeable to fluid and proteins, and confer 92% of the barrier to albumin flux across the blood–air barrier. In contrast, the capillary endothelium is a less effective barrier to movement of fluid and small molecules. Complementing this barrier function are Na^+-K^+-ATPase channels (sodium pumps) on the basolateral surface and passive sodium channels on the apical surface of type II pneumocytes. In addition, the surface tension in airways may draw fluid out of alveoli into distal bronchioles, where fluid resorption by Clara cells is driven by a similar bevy of ion channels. The net effect is actively to transport sodium out of the distal airspaces into the interstitium and to force water along the same pathway by osmosis, thus resulting in a slow but steady flow of liquid from the alveoli to the interstitium. Drainage of interstitial fluid from the interstitium to the lymphatics is facilitated by negative pressures in the lymphatic vessels. The rate at which fluid is cleared from the distal airspaces varies by species, being slowest in dogs, intermediate in sheep, and fastest in rodents and rabbits.

Active transport of alveolar fluid is enhanced by catecholamines (through β_2-adrenergic receptors) and glucocorticoids; this is probably important in clearance of fluid from the lungs of neonates, and is also used to advantage in the therapy of pulmonary edema. Conversely, these active transport mechanisms are impaired by hypoxia (as a result of high altitude), reactive oxygen and nitrogen species (as a result of inflammation), halogenated anesthetics, oleic acid, and perhaps lidocaine, suggesting that these factors – in addition to damage to type II pneumocytes or Clara cells – are additional contributors to development of pulmonary edema.

Causes of pulmonary edema *include elevated hydrostatic pressure, increased permeability of the alveolar wall, and several miscellaneous causes* (Table 5.2). *Elevated hydrostatic pressure* is commonly caused by elevated left atrial pressure in left-sided heart failure (*cardiogenic edema*), or less often from hypervolemia due to excessive fluid administration. In these situations, fluid loss into the alveoli may occur from either the alveolar septa or the peribronchiolar or perivascular connective tissue.

Table 5.2 Causes of, and contributors to, pulmonary edema

Increased venous hydrostatic pressure
- Left heart failure
- Increased blood volume
- Pulmonary venous occlusion

Increased permeability of the alveolar barrier
- Pneumonia
- Diffuse alveolar damage
- Endotoxemia/septicemia

Impairment of active transport of fluid from distal airspaces
- Damage to type II pneumocytes or Clara cells
- Hypoxia (high altitude)
- Oxygen and nitrogen radicals (increased by inflammation)
- Halogenated anesthetics
- Possibly lidocaine
- Malnutrition
- High alveolar protein content

Reduced oncotic pressure
- Hypoproteinemia (uncommon)

Lymphatic obstruction
- Neoplastic emboli in lymphatics or lymph nodes (rare)

Neurogenic pulmonary edema, secondary to brain trauma

Acute upper-airway obstruction
- Strangulation, hanging

Hypoglycemia

Increased permeability of the blood–alveolar barrier (noncardiogenic edema) is the second major mechanism of pulmonary edema, and is typified by a more rapid onset of high-protein edema. This form of edema develops in diffuse alveolar damage (discussed below in the section on interstitial and bronchointerstitial pneumonia), endotoxemia, anaphylaxis, and within the lesions of bacterial pneumonia. In the case of diffuse alveolar damage, edema may result from more minor injury than is needed to cause formation of hyaline membranes. Fumonisin toxicity in swine and *African horsesickness virus* and *Hendra virus* infection in horses are specific causes of spectacular pulmonary edema.

Several *additional causes of pulmonary edema* are uncommonly encountered in veterinary pathology. Hypoproteinemia from glomerular, intestinal, or liver disease may cause pulmonary edema, but edema in other tissues is usually more prominent. Obstruction of lymphatic vessels or lymph nodes by neoplastic cells is a rare cause of pulmonary edema. Increased intracranial pressure from trauma to the central nervous system causes "*neurogenic pulmonary edema*" by obscure means, probably related to both catecholamine-induced pulmonary hypertension and increased vascular permeability. Hypoxia due to high altitude induces pulmonary edema, an effect of both impaired alveolar active sodium transport and pulmonary hypertension. Acute upper-airway obstruction from strangulation or hanging causes pulmonary edema, probably from negative intrathoracic pressures or by similar mechanisms to neurogenic edema.

On **gross examination**, edematous lungs are wet, heavy, and do not completely collapse when the thorax is opened, and fluid oozes from the cut surface. The ratio of lung weight to body weight (or to heart weight in ruminants) is a useful measure of pulmonary edema. Edema is prominent in the pleura and the pulmonary interstitium, and may form shallow pools in the hilus of the lung or the mediastinum. In cattle and swine, the interlobular septa are obviously distended by clear fluid (Fig. 5.13). Foam often fills the trachea and bronchi and flows from the nostrils, although this is a common incidental finding in horses and sheep dying of a variety of causes. The thoracic cavity may contain excess fluid.

Histologically, edema fluid is acidophilic, homogeneous, or faintly granular material filling alveoli, except for occasional discrete holes that represent trapped air bubbles. The same material is often present in interstitial tissue and lymphatics around vessels and airways and in interlobular septa and subpleural zones in those species where these are well developed. Chronic edema is accompanied by a diffuse increase in the number of alveolar macrophages, and in heart failure these may contain phagocytosed erythrocytes or hemosiderin.

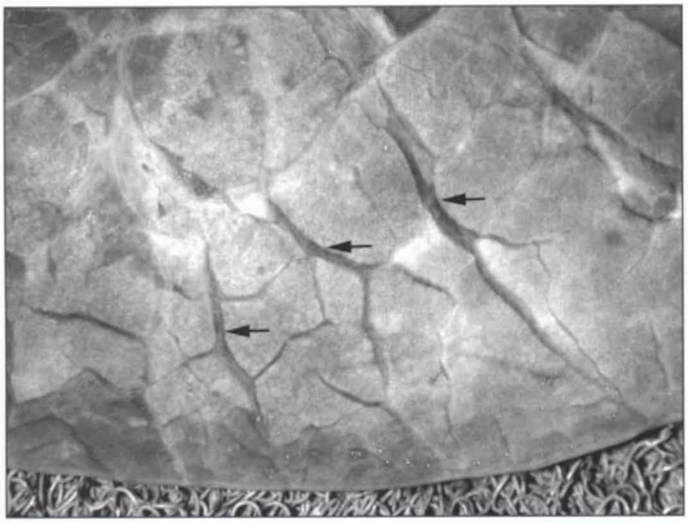

Figure 5.13 Pulmonary edema secondary to heart failure in a pig. Fluid in interlobular septa (arrows) accentuates the lobular pattern.

Table 5.3 Causes of pulmonary thrombosis and embolism

Pulmonary thrombosis

- Glomerulonephritis and glomerular amyloidosis
- Immune-mediated hemolytic anemia
- Hyperadrenocorticism or corticosteroid therapy
- *Dirofilaria immitis, Angiostrongylus vasorum*
- Disseminated intravascular coagulation: sepsis, neoplasia, pancreatitis, peritonitis, burns, massive trauma, bacterial pneumonia
- Heart disease
- Atherosclerosis, pulmonary vasculitis

Sources of emboli

- Valvular endocarditis
- Jugular thrombosis associated with catheterization
- Hepatic abscess with thrombosis of the hepatic artery (cattle)
- Thrombosis of uterine and pelvic veins (cattle)
- Thrombi in deep veins of the legs, in recumbent (downer) cows

Histopathology is neither sensitive nor specific for detection of pulmonary edema: the protein in edema fluid can leach from sections during processing and be quite inconspicuous; conversely, pink material often fills the alveoli in autolysed carcasses or those euthanized with barbiturates. Therefore, gross examination is usually a more accurate indicator of the presence and severity of edema.

Thrombosis, embolism, and infarction

Pulmonary thrombosis causes acute dyspnea, with open-mouth breathing and air hunger in some cases, and is often rapidly progressive and fatal. The underlying causes include Virchow's triad of increased coagulability of the blood, damage to endothelial cells or the vessel wall, or stagnation of venous blood flow (see Vol. 3, Cardiovascular system). The major causes are listed in Table 5.3. Thrombi that develop in the lung are usually microscopic, whereas grossly visible thrombi generally arise by embolism from a distant site. Microvascular thrombi may dissolve rapidly after death if the fibrinolytic system has been activated, as is expected in disseminated intravascular coagulation.

The lungs are strategically situated to catch **emboli** carried in venous blood, and the most common sources are listed in Table 5.3. *The significance and sequelae of pulmonary thrombosis and embolism depend on the extent of vascular obstruction, the rapidity of its development, and the presence of sepsis.* Minor thrombi or emboli may be inconsequential and not cause infarction, because the lung is supplied by both pulmonary and bronchial arteries and has extensive collateral channels. Pleural effusion is often noted, even when infarcts are absent. Emboli may cause alveolar hemorrhage without apparent necrosis of the lung tissue. Ischemia and infarction are more likely if thrombosis or embolism occurs at the periphery of the lung (rather than affecting the large central vessels), or if the bronchial or systemic circulation is also impaired, for example by concurrent heart failure. When they occur, infarcts form wedge-shaped, raised, firm, red-blue, hemorrhagic lesions at the periphery of the lung lobes, and fibrinous exudate may give the pleural surface a dull granular appearance. Emboli that obstruct large branches of the pulmonary artery may cause sudden death due to cor pulmonale and acute right heart failure; right ventricular dilation may or may not be present. Large thrombi are best detected by dissection of the major branches of the pulmonary arteries, as these functionally catastrophic lesions may be easily missed if only cross-sections of lung are examined.

Septic embolism with massive numbers of bacteria, as occurs when an abscess ruptures into a vein, induces acute pulmonary edema or interstitial pneumonia. Septic emboli that are less fulminant result in multifocal infarcts, abscesses, or chronic suppurative embolic pneumonia.

Fat embolism is rarely important in animals. The fat can originate from bone marrow at sites of fracture and from severe hepatic lipidosis when the hepatocytes rupture. The emboli lodge in alveolar capillaries and produce sausage-shaped distensions that are empty in routine paraffin sections. **Megakaryocytes** are frequently found in pulmonary capillaries, particularly in dogs. A small number of megakaryocytes derived from bone marrow are present in circulating blood and lodge in the lungs, where they continue to produce platelets. This is a normal occurrence, but may be accentuated when there is compensatory extramedullary hematopoiesis in spleen and liver. **Emboli of brain tissue** may be encountered in cattle when captive bolt guns are used with excessive vigor and induce marked increases in intracranial pressures.

Pulmonary hemorrhage

Pulmonary hemorrhages vary from petechiation to massive filling of large regions by blood. It is usually possible to distinguish hemorrhage from congestion based on the gross appearance: *hemorrhages are usually multifocal or patchy, whereas congestion is diffuse within the affected region of the lung*. Pulmonary hemorrhages occur frequently in the hemorrhagic diatheses, septicemias, disseminated intravascular coagulation, and severe congestion. They can also be caused by vasculitis, infarction, ruptured aneurysms, trauma, hemangiosarcoma, tumors that have undergone necrosis, or drug reactions. Aspiration of blood is frequent at slaughter, and has a characteristic pattern of multiple, small, bright-red foci with feathery or indistinct borders.

Abscesses *that erode large blood vessels may cause massive hemorrhage*. Affected animals may develop hemoptysis or be found dead with blood flowing from the nares, and expectorated blood is often detected in the stomach. They are most common in cattle in which liver abscesses erode the hepatic vein to cause pulmonary thromboembolism and lung abscesses.

Exercise-induced pulmonary hemorrhage *is common in racing horses*. Pulmonary hemorrhage can be detected in many racing horses following strenuous exertion, although epistaxis – blood at the nostrils – is apparent in only 1–10%. Examination of Perls' Prussian blue-stained preparations of alveolar macrophages reveals iron/hemosiderin in nearly all racing horses, suggesting that mild hemorrhage occurs in most or all racing horses during strenuous exercise. The frequency of exercise-induced hemorrhage increases with age and severity of exertion. The hemorrhage is probably the result of the marked elevations in pulmonary arterial and capillary pressures that occur during strenuous exercise, leading to stress-induced failure of capillary integrity. Bronchopulmonary anastomoses or uneven ventilation of neighboring lung lobules may further promote hemorrhage, but definitive confirmation of their importance is lacking.

The hemorrhage occurs in the dorsocaudal portions of both caudal lobes, and appears as red, brown, or gray discoloration of the lung or as patchy, blue-brown subpleural foci. Histologically, the main features in affected regions are hemosiderin-laden macrophages in airspaces and in the interstitium, alveolar septal fibrosis, and mild bronchiolitis and bronchiolar fibrosis. These changes are the result of intra-alveolar hemorrhage rather than the cause, and can be created by intrapulmonary injection of autologous blood. Increased prominence of bronchial arteries and thickening of the tunica media of interstitial arterioles are also noted in some cases. Massive pulmonary hemorrhage is on occasion the only detectable lesion in horses that die during exercise; hemosiderin-laden alveolar macrophages in such cases are an indicator of previous episodes of sublethal pulmonary hemorrhage.

Table 5.4 Causes of pulmonary arterial hypertension

Idiopathic (primary) pulmonary arterial hypertension

Left-to-right shunts
- Ventricular septal defect
- Patent ductus arteriosus

Increased resistance to blood flow through the lungs
- Left-sided heart failure causing pulmonary venous hypertension: mitral insufficiency or stenosis, subaortic stenosis, cardiomyopathy
- Hypoxic vasoconstriction of pulmonary arterioles: high altitude (brisket disease), bronchiolitis obliterans, chronic bronchitis or bronchiolitis (equine heaves)
- Pulmonary thromboemboli (including *Dirofilaria immitis*)
- Pulmonary arterial disease: pulmonary vasculitis, arteriosclerosis
- Chronic interstitial pneumonia with fibrosis and occlusion of pulmonary vessels

Pulmonary vasculitis, pulmonary hypertension

Pulmonary vasculitis is uncommon in domestic animals. *Septic pulmonary vasculitis* is caused by septicemia or showering of the lung with bacterial emboli, and results in numerous necrotic neutrophils in vessel walls and often thrombi occluding the lumen. Other infectious causes include *Feline infectious peritonitis virus*; *Dirofilaria immitis* in dogs; acute *Bovine viral diarrhea virus* infection, malignant catarrhal fever, *Histophilus somni* and *Aspergillus* sp. in cattle; purpura hemorrhagica, *Equine arteritis virus*, *Equid herpesvirus 1*, *African horse sickness virus*, and *Hendra virus* in horses; *Porcine reproductive and respiratory syndrome virus* (PRRSV), *Porcine circovirus* type 2, and *Nipah virus* in swine. Idiopathic suppurative or nonsuppurative vasculitis is occasionally encountered but poorly documented in dogs, and may result from immune-complex deposition or other immune-mediated vascular injury.

Pulmonary arterial hypertension is diagnosed by direct measurement of pressures in the live animal, but histologic lesions are highly suggestive. The causes of pulmonary arterial hypertension are listed in Table 5.4. Cardiac or vascular anomalies that cause *shunting of blood* from the high-pressure systemic circulation into the low-pressure pulmonary arteries induce pulmonary hypertension, which may eventually increase pulmonary vascular resistance to the extent that the flow reverses from right to left. *Left-sided congestive heart failure* provokes left atrial and pulmonary venous hypertension, which may progress to pulmonary arterial hypertension. Finally, *hypoxic pulmonary vasoconstriction* (constriction of the arterioles supplying alveoli experiencing low oxygen tension) or *thromboembolism* of the pulmonary vessels will increase resistance and induce hypertension. Other causes include sporadic primary pulmonary hypertension in humans, familial forms caused by mutations in the

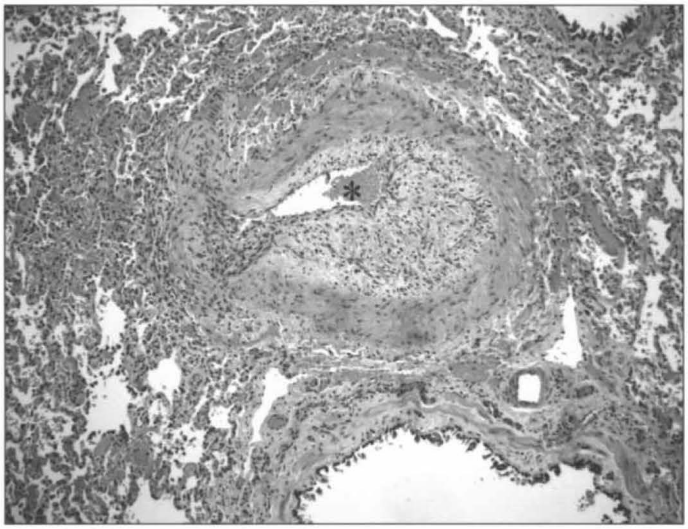

Figure 5.14 Pulmonary hypertension secondary to embolism in a dog. Pulmonary artery with thickening of the tunica intima and media, and a small lumen (asterisk).

gene encoding bone morphogenetic protein receptor 2, monocrotaline (a pyrrolizidine alkaloid in the seeds of *Crotalaria spectabilis*) toxicity, and adverse drug reaction. There is marked individual variation in severity of pulmonary hypertension in animals with known inciting causes, and genetic influences and perhaps other factors are important determinants of the course of disease. **Pulmonary venous hypertension** is expected in congestive left-sided heart failure, and is an important cause of pulmonary edema.

Acute pulmonary arterial hypertension causes endothelial degeneration, fibrinoid necrosis, and vasculitis. This lesion is reported during clinical crises in animals with patent ductus arteriosus, implying that it either causes or results from acute exacerbations of pulmonary hypertension. *Chronic remodeling of the pulmonary arterioles is a more common manifestation*, with thickening of the tunica intima by endothelial cell proliferation and fibrosis, hypertrophy of the tunica media, and more variable fibrosis or edema of the adventitia (Fig. 5.14). Small arterioles of the caliber that normally have a thin tunica muscularis may become muscularized. A *spectrum of morphologic variants* are described in human cases: concentric, eccentric, or obliterative intimal proliferation; thrombosis and recanalization of the lumen; and plexiform lesions. The latter consist of a web-like plexus of vascular lumens, each surrounded by concentric rings of endothelial cells and matrix, which extends through the vessel wall, and is thought to represent chronic attempts to repair pressure-induced aneurysms. In cattle, smooth-muscle hyperplasia may also be noted around bronchioles and in alveolar septa. These lesions are to be differentiated from the common finding of medial hypertrophy of medium-sized pulmonary arteries in cats, which is not associated with either clinical disease or pulmonary hypertension.

Vasoconstriction of pulmonary arterioles in cases of pulmonary hypertension is associated with increased levels of the vasoconstrictors thromboxane A_2 and endothelin-1, and reduced levels of the vasodilators prostacyclin and nitric oxide. Vascular endothelial growth factor and angiopoietin-1 are thought to mediate the remodeling of arterioles that result in the histologically apparent lesions in cases of pulmonary hypertension.

Pulmonary neoplasia

Primary pulmonary tumors are encountered most often in dogs and cats, and are rare in other species. Epithelial neoplasms are the most common category of neoplasms encountered in lung specimens. Because the vascular bed of the lung is a frequent site for metastatic neoplasms, it is essential to differentiate nonpulmonary metastases from intrapulmonary metastasis from primary lung neoplasms. Distinguishing between these two processes is particularly challenging when dealing with widespread epithelial neoplastic disease in the lung. The histologic features should be evaluated in light of the gross pathology findings. *Features supporting the diagnosis of a primary lung neoplasm include the presence of a single large mass along with any smaller metastases, and histologic demonstration of ciliated cells or a bronchioloalveolar pattern.* Since pulmonary carcinomas often form intrapulmonary metastases, the presence of tumor emboli within vessels is not helpful in distinguishing primary from metastatic tumors. In dogs, immunohistochemical detection of thyroid transcription factor-1 appears to be useful for distinguishing pulmonary or thyroid carcinomas from other tumors that have metastasized to the lung.

Because malignant lung tumors are often widespread within the lung at the time of diagnosis, it is often difficult to identify a specific site of origin. As a rule, hilar or central neoplasms are more likely of bronchial origin, while peripheral tumors are more likely to have arisen from distal bronchiolar or alveolar epithelium. Further confounding attempts to categorize lung carcinomas neatly are the variety of morphologic and immunohistochemical characteristics found within regions of some lung neoplasms. For example, adenocarcinomas with a predominantly bronchioloalveolar pattern of differentiation may also contain areas of papillary or tubular arrangement of the cells. Similarly, squamous cell carcinoma and adenosquamous carcinoma reflect a squamous pattern of differentiation, likely from foci of previous squamous metaplasia within airways, and do not imply an origin from squamous epithelium. With this in mind, the nomenclature of the neoplasms discussed below is based upon, and reflects, the predominant cellular phenotype or pattern of differentiation (Table 5.5).

Papillary adenomas are located in the bronchi or in the lung parenchyma, and are characterized by a papillary pattern of growth of well-differentiated epithelial cells that contain mucus in the cytoplasm. These are uncommon neoplasms that are described in cattle

Table 5.5 Classification of epithelial lung tumors in domestic mammals

Benign epithelial lung tumors

- Papilloma
- Adenoma: papillary or bronchioloalveolar patterns

Malignant epithelial lung tumors

- Bronchial gland carcinoma
- Squamous cell carcinoma
- Adenocarcinoma: papillary, acinar, solid, or mixed patterns; or bronchioloalveolar carcinoma
- Adenosquamous carcinoma
- Large-cell carcinoma
- Small-cell carcinoma
- Neuroendocrine tumor
- Pulmonary blastoma
- Combined carcinoma
- Carcinosarcoma

Based on Dungworth DL, et al. Histological Classification of Tumors of the Respiratory System of Domestic Animals. 2nd series. vol. VI. Washington, DC: Armed Forces Institute of Pathology. 1999.

and cats. **Bronchioloalveolar adenoma** is a relatively common incidental finding in the lungs of older dogs; reports in other species are infrequent. Grossly, these neoplasms are usually identified within the subpleural parenchyma as well-demarcated pale moderately firm masses. On cut section the surface may appear multicystic. Histologically, these cystic spaces correspond to alveolus-like structures lined by well-differentiated cuboidal or columnar epithelial cells that show no anisokaryosis and rare mitotic figures. The term bronchioloalveolar implies that the neoplastic cells differentiate to resemble Clara cells or type II pneumocytes and the alveolar architecture is retained, and implies an origin in the periphery of the lung rather than the bronchi. In some cases, epithelial cells form papillary protrusions that resemble papillary adenoma, but mucus production is not expected.

Pulmonary carcinomas *are the most common pulmonary neoplasms in dogs, cats, and cows*, and include two major groups: adenocarcinomas and bronchioloalveolar carcinomas. Adenocarcinomas may be subdivided into four major patterns: papillary, acinar, solid, and mixed. For practical purposes, only the papillary and acinar forms are commonly seen; purely solid carcinomas of the lung are rare and will not be discussed here. Bronchioloalveolar carcinomas are considered as a separate entity subsequently.

Dogs with pulmonary papillary/acinar adenocarcinoma typically exhibit coughing, dyspnea, or lethargy. The location in dogs is often peripheral rather than hilar, with no obvious origin from the bronchi. Thus, the term bronchogenic adenocarcinoma is not favored for these neoplasms. Thus, the term bronchogenic adenocarcinoma is not favored for these neoplasms. Adenocarcinomas arising from bronchi have a growth pattern similar to the papillary and acinar adenocarcinomas, and are difficult to distinguish unless there is clear association with the large conducting airways. Papillary/acinar adenocarcinomas form an irregularly shaped, usually poorly demarcated mass that is most often located in the caudal lung. Intrapulmonary metastases are common, and may be grossly apparent, although numerous smaller metastases and neoplastic emboli are often detected histologically. The angular neoplastic epithelial cells form papillae or acini, or, rarely, solid sheets, and extensive areas of necrosis are frequent. Mucus production is inconsistently demonstrated by PAS staining. Alveoli at the periphery of the tumor often contain neoplastic cells and/or increased numbers of macrophages. Indicators of a poor prognosis include clinical signs of respiratory disease and involvement of regional lymph nodes; other features that are of more limited prognostic significance are the identification of histologic patterns other than papillary, higher histologic grades, and multiple tumors. *Paraneoplastic syndromes* associated with pulmonary adenocarcinomas include hypertrophic osteopathy, hypercalcemia, fever, and secretion of adrenocorticotropic hormone.

Pulmonary adenocarcinoma is a relatively common neoplasm of older **cats**. The tumors may be single, multiple, or lobar. Affected cats may develop progressive dyspnea and coughing due to expansion of the tumor, intrapulmonary metastasis, or pleural invasion and implantation causing pleural effusion. However, many affected cats exhibit no evidence of respiratory disease, and the clinical signs result from metastasis to other viscera, brain, muscle, eye, bone, or skin. *A peculiar feature of this tumor is the propensity to cause lameness by metastasizing to the digits*, especially to the dermis of the skin on the dorsum of P3 and beneath the footpad epidermis. Even highly malignant feline pulmonary adenocarcinomas may appear histologically well differentiated, and well-formed ciliated neoplastic cells are occasionally discovered on careful inspection of the primary tumor or the metastases. Occasionally, the epithelial metaplasia associated with *feline idiopathic pulmonary fibrosis* (IPF) is mistaken for an adenocarcinoma or bronchioloalveolar carcinoma. Unlike true epithelial neoplasms, which have features consistent with their clonal origin, feline IPF is a heterogeneous lesion with evidence of smooth-muscle proliferation, fibrosis, and honeycomb lung formation. Conversely, cats with feline IPF can have coincident primary lung carcinomas, so it is important for the pathologist to inspect the pulmonary parenchyma away from the lung neoplasm to identify changes typical of feline IPF.

Bronchioloalveolar carcinoma is less common in dogs and cats than papillary/acinar adenocarcinoma. *This pattern is characteristic of jaagsiekte* (ovine pulmonary adenomatosis/carcinomatosis), the retroviral lung tumor discussed below in the section on Infectious respiratory diseases of sheep and goats. In dogs, they form subpleural masses, which by definition are formed by alveolar structures lined by cuboidal or columnar epithelium (Fig. 5.15). Mucus secretion is not expected, but some neoplasms have accumulations of eosinophilic secretion within the lumen of the tumor. The cell of origin is assumed to be the terminal bronchiolar nonciliated (Clara) cell or type II pneumocytes. Neoplastic cells with Clara cell-like differentiation contain Clara cell secretory protein-10, detectable by immunohistochemistry, and dense-core secretory granules (the storage site of CC-10) are detectable using electron microscopy. Cells that differentiate to type II pneumocytes express surfactant protein C and may have surface microvilli and lamellar bodies, both features of type II pneumocytes but not Clara cells. Some bronchioloalveolar carcinomas may have areas with a papillary growth pattern; this finding may blur the distinction between this tumor and pulmonary adenocarcinoma. This malignancy is differentiated from bronchioloalveolar adenoma by infiltrative growth extending beyond the alveoli immediately adjacent to the tumor, variable forms of differentiation within the tumor, cellular atypia, and presence of mitotic figures. The behavior in cats is similar to that described for other forms of pulmonary adenocarcinoma.

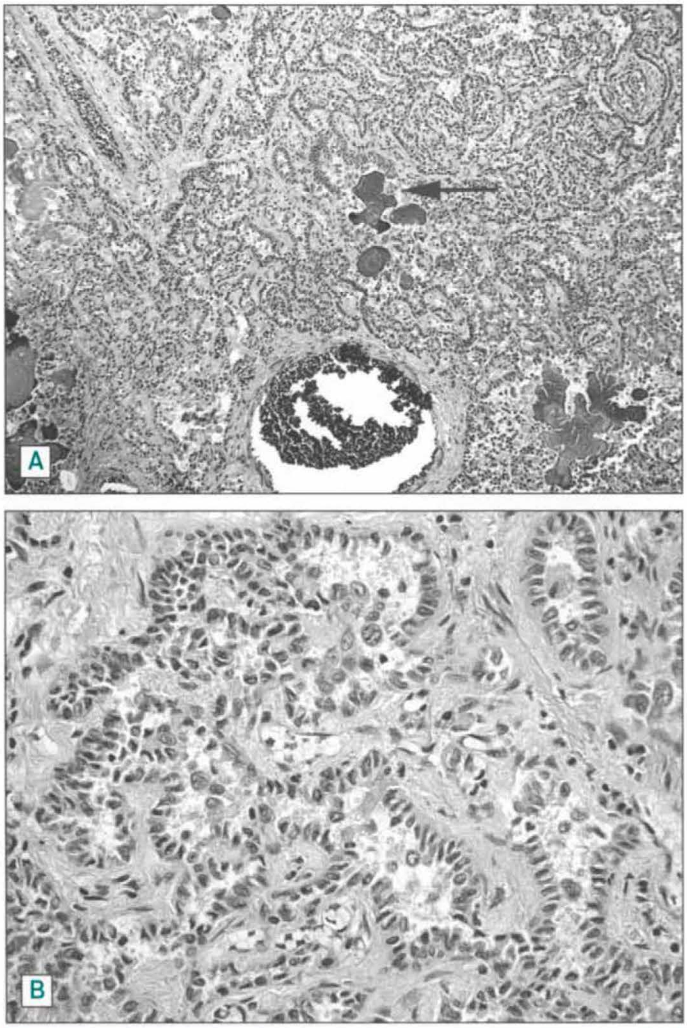

Figure 5.15 Bronchioloalveolar carcinoma in a dog. Low- and high-power photomicrographs of alveolus-like spaces lined by cuboidal epithelium. Several alveoli contain eosinophilic concretions of surfactant-like material (arrow in **A**).

Bronchial gland carcinoma is a rare low-grade malignancy that shows clear evidence of arising from the wall of a bronchus. The neoplastic cells form acini comprised of well-differentiated epithelial cells with prominent mucus production. **Squamous cell carcinoma** is common in the lung, and is histologically similar to that in other tissues. **Adenosquamous carcinoma** forms both acinar/tubular and squamous patterns of differentiation, and has a particularly aggressive growth habit. **Large-cell carcinoma** is a rare and anaplastic variant of pulmonary carcinoma, in which the individual neoplastic cells are large, with abundant cytoplasm; the cells tend to cluster around bronchioles and efface the lung tissue. Histiocytic sarcoma and large-cell neuroendocrine tumor are important differential diagnoses in suspected cases of large-cell carcinoma. **Carcinosarcoma** is a rare primary pulmonary tumor with both adenocarcinomatous and sarcomatous components, reported in a cat.

Neuroendocrine tumors in humans are classified as low-grade carcinoids, intermediate-grade atypical carcinoids, high-grade small-cell carcinoma, and high-grade large-cell neuroendocrine carcinoma. All are rare in domestic animals, and often affect the young. *Pulmonary neuroendocrine tumor is the preferred term because the validity of subclassifying these tumors in animals is unknown.* **Carcinoids** in humans are thought to arise from bronchial neuroendocrine tissue and exhibit the characteristic features of neuroendocrine tumors: arrangement in nests, palisades, or pseudorosettes; expression of chromogranin and synaptophysin; and the presence of dense-core granules visible by electron microscopy. Expression of neuron-specific enolase is considered nonspecific, and is found in some nonneuroendocrine carcinomas in humans. The few cases of pulmonary neoplasms in dogs that resemble carcinoids have developed adjacent to a bronchus, and have a neuroendocrine pattern of nests or ribbons of cells separated by delicate vascularized stroma. The cells are uniform, round to polygonal, with abundant pale eosinophilic cytoplasm and relatively small nuclei. Ultrastructural examination reveals many small, dense, secretory granules in the cytoplasm. They express neuron-specific enolase, but expression of other, more specific markers used for identifying neuroendocrine differentiation is poorly characterized. In human neuroendocrine tumors, the features indicative of a higher grade (i.e., atypical rather than typical carcinoid) are mitotic rate greater than 2 per 10 high-power fields, and coagulative necrosis of the tumor. In the few cases of neuroendocrine tumors reported in dogs, increasing tumor grade correlates with progression from well-demarcated nodules to infiltrative or metastatic neoplasms. **Small-cell carcinoma** is a rare and poorly characterized neuroendocrine tumor described in dogs and cows. It has a hilar location, and consists of loosely arranged packets of small cells (approximately 10 μm diameter) separated by a thin stroma. The neoplastic cells have scant cytoplasm, and may be round (resembling lymphocytes), fusiform ("oat cells"), or polygonal. The immunohistochemical staining patterns in domestic animals are not characterized.

Pulmonary blastoma, rarely described in adult cows, is a multinodular lesion that implants in the pleural cavity, metastasizes to lymph node, and invades extrapulmonary structures. Blastoma consists, by definition, of *malignant epithelial and mesenchymal components*, although there is much variation in the relative amount of each component between tumors and within different areas of the same neoplasm. The cuboidal epithelial cells are arranged in nests or branching tubules. The mesenchymal component appears embryonal, with loose matrix separating spindle-shaped, stellate, or angular cells with vesicular or hyperchromatic nuclei.

Granular cell tumor *is the most common primary lung tumor in horses, and is thought to originate from Schwann cells in the peribronchial tissue.* It is often discovered as an incidental finding in older horses, but can cause coughing or, rarely, dyspnea. Metastasis is not described. Grossly, the mass is white to beige, usually multinodular and unilateral. Granular cell tumors are associated with large bronchi, and often bulge into the bronchial lumen to cause variable degrees of obstruction. Histologically, the neoplasm is comprised of sheets or lobular aggregates of large, round, or angular cells with abundant cytoplasm containing innumerable tiny acidophilic granules (Fig. 5.16). There is minimal variation in cell size, and few mitotic figures are found. The granules will usually stain positively with Luxol fast blue and more variably with periodic acid–Schiff. Immunohistochemical markers for pulmonary granular cell tumors in horses are widely expressed in a variety of other cell types, and so are not pathognomonic for this neoplasm; S100 and vimentin are consistently present, with inconsistent expression of neuron-specific enolase and glial fibrillary acidic protein (GFAP).

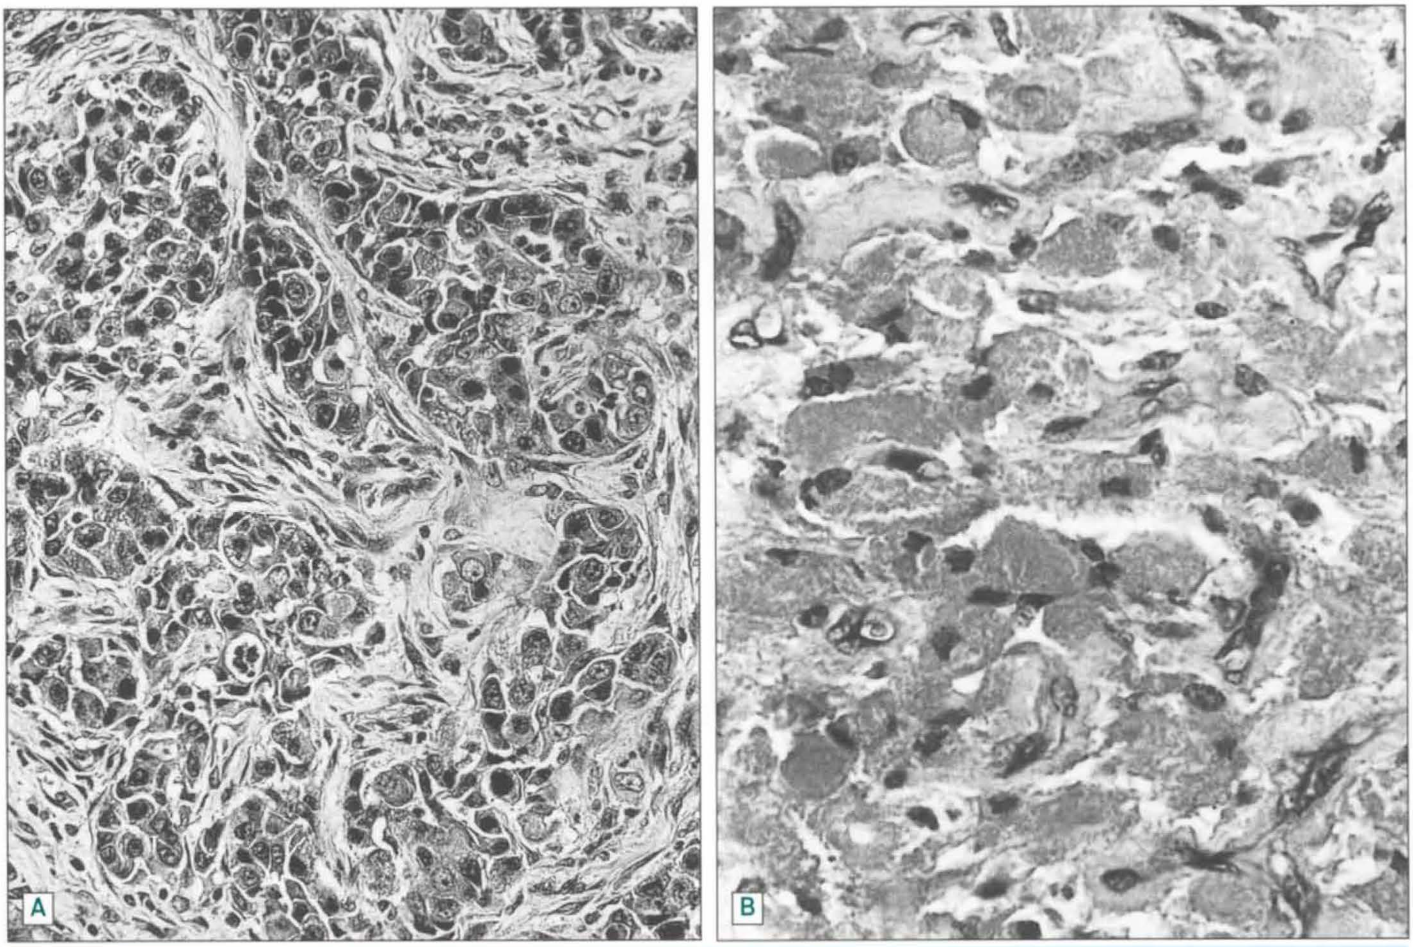

Figure 5.16 Granular cell tumor of the lung of a horse. The neoplastic cells are arranged in nests (**A**) and have abundant granular eosinophilic cytoplasm (**B**).

Lymphomatoid granulomatosis is a very poorly understood disease in veterinary and human medicine. Reports of this condition are not common, but occur mostly in dogs, and rarely in cats. While the disease is discussed here as a pulmonary neoplasm, there is considerable debate as to whether the analogous condition in humans represents a neoplasm or a non-neoplastic lymphoproliferative disorder. No data are available in veterinary medicine addressing the clonality of the lymphoid cells, so the biology of this disease remains enigmatic at this point. Most cases affect 4–9-year-old dogs, and cases as young as 9 weeks are recorded; this relatively young age of onset substantiates the doubts as to whether this is a neoplastic disorder. The pulmonary masses of lymphomatoid granulomatosis are usually multiple and found within the caudal lobes. They are poorly demarcated, and pale, or can occur as a diffuse infiltrate within the affected lobes. Lymphomatoid granulomatosis frequently involves the bronchial lymph nodes, and occasionally similar infiltrates are found within the liver and other viscera. Histologically, *lymphomatoid granulomatosis is an angioinvasive, destructive, pleocellular infiltrate.* The morphology of the infiltrating cells varies; the putative neoplastic cells are round, with distinct borders. They are highly variable in size and appearance and often have a high mitotic rate. Large histiocytic and plasmacytoid forms predominate, binucleate cells may be found, and eosinophils, small lymphocytes, and plasma cells may be numerous. *Invasion of the pleomorphic cells into the walls of blood vessels is the characteristic feature of this disease* (Figs 5.17 and 5.18). Infarction with coagulative necrosis and fibrosis is frequently present. The process may affect local lymph nodes, but it is the progressive involvement of the lung that is the cause of death in most cases. Although the neoplastic cells in dogs appear to be lymphocytes, and variable expression of CD3 has been reported in the atypical cells of canine lymphomatoid granulomatosis, immunophenotypic characterization of the pulmonary infiltrate in dogs diagnosed with this condition is incomplete. In human medicine, there is a growing body of evidence that lymphomatoid granulomatosis is associated with Epstein–Barr virus infection; no information is available pertaining to the role that viral infections play in the canine disease. The differential diagnosis includes eosinophilic granulomatosis, anaplastic carcinoma, and pulmonary round cell tumors such as histiocytic sarcoma, lymphoma, and mast cell tumor.

Histiocytic sarcoma *(malignant histiocytosis) is a malignant neoplasm derived from myeloid dendritic cells* (see Vol. 3, Hematopoietic system). It affects the lung and/or thoracic lymph nodes, usually with concurrent involvement of other organs. The infiltrate may replace an entire lung lobe, or form multifocal infiltrates throughout the lung. The morphology varies from individualized round cells with scant to abundant eosinophilic cytoplasm, to spindle-shaped or dendritic cells with indistinct borders. The nuclei are round or cleaved with marked anisokaryosis. Most cases have significant numbers of multinucleate cells, lymphocytes, and plasma cells intermingled with the neoplastic cells. Immunohistochemical

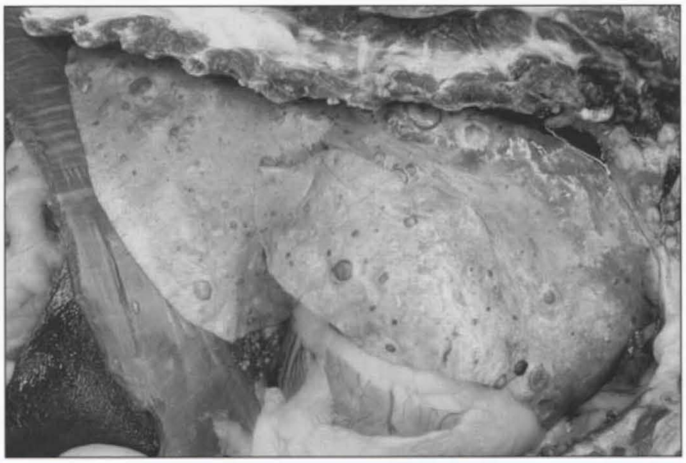

Figure 5.19 Pulmonary metastases of **malignant melanoma** in a dog.

identification is best performed on frozen sections, where the cells are CD1+, CD11c+, major histocompatibility complex class II+, and intercellular adhesion molecule (ICAM)-1+; demonstration of a CD18+, CD3–, CD79a– phenotype in formalin-fixed specimens provides tentative confirmation of the diagnosis.

Metastatic tumors commonly arise within the lung because of the organ's rich capillary and lymphatic network. As mentioned above, it is often difficult to distinguish metastatic disease arriving from a distant, nonpulmonary primary neoplasm from intrapulmonary spread of a primary lung neoplasm. This distinction is the most difficult with aggressive carcinomas. An important part of the diagnosis of a primary lung tumor is thorough examination of the body to exclude possible nonpulmonary sites of primary neoplasia. *The most easily recognizable pattern of metastatic tumors is of multiple, similarly sized nodules throughout the pulmonary parenchyma* (Fig. 5.19); *primary lung tumors usually form one or a few large tumors, sometimes with smaller intrapulmonary metastases.* Metastatic carcinomas may form acini, solid sheets, lepidic growth along pre-existing alveolar septa, and/or clusters within blood vessels. Some of the most common include lymphoma in all species; uterine adenocarcinoma in cows and sows; malignant melanoma in horses; and osteosarcoma, hemangiosarcoma, oral melanoma, mast cell tumor, transitional cell carcinoma, and adenocarcinomas of mammary, biliary, pancreatic, intestinal, anal sac, or thyroid origin in dogs and cats.

Anatomic patterns of lung injury

The pulmonary inflammatory response varies according to the nature of the causative agents, their distribution (particularly the route by which they reach the lung), and their persistence. Pulmonary diseases can be classified in several ways:

- *Morphologic pattern*, according to initial site of involvement and the pattern of spread of the lesion: bronchopneumonia, interstitial pneumonia, bronchitis/bronchiolitis, bronchointerstitial pneumonia, and embolic pneumonia.
- *Histologic character*: fibrinous, suppurative, granulomatous, necrotizing, proliferative, fibrosing.
- *Etiology*: viral, bacterial, parasitic, toxic, allergic.
- *Duration*: acute, subacute, chronic.
- *Functional abnormality*: obstructive versus restrictive.
- *Epidemiologic patterns*: shipping-fever pneumonia, enzootic pneumonia.

The approach described here emphasizes morphologic patterns of pneumonia, for two reasons. First, gross and histologic examination is usually sufficient to classify a condition by this scheme, even if the etiology cannot be identified. Second, knowledge of the pattern of pneumonia provides important clues as to the probable etiology, route of exposure to the causative agent, pathogenesis of the lesions, effect on pulmonary function, and the sequelae and complications. Emphasizing the similarities between specific diseases, by grouping them based on morphologic patterns, often enhances our ability to recognize the sometimes subtle differences among these conditions.

Bronchial necrosis and inflammation

Lesions that specifically target the airways include those that cause epithelial necrosis and those that induce airway inflammation; a combination of these patterns is frequently, but not always, present. Diseases may affect the bronchi, bronchioles, or both; and the diagnosis of bronchointerstitial pneumonia, described later, is appropriate when both airway and alveolar epithelial cells are damaged. *The major consequences of these diseases are coughing, airway obstruction, and impairment of lung defenses.* The flow of air can be obstructed by bronchoconstriction resulting from contraction of airway smooth muscle, by leukocytes or mucus within the lumen of the airway, and by thickening of the airway wall by edema and leukocytes. The result is failure of alveolar ventilation that may cause hypoxemia and hypercapnea, and reflex vasoconstriction that reduces perfusion of hypoventilated areas of lung. Pulmonary compliance is reduced because of the increased pressure needed to ventilate the alveoli. Clinically important airway obstruction is particularly notable with bronchiolar disease, where it manifests as expiratory dyspnea because the airway obstruction is exacerbated from the slight collapse that occurs during exhalation.

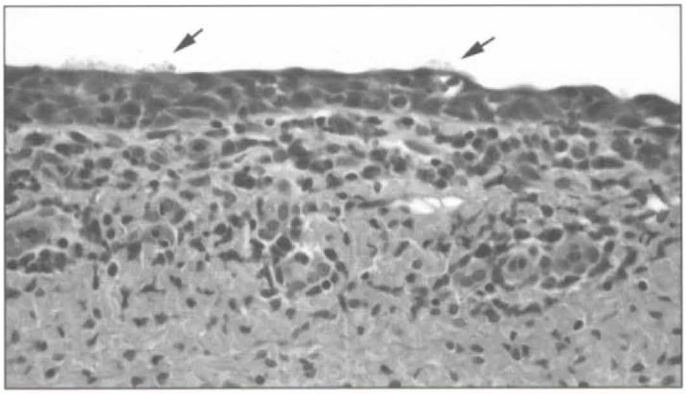

Figure 5.20 ***Nipah virus*** infection in a pig. Squamous metaplasia of bronchial epithelium, with two remaining islands of ciliated cells (arrows).

Bronchitis is relatively common in domestic animals but receives inadequate attention by pathologists because it is not usually fatal. Bronchitis and/or bronchial necrosis may be caused by viral or bacterial infection, parasitism, allergic disease, or exposure to irritants or toxins.

Morphologic manifestations of acute bronchitis include the same range of inflammation described for upper airways. The exudates may be catarrhal, mucopurulent, fibrinous, fibrinopurulent, or purulent. Ciliated epithelial cells are most sensitive to a wide array of injurious agents and are often the first to undergo necrosis and slough. *Catarrhal bronchitis* represents a relatively mild reaction in which the irritation induces both a mild neutrophil-dominated inflammatory response and secretion of mucus by goblet cells and bronchial mucosal glands. In *purulent bronchitis*, the exudate is yellow or white and viscid. *Fibrinonecrotic bronchitis* resulting from viral or occasionally mycotic infection is characterized by areas of epithelial necrosis with loosely adherent fibrinous exudate. In such cases, gentle removal of the exudate reveals a granular lesion of epithelial necrosis, which differentiates the lesion from the expectorated mucus that is often present in the large airways of animals with chronic bronchopneumonia. Animals with aspiration pneumonia often have extensive necrosis of the bronchial epithelium, with green-brown foul-smelling exudate.

Bronchial necrosis can resolve by epithelial regeneration if the offending stimulus is removed or neutralized. More severe or prolonged injury to epithelium results in fibrosis of the lamina propria, as well as accumulation of lymphocytes, macrophages, and plasma cells. Epithelial hyperplasia, mucous hyperplasia, and/or squamous metaplasia may also become prominent following mucosal injury of any cause (Fig. 5.20). Chronic infection with damage to the airway wall may result in bronchiectasis, discussed below. Fibrous polyps are a rare response to bronchial mucosal injury.

Common airway diseases in domestic animals include acute tracheobronchitis ("kennel cough") of dogs (discussed in the section on Infectious respiratory diseases of dogs, below), chronic bronchitis of dogs, feline asthma, heaves in horses, and *Dictyocaulus* spp. in cattle, sheep, goats, and horses. Bronchitis also results from inhalation of bacteria from the upper respiratory tract, and rarely when the focal lesions of tuberculosis or caseous lymphadenitis erode into a large airway. Bronchitis causes coughing that may be paroxysmal, and airway obstruction manifests in wheezing. However, it is not expected to be fatal unless the lesion induces widespread bronchoconstriction, obstructs a large airway, or leads to secondary bronchopneumonia as a result of aspiration of infected material or impaired mucociliary clearance.

Chronic bronchitis in dogs

Chronic bronchitis is a common condition in older, small and medium-sized dogs, and manifests as chronic productive or nonproductive cough, exercise intolerance, expiratory or inspiratory wheezes, reduced expiratory airflow, and hypoxemia. The etiology in individual cases is rarely identified, and the lesions are probably self-perpetuating. Proposed causes include dry air, airborne pollutants including sulfur dioxide and particulates, second-hand tobacco smoke, chronic gingivitis with aspiration of debris, immune-mediated inflammation, and viral infection. Opportunistic bacterial pathogens are occasionally isolated, but their significance as a primary cause is questionable; similarly, viral and bacterial infections are well recognized to induce acute exacerbations in human patients with chronic bronchitis in which infection is not the primary cause. Many dogs with chronic bronchitis also have chronic left heart failure, suggesting that cardiogenic pulmonary edema may result in chronic coughing that generates airway inflammation and mucus hypersecretion. Chronic exposure to sulfur dioxide or cigarette smoke are canine models of bronchitis, and cause similar histologic lesions to those in the natural disease.

The major gross finding is excessive mucus or mucopurulent exudate in the trachea and bronchi. The bronchial mucosa in severe cases is hyperemic, thickened, edematous, and granular rather than glistening, and lymphoid nodules or hyperplastic polyps may project into the lumen. Microscopically, the bronchial mucosa is edematous and contains many lymphocytes, plasma cells, and occasional macrophages and neutrophils (Fig. 5.21). Eosinophils are present in some cases but not in others. There is hyperplasia and hypertrophy of the mucosal glands, hyperplasia of goblet cells, and variable hyperplasia, ulceration, or squamous metaplasia of the surface epithelium. Intraluminal mucus is commonly mixed with abundant neutrophils. Many cases of uncomplicated bronchitis persist for years, but *sequelae* in severe cases include bronchiectasis; bronchopneumonia; or alveolar atelectasis leading to pulmonary hypertension, cor pulmonale, and medial hypertrophy of pulmonary arteries. Collapsing trachea and chronic bronchitis are frequent companions: chronic inflammation is thought to progress to malacia of the tracheobronchial cartilage in some cases and contribute to development of tracheal collapse. Emphysema is not an important sequel to chronic bronchitis in dogs, in contrast to chronic obstructive pulmonary disease in humans.

Eosinophilic bronchitis is common in dogs. Most cases are probably allergic; these are rarely fatal, and the histologic features of mild cases are not well described because they often respond favorably to corticosteroid therapy. The nematodes *Crenosoma vulpis, Eucoleus aerophilus* (*Capillaria aerophila),* and *Oslerus osleri* are additional causes of eosinophilic airway disease.

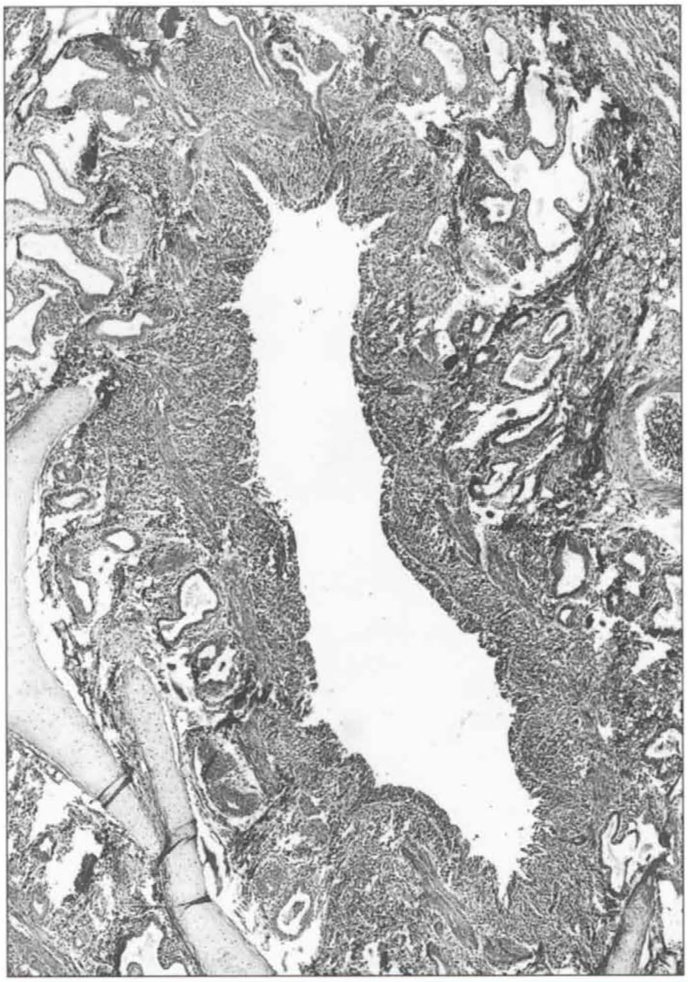

Figure 5.21 Chronic bronchitis in a dog.

Eosinophilic bronchopneumopathy is a rare condition of young dogs, and Siberian Huskies are overrepresented. It causes chronic gagging, cough, dyspnea, nasal discharge, and variable blood eosinophilia and neutrophilia. The diffuse lung lesions are not completely described, but include chronic eosinophilic bronchitis with epithelial hyperplasia, ulceration, or squamous metaplasia. Bronchiectasis is a reported complication in some cases. The disease shares several features with eosinophilic pulmonary granulomatosis, which is discussed below.

Acute and chronic bronchitis in cats

Feline asthma *is relatively common, and is defined by the clinical findings of reversible airway obstruction with inflammation.* Most cases have an acute onset or recurrent bouts of dyspnea or wheezing that respond to treatment with bronchodilators and corticosteroids, and are *mainly the result of bronchoconstriction due to airway smooth-muscle hyperreactivity.* Thickening of the bronchial wall may be noted radiographically, and eosinophils are usually numerous in bronchoalveolar lavage fluid. Neutrophils or macrophages predominate in bronchoalveolar lavage fluid in some cases that are otherwise typical of feline asthma. Other cats have chronic coughing or wheezing, although chronic bronchitis is a more accurate, albeit nonspecific, diagnosis in these cases if it cannot be demonstrated that the signs are readily reversible. Cats parenterally sensitized then challenged with Bermuda grass allergens develop allergen-specific immunoglobulin E (IgE), IgG, and IgA; airway hyperreactivity; and the following histologic lesions in the bronchi: narrowing of the lumen, smooth-muscle hyperplasia, infiltrates of eosinophils in the wall and lumen, hypertrophy and hyperplasia of goblet cells and mucosal glands, and erosion of the surface epithelium. The histologic findings in natural cases are not as well characterized because mortality is uncommon. In addition to smooth-muscle hyperplasia and eosinophil infiltration, lymphoplasmacytic infiltrates with lymphoid follicles may develop in the adventitia of the bronchi, and bronchioles may contain similar lesions (Fig. 5.22).

Chronic bronchitis in cats may be a manifestation of ongoing low-grade allergic reactions, although these do not fulfill the criteria of acute onset of reversible airway obstruction, as is necessary for the diagnosis of asthma. The role of infectious agents, including *Mycoplasma* spp., as causes of chronic bronchitis in cats is controversial. Bronchial parasites are rare in cats.

Bronchiectasis

Bronchiectasis is defined as permanent dilation of bronchi, as a result of chronic bronchial obstruction and infection. Although most cases are a complication of bronchopneumonia or bacterial bronchitis, bronchiectasis may result from focal bronchial obstruction by an inhaled foreign body, granuloma, tumor, or broncholith. It rarely occurs as a congenital malformation, and immune-mediated bronchitis may lead to bronchiectasis in humans and animals. The lesion is most common in **cattle**, where it is almost always a sequel to bronchitis that occurs within the cranioventral lesions of bacterial bronchopneumonia. Bronchiectasis is relatively common in cattle with chronic bronchopneumonia, because complete lobular septation and lack of collateral ventilation both impair resolution of bronchopneumonia and lead to more extensive atelectasis because of airway blockage. Bronchiectasis is common in **dogs**, and Cocker Spaniels and Miniature Poodles may be overrepresented. Many have chronic cough, but it is uncertain whether bronchiectasis is the initial cause of the cough or a complication of underlying chronic bronchitis. The lesions commonly affect the right cranial or middle lung lobes, and are usually the result of bacterial infection or occasionally of tumors or bronchial foreign bodies. Bronchiectasis is common in dogs with ciliary dyskinesia. The condition in **cats** usually affects the caudal or middle lobes, and is often a sequel to chronic bronchitis, bronchopneumonia, or pulmonary neoplasia. Endogenous lipid pneumonia and emphysema are concurrent findings in some cases. Bronchiectasis infrequently develops in **pigs, sheep**, and **goats** with severe parasitic bronchitis, and in **horses** with chronic heaves. There are three anatomic forms of bronchiectasis: (1) *cylindrical bronchiectasis* causes relatively uniform dilation of the bronchus; (2) *saccular bronchiectasis* is probably a more advanced stage, where there are circumscribed or fusiform cyst-like lesions at the end of progressively dilated airways; and (3) *varicose bronchiectasis* – rarely identified in animals – forms focal constrictions along dilated airways. The smaller distal bronchi are usually affected by bronchiectasis, and a similar lesion may involve the bronchioles.

Obstruction of bronchi by purulent exudate is the key to development of bronchiectasis, and the resulting destruction of bronchial walls leads to their permanent dilation. In these situations, neutrophil-derived proteases and oxygen radicals damage the bronchial epithelium and connective tissue. This results not only in weakening of the bronchial wall, but also permanent failure of mucociliary clearance that perpetuates the infection and pooling of exudates in the lumen. Exudates in more distal airways and alveoli cause airway obstruction and atelectasis; as a result, the weakened larger airways are pulled outward with each inspiration and thus dilate over time.

The dilated bronchi are filled with viscid yellow-green creamy exudate, which may eventually form caseous or inspissated masses in the lumen. The intervening parenchyma is atelectatic and often fibrotic. The bronchi may be so dilated as to be visible from the pleural surface, but are best appreciated when sectioned transversely

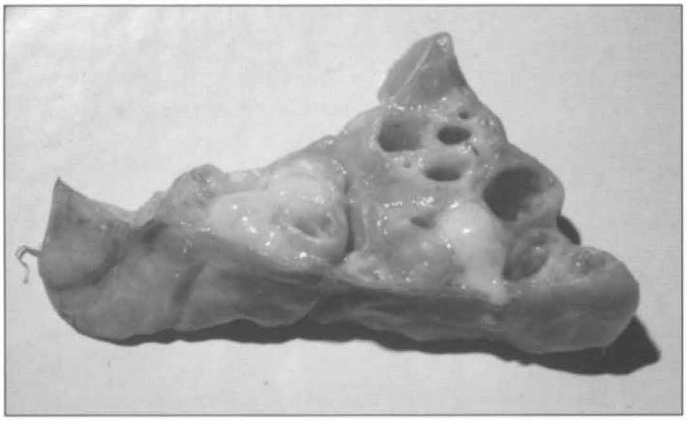

Figure 5.23 Bronchiectasis in a dog. The lung contains many greatly dilated bronchi filled with purulent exudate.

(Figs 5.23 and 5.24). *They may be confused with abscesses, but the clues to their origin include their linear and regular rather than haphazard distribution, the finding of remnants of cartilage, and their eventual continuity with recognizable bronchi.* In severe cases, the dilated bronchi give a honeycombed or cystic appearance to the lobe. Microscopically, the lumen is filled with mucus, cellular debris, leukocytes, and occasionally blood. The epithelium often shows some combination of attenuation, ulceration, mucous or squamous metaplasia, and hyperplasia. The mucosa and submucosa are densely infiltrated with all types of leukocytes and are often obscured by granulation tissue, and this destructive and fibrotic lesion may extend to the deeper tissues and destroy cartilage and submucosal glands; *complete destruction of the bronchial wall leads to formation of a lung abscess.* Normal bronchi are dynamic structures that actively regulate airflow and defend the lung through mucociliary clearance; those crippled by

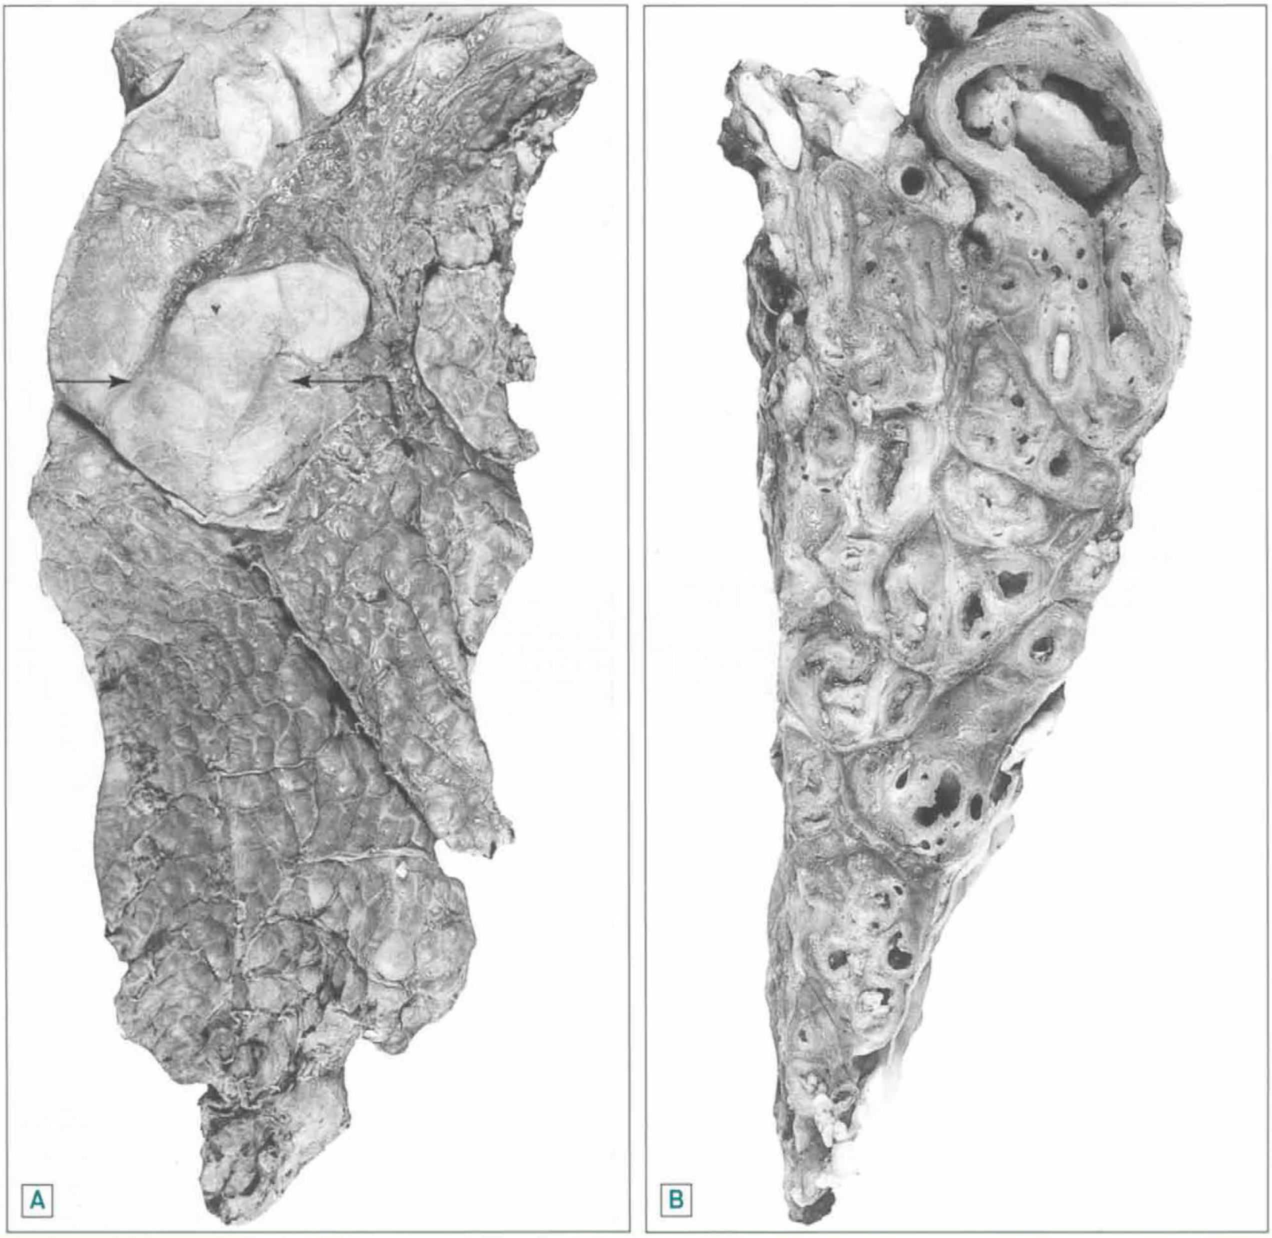

Figure 5.24 Bronchiectasis in a calf. **A.** Nodular lesions visible on the pleural surface correspond to (**B**) dilated bronchi filled with exudate. There is air trapping in the adjacent lobules (arrows in **A**).

bronchiectasis are forever dilated and unable to clear their burden of harmful pus and pathogens.

Primary ciliary dyskinesia

Cilia are complex structures: the "9 + 2" or "9 + 0" arrangement of microtubular doublets forms the basic structure, inner and outer dynein arms are the motors that forces the cilium to bend, and nexin links and radial arms provide support. These structures contain hundreds of proteins, so it is not surprising that *primary ciliary dyskinesia is a diverse collection of disorders* involving mucus-propelling cilia in the nasal cavity and bronchi, sperm flagella, nodal cilia in the developing embryo, water-propelling cilia in the ependyma and epididymis, and cilia in the middle ear and retina. Primary ciliary dyskinesia or *immotile cilia syndrome* is an inherited condition reported infrequently in many dog breeds, which manifests as recurrent or persistent rhinitis and sinusitis, bronchiectasis, bacterial pneumonia, and/or male infertility due to reduced spermatozoal motility with abnormal tails. About half of affected humans and dogs have *Kartagener's syndrome*, defined as the combination of sinusitis, bronchiectasis, and situs inversus. The latter represents left–right reversal of the thoracic and/or abdominal viscera due to dysfunction of cilia in the embryological node. Otitis media or hydrocephalus may occasionally be present.

The *diagnosis* of ciliary dyskinesia is based on abnormal ciliary motility in short-term cell cultures, in vivo imaging studies to measure movement of mucus, and/or detection of ultrastructural abnormalities in cilia. Since bacterial toxins or adhesion of *Bordetella* or perhaps *Mycoplasma* cause ciliary dysfunction, detection of dysfunction in cilia from more than one tissue is necessary. Ultrastructural studies are also useful in differentiating primary from acquired ciliary dyskinesia. Absence or reduced number of inner and/or outer dynein arms, of the radial spokes that extend from these arms, and/or of the central microtubules are common ultrastructural lesions in primary ciliary dyskinesia, and other primary and secondary changes are described. The ultrastructural diagnosis depends heavily on the quality of the preparation, and some dogs with the syndrome do not have ultrastructural changes in cilia.

Bronchiolar necrosis and inflammation

Bronchiolitis and/or bronchiolar necrosis are *caused by* viral infection, inhalation of toxic gases, toxins that are metabolized by cytochrome P450 in nonciliated Clara cells, hypersensitivity reactions, or inflammatory reactions to inhaled irritants (Fig. 5.25). Autoimmune disorders, drug reactions, and reactions to mineral dusts are further causes of bronchiolar injury in humans. In addition, bronchiolar lesions are frequently an extension of bronchitis, bronchiectasis, or bacterial bronchopneumonia. The designation of *bronchointerstitial pneumonia* is appropriate when necrosis targets both the bronchiolar and the alveolar epithelium, as occurs particularly in viral infections and toxic injury.

Airway obstruction occurs more readily in bronchioles than in bronchi, because their lack of cartilage rings and small luminal size readily permits collapse and occlusion by exudate. According to Poiseuille's law of frictional resistance, resistance to airflow varies with the fourth power of the radius, so narrowing of the airway by half will increase airway resistance 16-fold. Thus, if diffuse in its distribution, even minor airway obstruction by bronchoconstriction, intraluminal exudates or mucus, or edema of the wall has profound effects on the work of breathing and on alveolar ventilation. These functional changes manifest as forced expiratory efforts, hypoxemia, and hypercapnea in the later stages. *Complete airway obstruction causes atelectasis, while partial obstruction leads to air trapping and overdistension of alveoli.* Both of these situations lead either to shunting of nonoxygenated blood past the perfused but hypoventilated alveoli, or arteriolar constriction that reduces perfusion of these hypoventilated alveoli but causes pulmonary hypertension if the airway obstruction is widespread.

Bronchiolitis obliterans (also known as *bronchiolitis fibrosa obliterans, obliterative bronchiolitis,* or *organizing bronchiolitis)* is a sequel to

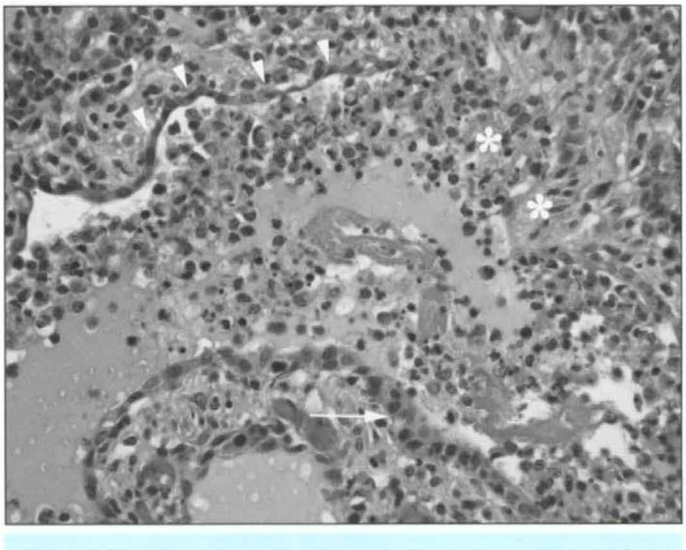

Figure 5.25 ***Nipah virus*** infection in a pig. A bronchiole is filled with fibrin and necrotic cells. The epithelium varies from eroded (asterisks), to attenuated (arrowheads), to normal (arrow).

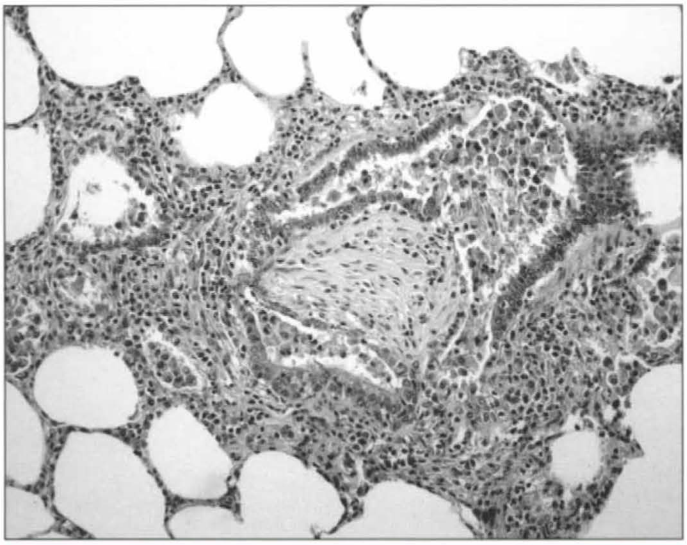

Figure 5.26 Bronchiolitis obliterans in a calf. The lumen of the bronchiole is occluded by a mass of fibrous tissue covered by cuboidal epithelium.

chronic bronchiolar damage. The term is used here to describe the presence of fibrous polyps occluding the bronchiolar lumen; bronchiolitis obliterans is occasionally employed elsewhere to describe acute lesions in which intraluminal aggregates of neutrophils obstruct airflow. The lesion is distinct from **constrictive bronchiolitis**, a lesion not commonly identified in animals, in which fibrosis of the bronchiolar wall causes external compression that reduces the diameter of the lumen.

Bronchiolitis obliterans is wound healing gone awry. Any agent that severely damages the bronchiolar epithelium – viral infection, neutrophil-mediated injury due to bacterial pneumonia, toxic gases, toxins metabolized by Clara cells, lungworms, and rejection of transplanted lung – may lead to fibrin formation in the bronchiolar lumen. As in any wound, fibrinous exudates that are not rapidly removed heal by fibroblast infiltration, neovascularization, and sliding and proliferation of epithelial cells across their surface. Organization of exudate into granulation tissue can take place in as little as 7–10 days after injury, and regeneration of epithelium over its surface can occur in the same time period. Although this repair proceeds with the best intentions, *fibrous polyps occluding the airway may have disastrous and permanent effects on airflow and alveolar ventilation.*

Bronchiolitis obliterans is commonly identified within lesions of chronic bronchopneumonia in cattle, as a consequence of viral or neutrophil-mediated epithelial damage. Calves with a prior history of viral pneumonia occasionally develop right heart failure with right ventricular dilation, subcutaneous edema, hepatomegaly, and ascites. The gross lung lesions in such calves may be minor, but histologic examination reveals epithelium-covered fibrous polyps that occlude the lumen of most bronchioles (Fig. 5.26), as well as medial hypertrophy of pulmonary arterioles. The latter is a histologic indicator that widespread alveolar hypoventilation has incited pulmonary hypertension, which has in turn caused cor pulmonale with right heart failure.

Scattered subpleural foci of **bronchioloalveolar hyperplasia** are a common incidental finding in dogs. The lesions can be difficult to distinguish from early bronchioloalveolar carcinoma, but the hyperplastic lesions are usually multifocal, line terminal bronchioles, do not enlarge to form masses, are usually associated with fibrosis and lymphocytic inflammation of the adjacent tissue, and have no features of cellular atypia.

Heaves in horses

Heaves is a common condition of mature horses. *The term chronic obstructive pulmonary disease is inappropriate for the equine disease*, as the condition differs from this human condition and is more similar to human asthma. *Heaves is a nonseptic, inflammatory, obstructive airway disease of adult horses characterized by airway hyperresponsiveness and reversible airway obstruction due to bronchospasm.* Other mechanisms of airway obstruction include accumulation of mucus and neutrophils in bronchiolar lumina and thickening of the bronchiolar wall. It is usually induced or exacerbated by exposure to organic dusts (particularly dusty, poor-quality hay) that may contain allergens, endotoxins, fungi, actinomycetes, and particulate irritants.

Although heaves is undoubtedly an inflammatory disease, it remains controversial whether allergy (IgE- and mast cell-mediated type I hypersensitivity) is important to the pathogenesis. Evidence supporting a mast cell-dependent or allergic basis includes elevated levels of IgE and histamine in bronchoalveolar lavage fluid, and enhanced histamine release from pulmonary mast cells of horses with heaves. However, skin test results do not correlate with airway reactivity, and bronchoalveolar lavage cells in horses with heaves express both interleukin-4 (IL-4) and interferon-γ (in addition to tumor necrosis factor-α, IL-1β, and IL-8) mRNA, suggesting that a pure T-helper-2 immune response is not characteristic of this disease. Challenge with molds, mold extracts, or endotoxin-containing dusts has induced airway neutrophilia and obstruction in heave-susceptible but not normal horses, implying that all of these factors may contribute to the airway responses.

The disease occurs in stabled horses in northern regions and as a summer pasture-associated form in warm wet climates. *Affected horses have chronic cough, increased expiratory effort, wheezing, variable nasal discharge, and exercise intolerance.* Increased pulmonary resistance and reduced dynamic compliance are typical functional changes, and the bronchioles are hyperresponsive to agonists. The signs wax and wane depending on exposure to dusts, and a seasonal effect is common, but many cases are slowly progressive over the course of months or years.

The lesions specifically target the small bronchioles, and alveolar changes are usually minor. Bronchioles contain mucus, neutrophils, and sloughed epithelial cells in their lumens; increased numbers of goblet cells in the epithelium with degeneration and sloughing of Clara cells; and lymphocytes, plasma cells, and mast cells in the lamina propria and adventitia (Fig. 5.27). Eosinophils are usually infrequent, but are numerous in some cases; their presence perhaps reflects a different stage of the disease. Peribronchiolar fibrosis and bronchial epithelial hyperplasia are inconsistent. The smooth muscle may be hypertrophied as a result of chronic bronchoconstriction, but muscular

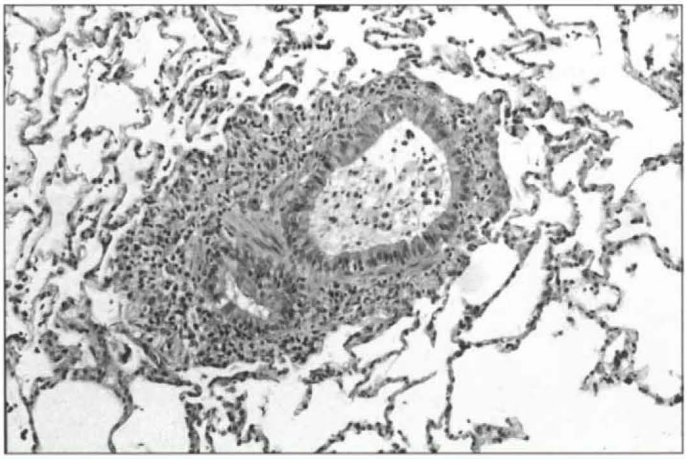

Figure 5.27 Heaves in a horse. The alveoli are normal, but the bronchiole is filled with mucus and neutrophils, and surrounded by lymphocytes.

hypertrophy cannot be readily assessed histologically because the bronchospasm that occurs at death or when tissues are biopsied induces artifactual thickening of the tunica muscularis. Mucus spills into the adjacent alveoli in severe cases, and overinflation of alveoli may result from trapping of air distal to the obstructed bronchioles, but true emphysema with destruction of alveolar septa is not expected. The number of mast cells in the bronchiolar wall and neutrophils in the lumen are positively correlated with clinical severity, although histologic lesions do not correlate well with clinical severity or prognosis.

Inflammatory airway disease is a term used to describe a heaves-like condition in younger horses. It occurs in 2–4-year-old horses, and results in a similar pattern of chronic, episodic, nonseptic bronchiolitis leading to cough, excessive airway mucus production, and/or poor racing performance. Bronchoalveolar lavage cytology reveals neutrophilia in some cases, eosinophilia in others, and some with increased numbers of mast cells. The histologic features are not described. Prior viral infection and exposure to airborne environmental allergens, dusts, and/or endotoxins are proposed causes. Whether it is a different disease or an early stage of heaves is uncertain.

Bronchopneumonia

The hallmarks of bronchopneumonia are an exudative lesion originating at the bronchiolar–alveolar junction, and an airborne route of entry of the causative agent. Bronchopneumonia is caused by bacterial or fungal infection.

The lesions most often affect the cranioventral regions of the lungs, with neutrophils and sometimes fibrin or macrophages filling the bronchioles and alveoli.

The bronchiolar–alveolar junction is the major site of deposition of 0.5–3.0 μm diameter particles, yet it seems to be particularly vulnerable to bacterial infection. In particular, the terminal bronchioles receive limited protection from the mucociliary clearance that is more active in the larger airways, or from the alveolar macrophages that protect the more distal airspaces. This situation is worsened by the fact that clearance of large volumes of debris from the alveoli requires that this material transits the narrow lumen of the bronchiole, so inflammation of the bronchiole readily obstructs clearance of bacteria and exudates from the alveoli, especially in species that lack collateral alveolar ventilation.

The characteristic cranioventral distribution of bacterial bronchopneumonia in animals is probably largely explained by gravitational influences, which result in both increased deposition of inhaled particles and pooling of aspirated secretions in these regions. There is evidence that *intravenous* administration of *Mannheimia haemolytica* also causes pneumonia in cranioventral regions, lending some support to the idea that defenses might be less effective in this area of the lung.

Causes and predisposing factors

Bronchopneumonia is in most cases caused by opportunistic bacterial pathogens (Table 5.6), and development of disease requires increased exposure of the lung to bacteria, impairment of the pulmonary defenses, or both. *Aspiration pneumonia* is an obvious situation where pulmonary challenge with massive numbers of bacteria overcomes the lung defenses. Common conditions predisposing to aspiration pneumonia in animals include force-feeding or concurrent gastric intubation, vomiting and regurgitation, anesthesia, cleft palate, and neurologic disease causing laryngeal dysfunction. Similarly, in cattle, *stress* leads to increased numbers of *Mannheimia haemolytica* bacteria colonizing the nasopharynx, which presumably results in increased number of bacteria within inhaled droplets. The *causes of impaired lung defenses* have received more attention, and include viral and mycoplasmal infection, exposure to cold, toxic gases, and inherited conditions. Agents or conditions that impair

Mannheimia haemolytica *Histophilus somni* *Pasteurella multocida*	*Actinobacillus pleuropneumoniae* *Pasteurella multocida* *Streptococcus suis* *Haemophilus parasuis* *Actinobacillus suis* *Bordetella bronchiseptica*	*Streptococcus* spp. *Rhodococcus equi* *Actinobacillus* sp. *Klebsiella* sp.	*Bordetella bronchiseptica* *Pasteurella* spp. *Streptococcus* spp. *Staphylococcus* sp. *Escherichia coli* Anaerobic bacteria

mucociliary clearance include exposure to cold, *Bovine herpesvirus 1*, *Bovine respiratory syncytial virus*, *Bovine parainfluenza virus 3*, *Mycoplasma hyopneumoniae*, a variety of toxic gases, and ciliary dyskinesia. Alveolar macrophage function is reduced by *Bovine herpesvirus 1*, *Porcine reproductive and respiratory syndrome virus*, stress, aflatoxin, and T-2 mycotoxin. Conditions that reduce the number or function of circulating neutrophils may also predispose to opportunistic bacterial pneumonia, including parvoviral enteritis, acute *Bovine viral diarrhea virus* infection, chemotherapy, stress, acidosis, uremia, and several mycotoxins.

Morphology

The typical gross appearance of bronchopneumonia is irregular consolidation in cranioventral regions, and most cranioventral lung lesions in domestic animals represent bronchopneumonia. There are, however, several exceptions to this rule. First, some viral infections, including *Bovine respiratory syncytial virus*, typically induce a cranioventral pattern of bronchointerstitial pneumonia that can easily be mistaken for bronchopneumonia. Second, the lesions of bronchopneumonia in swine caused by *Actinobacillus pleuropneumoniae* and *Actinobacillus suis* usually affect the middle or caudal lung lobes. Third, while the lesions of bronchopneumonia in dogs and cats may be cranioventral, it is not unusual to find a patchy distribution throughout the lung. *Consolidated lung is best detected by its firm texture on palpation.* These lesions may be dark red, gray-pink, or gray depending on the age and nature of the process, but a color change without altered texture may simply represent patchy areas of congestion or hemorrhage rather than bronchopneumonia. The cut surface is usually edematous, and catarrhal or purulent material can be expressed from small airways in subacute cases. In contrast, exudate is not apparent in cases of fulminant fibrinous bronchopneumonia because leukocytes are enmeshed in a tangle of fibrin, and the affected lung is discolored, dry, or edematous, and cuts crisply.

The lesions of bronchopneumonia may be lobular or lobar.

- **Lobular bronchopneumonia** is generally less severe and more slowly progressive, and *the angular outlines of individual lobules are visible at the margin of affected and normal lung tissue* (Fig. 5.28). The lobular pattern is most apparent in cattle and swine, which have well-developed interlobular septa.
- **Lobular pneumonia** *is characterized by consolidation of the entire pulmonary lobe* (Fig. 5.29). This is usually a fulminating bronchopneumonia, and typical causes are *M. haemolytica* in cattle, *Actinobacillus pleuropneumoniae* in swine, and aspiration pneumonia. In many such cases, the pulmonary parenchymal lesions are accompanied by *pleuritis*, which may vary from a dull granular appearance to a spectacular coating of fibrin with large pockets of edema.

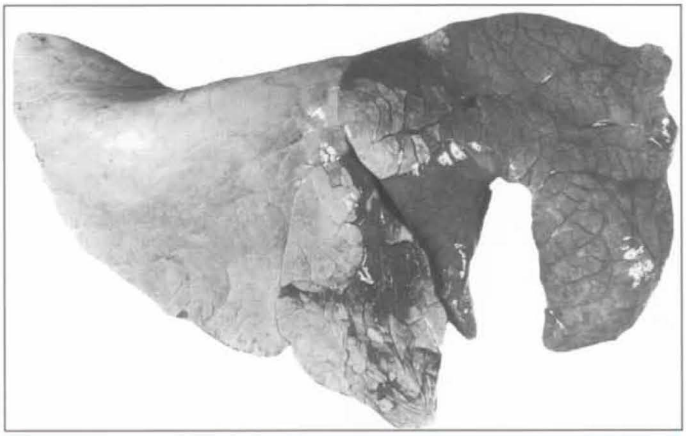

Figure 5.28 Acute lobular bronchopneumonia in a calf. The border between affected and unaffected lung follows a lobular pattern. Lobulation is emphasized in dark areas of consolidation by interlobular edema.

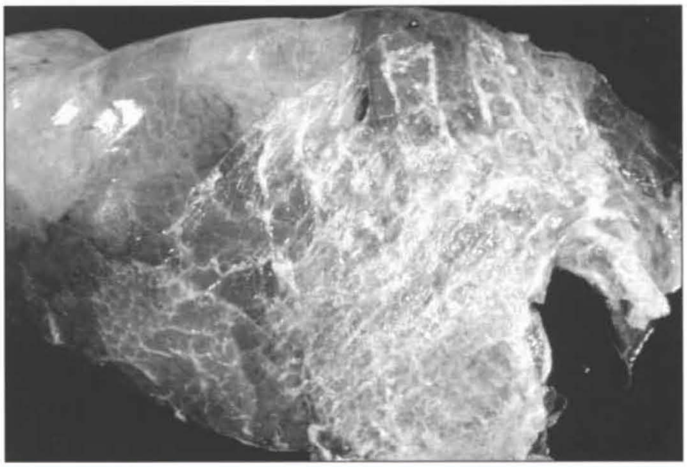

Figure 5.29 *Mannheimia haemolytica* pneumonia in a calf. The cranioventral lung is dark red and hard, and covered by a veil of fibrin.

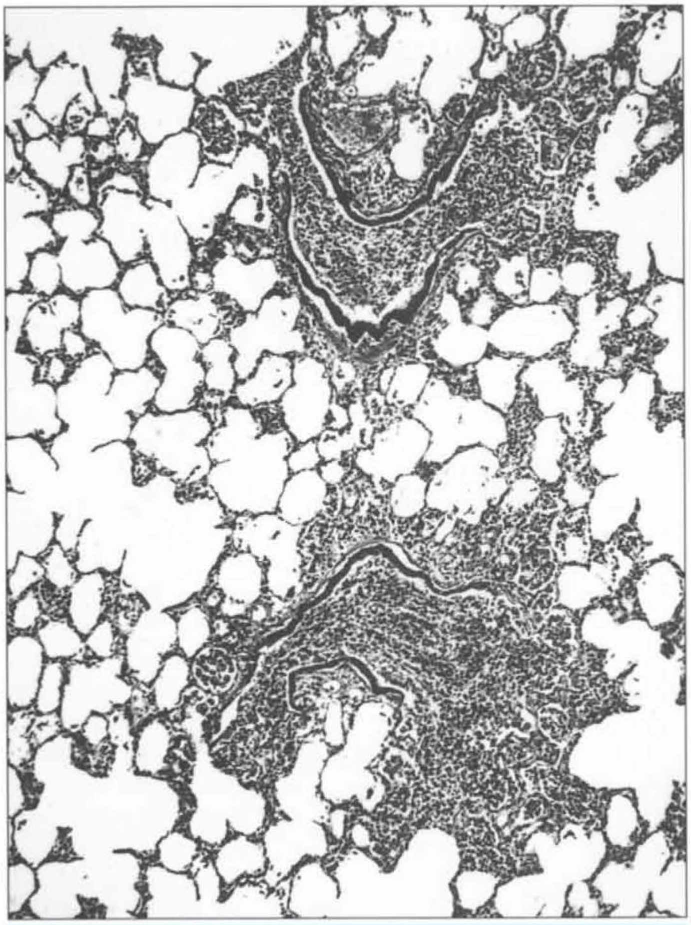

Figure 5.30 Initial lesion of **bronchopneumonia** at bronchioloalveolar junction.

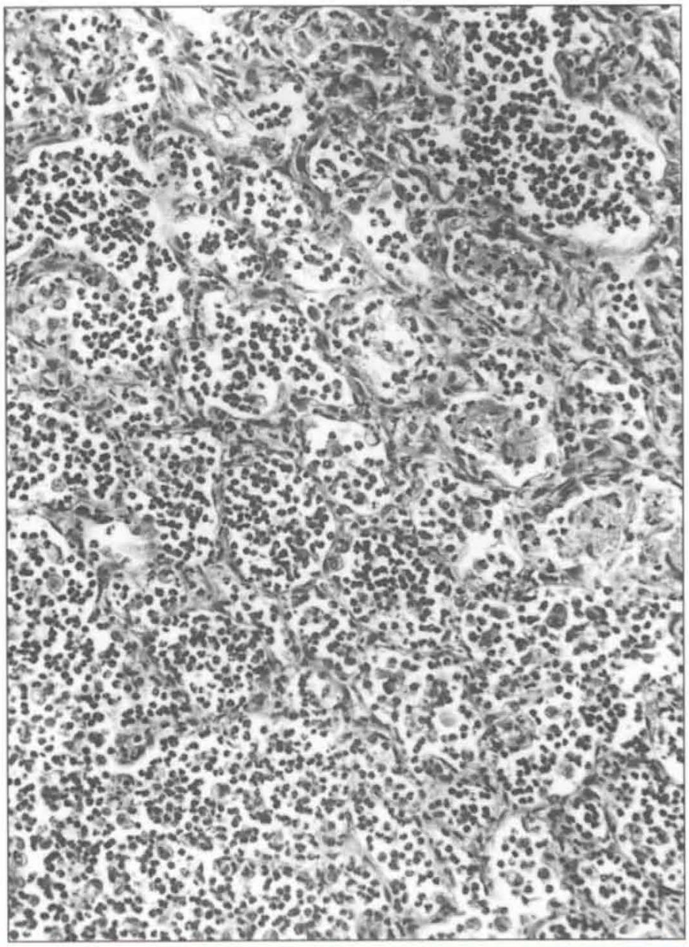

Figure 5.31 Subacute suppurative bronchopneumonia in a pig. Neutrophils fill alveoli.

Histologically, the nidus of inflammation in bronchopneumonia is in the bronchiolar–alveolar junction. In early bronchopneumonia, bronchioles and adjacent alveoli are filled with neutrophils and sometimes cell debris, mucus, fibrin, and macrophages, and the wall of the bronchiole may be edematous and infiltrated by neutrophils (Fig. 5.30). By the time the bronchopneumonia is clinically apparent, the exudate has usually filled the bronchioles and alveoli, and it is often impossible to appreciate that the lesion is centered on the terminal airways (Fig. 5.31). In mild cases the bronchiolar epithelium is usually normal; extensive bronchiolar necrosis suggests an underlying viral infection. However, bronchiolar necrosis can develop during experimental infection with *M. haemolytica* and probably with other bacteria, and is thought to represent neutrophil-mediated damage to the epithelium. Suppurative or lymphoplasmacytic inflammation may be visible in the bronchi. The alveoli in mild or early lesions are atelectatic and edematous, but this is obscured by the suppurative infiltrate in severe lesions.

Resolution and sequelae

Resolution of bronchopneumonia is possible if the infectious agent is destroyed by the immune response or antimicrobial therapy. Neutrophils rapidly undergo apoptosis, and fibrin may be removed by plasmin and/or phagocytosis by macrophages. Macrophages and extracellular debris are mostly cleared through the airways with the aid of coughing and collateral ventilation. If there is minimal damage to the alveolar septa and blood vessels, catarrhal or mild purulent bronchopneumonia can begin to resolve within 7–10 days and return to normal within 3–4 weeks. In ruminants and swine, the lack of collateral ventilation impedes clearance of alveolar exudates, and these species have a greater propensity to develop chronic suppurative bronchopneumonia.

Death from fulminant lobar bronchopneumonia may occur with only 20–40% of the lung affected. In such cases, the cause of death is not respiratory failure but rather *toxemia*, and these animals are profoundly depressed and have grossly apparent petechiation of serosal surfaces and muscles throughout the body. The extent of lung involvement in animals with chronic bronchopneumonia – up to 80% of the lung in some calves with chronic *Mycoplasma bovis* pneumonia – highlights the tremendous reserve capacity of the lung that must be consumed before bronchopneumonia causes death by simple filling of alveoli with exudate.

Chronic suppurative bronchopneumonia *develops if the infection remains active.* In many such cases, the lesions are colonized by secondary pathogens – such as *Arcanobacterium pyogenes* in cattle – and the primary cause can no longer be identified. Chronic bronchopneumonia may manifest simply as filling of bronchioles and alveoli with neutrophils, due to persistent bacterial infection and ongoing recruitment of neutrophils. In other cases, the chronic infection results in *pulmonary fibrosis, bronchiectasis, abscessation, or sequestration.* Extensive fibrinous exudate or injury to alveolar septa may heal by fibroplasia, which may either cause thickening of alveolar septa or locally extensive areas of fibrosis. Organization of fibrin-containing pleural exudate often produces *pleural adhesions. Abscesses* may develop within areas of chronic bacterial infection, and occasionally erode blood vessels to cause fatal hemorrhage.

A **sequestrum** is *a mass of necrotic lung parenchyma, separated from viable lung tissue by purulent exudate, and usually encased in a fibrous capsule.* Sequestra commonly develop from the infarcted lung tissue in contagious bovine pleuropneumonia, and in pneumonia caused by *Mannheimia haemolytica* in cattle or *Actinobacillus pleuropneumoniae* in swine. Expansion of the caseous lesions associated with *Mycoplasma bovis* appears grossly similar. The lesions vary in size from several centimeters to large masses that occupy the entire side of the lung, and are firm, gray or red, and may be friable or have a foul odor. Histologically, the sequestered tissue retains the ghost-like remnants of the alveolar architecture, but all of the cells are necrotic. The surrounding fluid exudate is key to sequestering the nonviable lung tissue, because macrophages cannot effectively swim across the exudate to remove the necrotic tissue. As a result, *sequestra are permanent and nonfunctional, and act as a nidus of persistent bacterial infection.* The term "pulmonary sequestration" describes a quite different condition in human pathology, where a congenitally anomalous mass of pulmonary tissue, which may be separate from or contiguous with the lung itself, is not connected to the bronchial tree and is perfused by an anomalous vascular supply.

Aspiration pneumonia

Aspiration pneumonia refers to pneumonia caused by aspiration of foreign material, often in liquid form, reaching the lungs through the airways. This distinguishes it from most bronchopneumonias that are caused by inhalation of tiny particles. The response to the aspirated material depends on three factors: (1) the nature of the material; (2) the bacteria that are carried with it; and (3) the distribution of the material in the lungs.

Widespread distribution of inhaled milk or combination of milk and gruel is occasionally observed in *pail-fed calves.* The course of the disease in these cases can be as short as 1 day. The gross appearance is not characteristic. The lungs remain inflated; they are hyperemic and small amounts of exudate can be expressed from the small airways. Histologically, there is acute bronchiolitis with various degrees of acute alveolitis. Lipid droplets, and sometimes plant material, can be seen in the lesions. Aspiration of ruminal contents can produce a similar picture in recumbent cattle, but in these cases the aspirated material is usually obvious, and there is often hemorrhagic tracheobronchitis.

When the distribution of foreign material is more localized, discrete foreign-body granulomas, bronchopneumonia, lobar pneumonia, or gangrene of the lungs occurs. Cattle and lambs frequently aspirate inflammatory exudate from necrotic laryngitis. Lambs with nutritional myopathy affecting the muscles of deglutition aspirate milk and plant material, including whole grain. Pigs in dry, dusty environments and fed dry finely particulate food can aspirate starch granules and particles of plants from the feed. *Any cause of dysphagia or regurgitation, including pharyngeal paralysis and megaesophagus, is likely to lead to aspiration pneumonia.* It is also a hazard of anesthesia. Aspiration of vomitus and medications occurs in all species. The aspiration of vomitus in a simple-stomached animal is often rapidly disastrous and death can occur from laryngeal spasm or acute pulmonary edema before there is time for much inflammation to develop. The possibility of aspirated material being responsible must always be considered in any case of fulminating lobar or bronchopneumonia, especially if the history suggests one of the predisposing conditions just mentioned, or if the lesions are unilateral and necrotizing. Careful search will usually reveal evidence of foreign material, but this is not the case when the material is largely or entirely liquid.

Interstitial and bronchointerstitial pneumonia

Interstitial pneumonia *(or interstitial lung disease) is a broad term that describes damage to, or inflammation involving, the alveolar or interlobular septa, which represent the interstitium of the lung.* This contrasts with *bronchitis and bronchiolitis* that involve the airways, and *bronchopneumonia* which forms exudate in the airspaces of the alveoli and distal airways. The terminology used to classify the interstitial pneumonias suffers from a lack of consensus in veterinary pathology. We use the term interstitial pneumonia to define a broad range of conditions affecting the alveolar and interlobular septa. There are many histologic patterns of interstitial pneumonia identified in human pathology, including diffuse alveolar damage, usual interstitial pneumonia, nonspecific interstitial pneumonia, organizing pneumonia, respiratory bronchiolitis, desquamative interstitial pneumonia, lymphoid interstitial pneumonia, and granulomatous interstitial pneumonia; yet the relevance of most of these terms to diseases of domestic animals has not been defined. The term "*atypical pneumonia*" has been used in the past to describe interstitial pneumonias; we suggest that its use be abandoned because it is also used for unusual forms of bronchopneumonia.

Diffuse alveolar damage

The most commonly identified form of interstitial pneumonia is diffuse alveolar damage, which represents diffuse injury to type I pneumocytes or endothelial cells in the alveolar septa, and results in formation of hyaline membranes, proliferation of type II pneumocytes, and interstitial fibrosis. Note that other authors define interstitial pneumonia synonymously with diffuse alveolar damage. *Acute respiratory distress syndrome* is a clinically defined condition with an acute onset of bilateral pulmonary disease characterized by hypoxemia but no evidence of left atrial hypertension, with diffuse alveolar damage as the histologic lesion in many cases.

Gross lesions *are widely distributed throughout the lungs, often with greater involvement of dorsocaudal regions* (Fig. 5.32). This pattern is in sharp contrast to the cranioventral distribution of lesions in most cases of bronchopneumonia. Histologically, most causes of diffuse alveolar damage follow a stereotyped pattern of response, with an acute exudative phase, subacute proliferative phase, and chronic fibrosing phase. Because of the similar histologic appearance of this response, irrespective of the etiology, identifying the specific cause in a particular case is often based on clinical investigations and identifying lesions in other organs.

In the **acute exudative phase**, the alveolar septa are congested and the alveoli contain protein-rich edema fluid with delicate

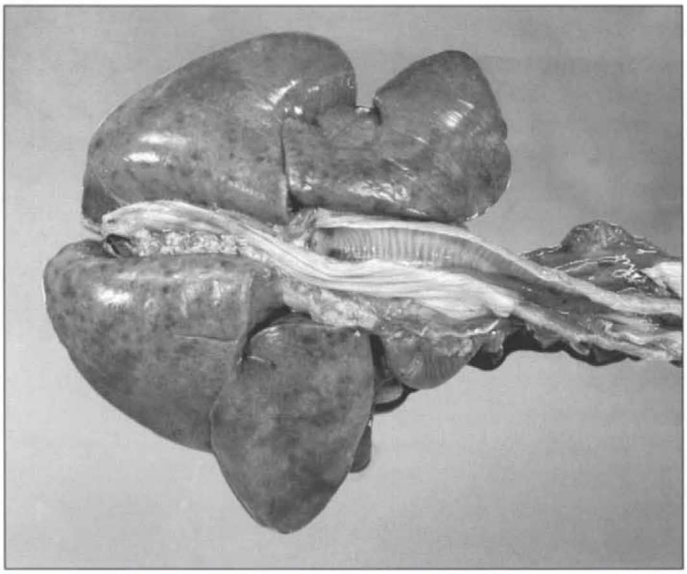

Figure 5.32 Diffuse alveolar damage in a dog. The lung is diffusely rubbery and fails to collapse. Multifocal hemorrhages are present.

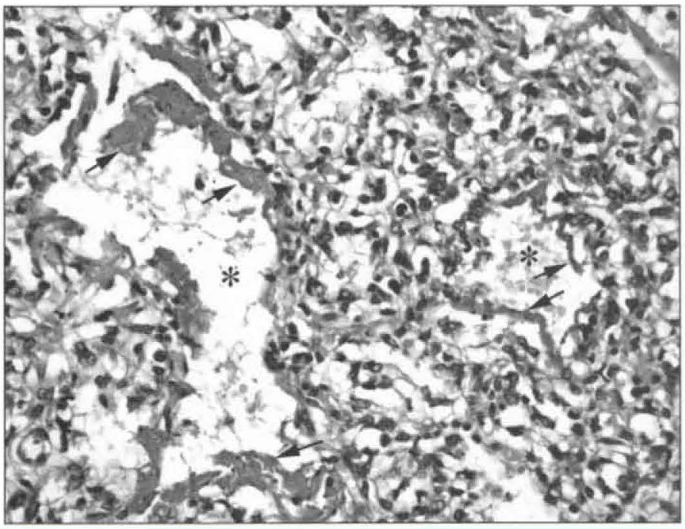

Figure 5.33 Diffuse alveolar damage in a neonatal puppy. The alveoli (asterisks) are lined by hyaline membranes (arrows), and the interstitium is thickened and hypercellular due to immaturity.

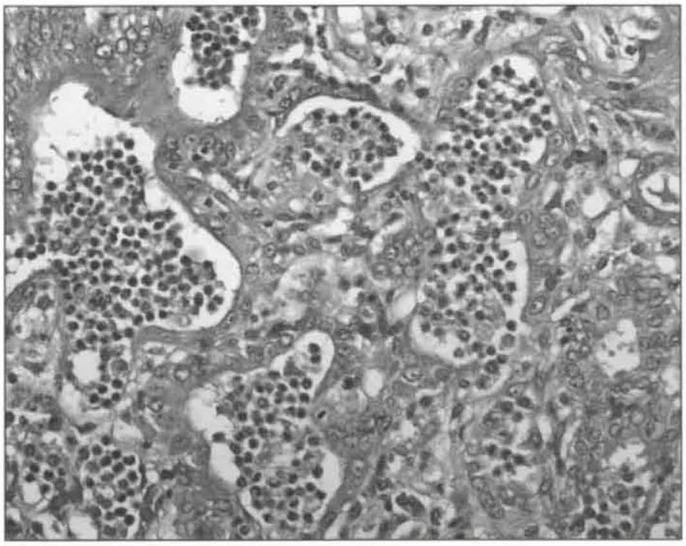

Figure 5.34 Porcine reproductive and respiratory syndrome. Alveoli are completely lined by cuboidal type II pneumocytes, and contain neutrophils and macrophages in the lumen.

interlacing fibrin strands and variable numbers of neutrophils and macrophages. However, *the characteristic lesion is the presence of hyaline membranes,* which are aggregates of fibrin, other serum proteins, and cell debris. These appear as linear masses of discrete, densely eosinophilic material lining the junction between the alveolus and the alveolar septa (Fig. 5.33). Since type I pneumocytes are 10 times less permeable than endothelial cells, injury to type I pneumocytes causes loss of interstitial fluid into the alveolus. Alveolar type II pneumocytes (and possibly type I pneumocytes) reabsorb alveolar fluid by active transport, so injury to these cells further promotes alveolar edema. Although type II pneumocytes cover only 10% of the alveolar surface, they are critical in production and recycling of surfactant lipids and proteins, and their damage leads to abnormal intra-alveolar surface tensions that may further damage the epithelium.

Type II pneumocytes *repair the alveolar epithelium by spreading along the alveolar surface, proliferating to repopulate the epithelium, secreting new basement membrane components, and differentiating into membranous type I pneumocytes.* Type II pneumocytes rapidly spread to cover the denuded alveolar surface prior to undergoing mitosis, but this feature is not recognized in histologic sections. Single type II pneumocytes are impossible to distinguish on hematoxylin and eosin-stained sections from alveolar macrophages; however, type II pneumocytes are more easily recognized when they form a single layer of cuboidal cells lining the alveolus (Fig. 5.34), and cytokeratin immunohistochemistry is useful to detect or confirm subtle lesions. Proliferation of type II pneumocytes is initially observed at 2–3 days and is extensive by 6 days after insult; it represents a dysfunctional stage of epithelial repair because these cuboidal cells block effective gas exchange. Type II pneumocytes are the major source of basement membrane if this structure has been previously damaged. If the injurious stimulus has been removed, then the type II cells differentiate into type I pneumocytes, and surplus cells undergo apoptosis. The cuboidal type II cells may no longer be visible histologically by 5–7 days after a mild single injurious stimulus, but may remain for prolonged periods if the injurious stimulus persists or in the presence of interstitial fibrosis. In some cases, the remarkable proliferation of type II pneumocytes may be mistaken for carcinoma.

Interstitial fibrosis develops in two ways. Fibrinous alveolar exudates may be invaded by fibroblasts and organized into fibrous tissue that resembles granulation tissue in a skin wound; this fibrous tissue is later incorporated into the alveolar wall and covered by type II pneumocytes. Alternatively, fibrous tissue may develop within the alveolar septum itself as a consequence of repetitive, persistent, or severe damage to epithelial or endothelial cells, or by persistent inflammation in the alveolar septum. Fibroblasts can appear within alveoli by 3–5 days after severe fibrinous exudation, collagen fibers can be detected histologically by 5–7 days, and fibrosis may be well developed by 14 days (Fig. 5.35). Myofibroblasts or smooth-muscle cells are a prominent feature of some interstitial pneumonias, such as maedi.

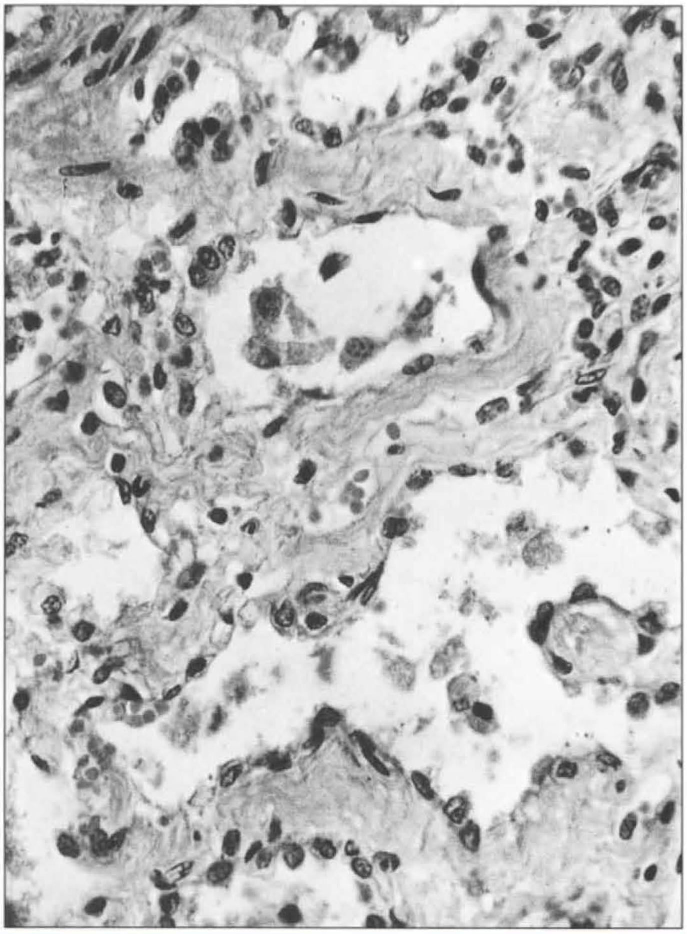

Figure 5.35 Fibrosis of alveolar septa and persistence of type II pneumocytes, as a **sequel to diffuse alveolar damage** in an ox.

The intimate encounters shared by alveolar epithelial cells, fibroblasts, and macrophages are key to understanding the chronic sequelae of diffuse alveolar damage. Normal type II pneumocytes limit fibroblast proliferation and the development of fibrosis; conversely, repetitively injured type II pneumocytes and macrophages secrete transforming growth factor-β and other growth factors that stimulate interstitial fibrosis. On the other hand, growth factors secreted by fibroblasts and macrophages promote type II pneumocyte proliferation and may preclude their differentiation to type I pneumocytes, and this possibly accounts for the observation that fibrotic alveolar septa are often lined by cuboidal epithelial cells. Alveolar fibrosis is not necessarily permanent, as fibrous tissue is remodeled and may be removed by matrix metalloproteases. However, since this process occurs over many months, and because the cause of chronic injury to the alveolar septa is often not identified or eliminated, *the finding of marked interstitial fibrosis confers a guarded prognosis*.

Diffuse alveolar damage causes hypoxemia that is refractory to oxygen supplementation, the difference between alveolar and arterial oxygen tension resulting from the barrier to diffusion of oxygen across the alveolar wall. Carbon dioxide diffuses more readily than oxygen, and hypercapnea is an inconsistent finding. Pulmonary compliance is reduced, which increases the work of breathing and may reduce the functional lung volume. Cardiac function is expected to be normal.

Table 5.7 Causes of acute or chronic diffuse alveolar damage, a form of interstitial pneumonia

- Pulmonary infections: many viruses, *Toxoplasma gondii*, *Feline infectious peritonitis virus*, ascarid larval migration, *Dictyocaulus*
- Thermal injury: inhalation of steam or smoke in barn or house fires
- Acid-induced injury from aspiration of sterile vomitus in monogastric animals
- Toxic gases: nitrogen dioxide, sulfur dioxide, chlorine, 100% oxygen, ammonia, phosgene, ozone
- Ingested toxins: paraquat, kerosene, 3-methylindole, ipomeanol, perilla mint ketone, *Brassica*, Crofton weed
- Septicemia and endotoxemia, disseminated intravascular coagulation, possibly shock
- Massive trauma, strangulation, near drowning, pulmonary contusion
- Ischemic lung injury: lung lobe torsion, reperfusion injury
- Chronic left heart failure
- Pancreatitis, uremia, parvoviral enteritis, irradiation
- Surfactant dysfunction: prematurity (hyaline membrane disease), inherited defects in surfactant proteins B or C
- Ventilator-induced lung injury
- Adverse drug reactions
- Acute hypersensitivity pneumonitis

The causes of diffuse alveolar damage are legion (Table 5.7), and most cause direct injury to alveolar epithelial cells or capillary endothelial cells in the alveolar septa. Many **infectious agents** infect type I pneumocytes, including respiratory syncytial viruses, parainfluenza viruses, herpesviruses, *Feline calicivirus*, adenoviruses, and *Toxoplasma gondii*. Many viruses also infect airway epithelial cells and cause bronchiolar necrosis; this pattern of damage to bronchioles and alveoli represents bronchointerstitial pneumonia, and is discussed below.

Noninfectious causes of direct injury to type I pneumocytes include *thermal and chemical injury* from inhalation of steam or smoke, as occurs in barn or house fires, *acid-induced injury* from aspiration of sterile vomitus in monogastric animals (associated with vomiting, anesthesia, or seizures), and inhalation of *toxic gases* such as chlorine, nitrogen dioxide, sulfur dioxide, phosgene gas, and high concentrations of oxygen. Other xenobiotics must be *metabolized* to reactive intermediates that damage the alveolar epithelium. These include 3-methylindole, ipomeanol, perilla mint, and Crofton weed, and are considered in the section on Toxic lung injury, p. 573.

Ventilator-induced lung injury occurs when high tidal volumes cause injury to the alveolar septa and/or the small bronchioles. The most intuitive mechanism is overdistension of alveoli with damage to the septa, leading to interlobular emphysema, pneumomediastinum, or pneumothorax. Less obvious is the repetitive trauma suffered by alveoli and small bronchioles as they collapse at the end of expiration and are subjected to the high pressures required for reinflation. This mechanical strain and shear stress damages the type I pneumocytes and endothelial cells, and thus results in alveolar edema, formation of hyaline membranes, and infiltration of neutrophils in the alveoli or terminal bronchioles. Finally, ventilator-induced injury may result in neutrophil influx and increased levels of proinflammatory cytokines in the alveolar lining fluid, and this inflammatory response may be stimulated by abnormal stretch or strain pressures on macrophages or epithelial cells. The histologic lesions may include hyaline membranes, bronchiolar necrosis, and/or neutrophil infiltration into alveoli, but it is usually impossible to determine if these lesions are caused by mechanical ventilation or by pre-existing lung

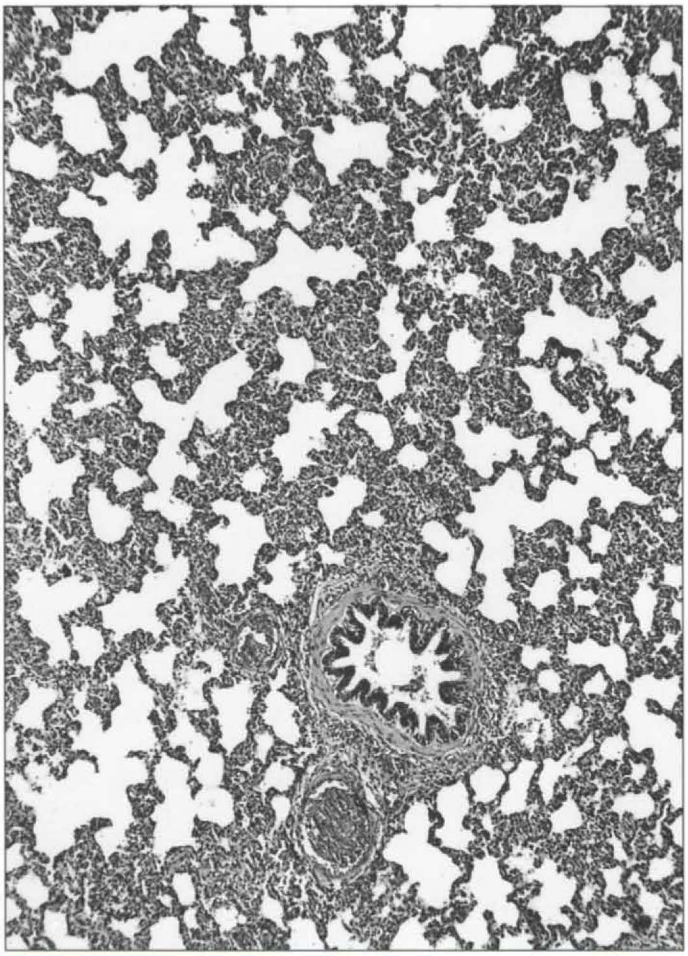

Figure 5.36 Acute interstitial pneumonia in septicemic salmonellosis in a pig. Thickening of alveolar walls by leukocytes.

disease. Pneumothorax, if present, is more suggestive of ventilator-induced injury, if the clinical history is supportive.

Septicemia and endotoxemia *are well-recognized causes of interstitial lung lesions.* Sepsis induces an inflammatory cascade that affects the function of endothelial cells in the alveolar septa, by cytokine-induced retraction of endothelial cells leading to increased permeability, neutrophil-mediated damage to the endothelium or matrix proteins, and/or by promoting capillary thrombosis. Sepsis also causes surfactant dysfunction; in addition to direct injury to surfactant-producing type II pneumocytes, the serum proteins that flood the alveoli inhibit surfactant function. This in turn provokes atelectasis and abnormal surface tensions in the alveoli that physically damage the type I pneumocytes.

Septicemic lung injury may manifest as a pulmonary interstitial reaction, in which the alveolar septa appear hypercellular due to hypertrophy of pulmonary intravascular macrophages and/or aggregation of neutrophils (Fig. 5.36). With more severe disease, there are diffuse or patchy areas within the lung of marked congestion and serofibrinous exudation into the alveoli. Although the alveoli contain loosely fibrillar deposits of fibrin, hyaline membranes and type II pneumocyte proliferation are variably identified in septicemic lung injury. Thrombi may be identified in small venules and capillaries, but this is an infrequent and inconsistent finding in animals dying of septicemia.

Additional causes of diffuse alveolar damage *include massive trauma, shock, disseminated intravascular coagulation, pancreatitis, and uremia.* Although these associations are well established, the exact mechanisms are poorly described. Neutrophil-induced lung injury contributes to diffuse alveolar damage in several experimental models, but the importance of this effect in natural disease is controversial.

Bronchointerstitial pneumonia

Bronchointerstitial pneumonia is characterized by the presence of both bronchiolar necrosis and diffuse alveolar damage, and is thus a manifestation of injury to both the bronchiolar and the alveolar epithelium. Bronchointerstitial pneumonia is commonly caused by aerogenous viral infections that infect both of these cell types, or by toxins that are metabolized by both Clara cells in the bronchioles and type II pneumocytes in the alveoli. This pattern is not to be confused with bronchopneumonia, in which the bronchioles and alveoli are filled with leukocytes as a result of bacterial infection, but necrosis of the bronchiolar or alveolar epithelium is not usually present.

Other forms of interstitial pneumonia

Several forms of pneumonia encountered in veterinary pathology clearly target the alveolar or interlobular septa, but do not follow the pattern of diffuse alveolar damage. Some examples include the following:

- **Granulomatous pneumonia**, caused by mycobacteria, fungi, *Actinobacillus*, *Actinomyces*, *Nocardia*. Miscellaneous causes of granulomatous pneumonia include silicosis, intravenous injection of Freund's complete adjuvant or immunostimulants containing mycobacterial cell wall extracts, and porcine dermatosis vegetans.
- **Maedi**, in which there are perivascular and peribronchiolar cuffs of lymphocytes, and hyperplasia of smooth muscle in the alveolar septa, but usually minimal type II pneumocyte proliferation.
- **Porcine reproductive and respiratory syndrome**, characterized by thickening of alveolar septa with mononuclear cells, and variable hyperplasia and necrosis of pulmonary macrophages. Type II pneumocyte proliferation may be present, but is usually not prominent.
- **Metastrongylid nematode infections**, such as *Muellerius* and *Aelurostrongylus*, in which the nematodes inhabit the alveoli and terminal bronchioles, and incite a chronic inflammatory response, smooth-muscle hyperplasia, and occasionally fibrosis of the alveolar septa.
- **Pneumoconiosis**.

Specific noninfectious interstitial pneumonias

Anaphylaxis and hypersensitivity pneumonitis

Anaphylaxis and anaphylactoid reaction affect the lungs in cattle, resulting in bronchoconstriction, apnea, pulmonary edema with blood-stained froth in the airways, emphysema, pulmonary hypertension, and systemic hypotension. Bronchoconstriction without marked alveolar changes is more typical of anaphylaxis in cats and horses. The lungs are congested and contain alveolar and interlobular edema, the trachea and bronchi contain froth, and emphysema may result from the marked dyspnea. Congestion or edema of the larynx is prominent and potentially fatal in some cases.

Hypersensitivity pneumonitis (extrinsic allergic alveolitis) in animals occurs mainly in adult cattle reared in confinement and rarely in horses, and often affects multiple animals in the group. It results from chronic inhalation of spores of thermophilic actinomycetes (especially *Saccharopolyspora rectivirgula*, formerly *Micropolyspora faeni*) in moldy hay, leading to inflammatory reactions that occur through several mechanisms concurrently. The bacteria directly activate complement by the alternative pathway and there is solid evidence for immune-complex (type III) reactions, even though the morphology suggests a delayed (type IV) hypersensitivity reaction. In cattle, tiny gray foci may be grossly visible throughout the lung. Lymphoplasmacytic or granulomatous infiltrates are consistently present in the alveolar septa and often around the bronchi and bronchioles, and multinucleate macrophages are occasionally seen. The more characteristic lesions, present during acute exacerbations of disease, are noncaseating granulomas in the alveoli that are accompanied by edema and infiltration of eosinophils, neutrophils, and lymphocytes. Proliferation of alveolar type II pneumocytes, fibrosis of the alveolar septa and peribronchiolar tissue, and bronchiolitis obliterans may be noted in chronic cases. Hyaline membranes are uncommon but may occur following acute challenge.

Eosinophilic interstitial lung diseases

The eosinophilic interstitial pneumonias are a compilation of pulmonary diseases united by the presence of eosinophils in the alveoli or alveolar septa. They generally correspond to the clinical term **pulmonary infiltrates with eosinophilia**, defined by blood eosinophilia and radiographic evidence of generalized pulmonary infiltrates. The best described are those caused by parasites, which are discussed more fully in later sections but include both adult parasites residing in the lung and migrating larva. Less well characterized are those forms that probably represent hypersensitivity reactions. Those primarily affecting the airways (including eosinophilic bronchopneumopathy) are discussed above. **Eosinophilic pulmonary granulomatosis** is a rare condition in dogs, characterized by chronic cough, variable dyspnea, and blood eosinophilia. The lungs contain nodular necrotizing lesions formed by eosinophils, epithelioid macrophages, and fibrosis, with type II pneumocyte proliferation and eosinophil infiltrates in the surrounding alveoli. Many dogs with eosinophilic pulmonary granulomatosis have heartworm disease, although microfilariae are not detected in the granulomas. Other cases are clearly not infected with *Dirofilaria*, and may be hypersensitivity reactions. **Less severe eosinophilic pneumonias** are poorly described in dogs and cats, in part because the steroid-responsiveness of many cases precludes their examination at necropsy. The alveoli contain eosinophils, lymphocytes, and macrophages, and the degree of fibrosis is variable. **Other causes** of eosinophilic lung disease in dogs and cats include eosinophilic bronchitis and eosinophilic bronchopneumopathy (discussed above), angiotropic T-cell lymphoma (lymphomatoid granulomatosis), eosinophil infiltrates associated with carcinomas and lymphomas, other parasitisms, and fungal infections. Drug reactions cause eosinophil-rich lesions in humans, but are not described in dogs and cats.

Acute interstitial pneumonia in feedlot cattle

Interstitial pneumonia commonly causes an acute onset of dyspnea and open-mouth breathing in feedlot beef cattle, particularly those approaching slaughter weights, and is most prevalent in the summer and autumn. Heifers are disproportionately affected in many reports, and the case fatality rate is high. The gross lesions are often variegated due to a lobular distribution, and are most prominent in the dorsocaudal lung. The red, rubbery, edematous, heavy lungs fail to collapse when the chest is opened, and interlobular and subpleural emphysema are frequent. Many cases have concurrent gross lesions of acute or chronic bacterial bronchopneumonia in the cranioventral lung. *Hyaline membranes* are the characteristic histologic feature of the acute lesions, and *type II pneumocyte proliferation* is often present. More variable lesions include bronchiolitis obliterans, infiltration of neutrophils and eosinophils, and patchy alveolar hemorrhages that possibly arise from emphysematous rupture of alveolar septa.

The cause is uncertain. Epidemiologic evidence suggests 3-methylindole, melengestrol acetate (fed to feedlot heifers to suppress estrus), dusty environment, hot weather, and concurrent bacterial infection as possible causes or contributing factors. Although *Bovine respiratory syncytial virus* occasionally causes acute bronchointerstitial pneumonia soon after arrival in feedlots, it seems not to cause diffuse interstitial pneumonia late in the feeding period. Some more chronic cases, in which eosinophils and granulomas are present, may represent a hypersensitivity reaction.

Interstitial and bronchointerstitial pneumonia in foals

Bronchointerstitial pneumonia in 1–4-month-old foals has been recognized as a sporadic disease for many years, yet the etiology remains mysterious. Affected foals may be found dead without premonitory signs or develop acute onset of severe dyspnea, tachypnea, and pyrexia, with profound hypoxemia and variable hypercapnea. Case fatality rates are high and the foals respond poorly to therapy. It remains possible that there is not a single etiology for this disease, but that the reaction pattern may result from any of several infectious and noninfectious insults.

At necropsy, lesions are present throughout the lungs in a diffuse or lobular pattern. The lungs are firm, heavy, edematous, reddened, and fail to collapse. Concurrent lesions of *Rhodococcus equi* pneumonia are present in up to 40% of cases, with cranioventral bronchopneumonia or scattered foci of liquefactive pyogranulomatous pneumonia. *Histologic lesions* reflect the bronchointerstitial pneumonia, and include necrosis of the epithelium lining terminal bronchioles, alveolar hyaline membranes, exudation of fibrin and few neutrophils in alveoli, and syncytial cells in the bronchi or alveoli. The prevalence of syncytial cells and the extent of bronchiolar versus alveolar lesions are variable, supporting the hypothesis that more than one etiology may induce this pattern of reaction.

A viral etiology seems likely, as the age of affected foals correlates with waning maternal passive immunity. A respiratory syncytial virus and *Equid herpesvirus 2* (EHV-2) have been identified in some cases using polymerase chain reaction, indirect immunofluorescence, and enzyme-linked immunosorbent assay antigen detection tests for respiratory syncytial virus; or virus isolation and indirect immunofluorescence tests for EHV-2. However, attempts to identify viral agents in the vast majority of cases have been unsuccessful. Other proposed causes include an aberrant response to *R. equi* or other bacterial pathogens, a complication of hyperthermia resulting from bacterial pneumonia or treatment with erythromycin, endotoxemia, and xenobiotics including 3-methylindole, pyrrolizidine alkaloids, and pentachlorophenol that are metabolized by Clara cells and type II pneumocytes.

Equine multinodular pulmonary fibrosis

A progressive fibrotic lung disease occurs in adult horses. The lesions are restricted to the alveolar parenchyma, and form *distinctive, grossly apparent nodules of pulmonary fibrosis*. These lesions can be tumor-like, with discrete borders separating the edge of the fibrotic nodule from the unaffected alveolar parenchyma (Fig. 5.37A). The second gross manifestation is of multiple coalescing foci of fibrosis. In each instance, the nodules of fibrosis involve all of the lung lobes. Histologically, the foci of fibrosis follow the septal walls, which are expanded by abundant mature collagen; the lumens of the airspaces frequently contain a mixed inflammatory infiltrate of macrophages and neutrophils. Small numbers of macrophages within the infiltrate are hypertrophic and there are large eosinophilic intranuclear viral inclusion bodies within these cells (Fig. 5.37B). Preliminary analysis of affected tissues has identified consistent presence of a γ-herpesvirus, similar to *Equid herpesvirus 5*. The association of the virus with the fibrotic lung disease remains only an association, and its role in causation is not clear.

Interstitial pneumonia in dogs

Diffuse alveolar damage manifesting clinically as **acute respiratory distress syndrome** is occasionally encountered in dogs. Affected animals develop acute onset of dyspnea with tachypnea, and variable coughing and lethargy, which is usually rapidly progressive and fatal within 3 days. Findings considered secondary to dyspnea include pneumothorax and subcutaneous emphysema, and gastroesophageal intussusception. At necropsy, the lungs are diffusely firm with a liver-like texture, edematous and heavy, and mottled. *Hyaline membranes* are a nearly consistent feature, with proliferation of type II pneumocytes in the less fulminant cases. The predisposing causes include septicemia, bacterial pneumonia in other areas of lung, aspiration of sterile gastric acid, massive trauma, shock, and strangulation. Many cases are idiopathic. Similar findings may be identified in lung lobes that have undergone torsion, but are restricted to the affected lobe.

A syndrome of interstitial fibrosis is described in 6–12-year-old **West Highland White Terrier dogs** with chronic dyspnea, exercise intolerance, or coughing. Histologic lesions include deposition of collagenous matrix in the alveolar septa and interstitial infiltrates of lymphocytes, plasma cells, and macrophages; severely affected cases have proliferation of alveolar type II pneumocytes. The interstitial fibrosis may be diffuse, regional, or multifocal in distribution, and is quite variable in severity. Mildly affected cases have discontinuous deposition of matrix in alveolar septa that is most obvious when it forms concentric rings around alveolar capillaries.

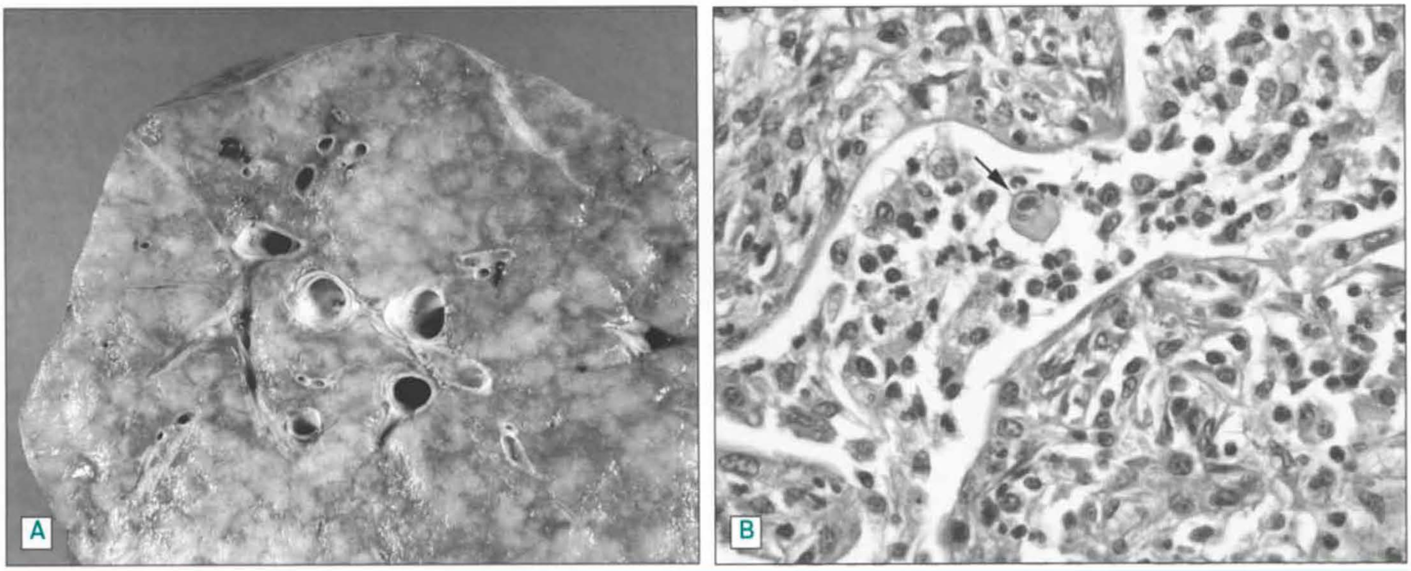

Figure 5.37 Equine multinodular pulmonary fibrosis. A. The entirety of the lung parenchyma contains pale nodules of fibrosis separated by darker regions of less affected lung. **B.** Within the remnant airspaces are neutrophils and macrophages, with small numbers of large macrophages containing prominent intranuclear viral inclusion bodies (arrow).

An apparently inherited condition characterized by diffuse alveolar damage is reported in 4–10-month-old **Dalmatian dogs**. Affected dogs have a short course of tachypnea, increased respiratory noise, and dyspnea. The lungs are diffusely wet, heavy, firm, and purple-red with scattered hemorrhages. The microscopic findings include a patchy distribution of edema, infiltration of lymphocytes and plasma cells, hyaline membranes and type II pneumocyte proliferation, metaplasia and atypia of the bronchiolar epithelium, and focal fibrosis.

Idiopathic pulmonary fibrosis in cats

Chronic interstitial lung disease is uncommon but not rare in cats, and is usually seen as *chronic progressive tachypnea, respiratory distress, and cough in middle-aged to older cats*. The disease has been likened to idiopathic pulmonary fibrosis (cryptogenic fibrosing alveolitis) in humans. Lesions are often present throughout the lung, but tend to be patchy or multinodular rather than diffuse. The histologic lesions include multifocal or irregular areas in which alveolar septa are remarkably thickened by smooth muscle, fibrosis, and focal clusters of fibroblasts. Alveoli are lined by prominent cuboidal or columnar epithelial cells, which often contain mucus or occasionally undergo squamous metaplasia (Fig. 5.38). There is variation in the relative prominence of the epithelial proliferation and matrix deposition. Interstitial infiltration of lymphocytes is a variable finding, and concurrent bronchioloalveolar carcinomas are identified in some affected cats.

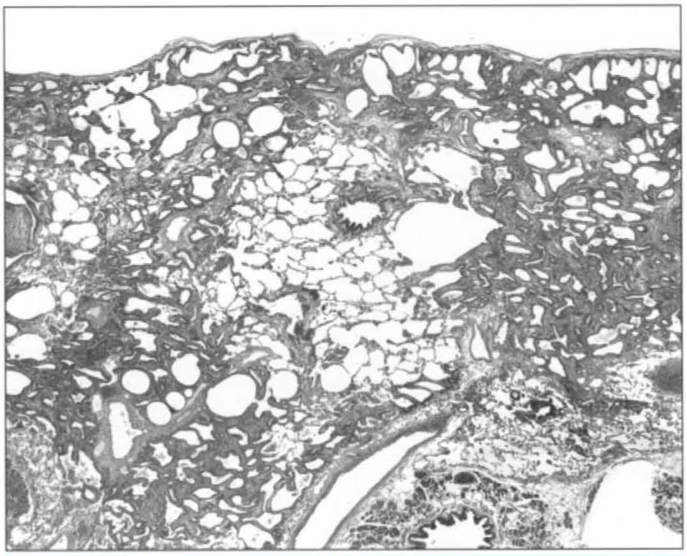

Figure 5.38 Feline idiopathic pulmonary fibrosis. Lung remodeling is patchy, with fibrosis and honeycomb lung interspersed with relatively unaffected lung. Note the extensive subpleural involvement.

Neonatal respiratory distress syndrome

Interstitial and bronchointerstitial pneumonia is common in neonatal foals and is occasionally encountered in other species. In foals, the causes include *Equid herpesvirus 1*, septicemia, hyaline membrane disease, and meconium aspiration. Other causes of respiratory disease in neonates include bronchopneumonia secondary to placentitis or aspiration of ingesta, and persistent pulmonary hypertension.

The **biology of pulmonary surfactant** *is central to the pathogenesis of hyaline membrane disease.* Surfactant is composed of dipalmitylphospatidyl-choline (DPPC, which is responsible for much of the surface tension-lowering function), other lipids, and the surfactant proteins (SP) A–D. Surfactant lipids are synthesized in type II pneumocytes and some are also produced by Clara cells, initially stored in lamellar bodies, then secreted on to the alveolar surface, where they arrange in a functional surface-active form known as *tubular myelin* that adsorbs to the alveolar air–liquid interface. The biology of the system is quite dynamic: with each breath, some of the tubular myelin is converted to a less functional vesicular form that is recycled by type II pneumocytes or degraded by alveolar macrophages. SP-A, SP-B, and SP-C are important for secretion and recycling of the surfactant lipid, formation of tubular myelin, and the proper insertion of these lipids into the alveolar surface film; SP-A and SP-D also function in innate defense of the lung.

Neonatal hyaline membrane disease is well recognized in premature or full-term foals, and is occasionally seen in premature puppies, calves, lambs, and piglets. The pathogenesis in domestic species is assumed to result from a *failure of the immature type II pneumocytes to secrete functional surfactant*, leading to elevations in surface tension that cause alveoli and small bronchioles to collapse with each exhalation. The tensions and shear stresses during reinflation of these collapsed airspaces injure type I pneumocytes and Clara cells. Abnormalities of surfactant have been documented in premature calves with hyaline membrane disease, but have not been adequately investigated in other species of domestic animals. Fetal hypothyroidism and possibly hypoadrenocorticism are causes of the condition in piglets, because thyroid hormone is necessary for maturation of type II pneumocytes. Other contributing factors in all species are fetal asphyxia, aspiration of amniotic fluid, reduction in pulmonary arteriolar blood flow, and inhibition of surfactant by fibrinogen, other serum constituents in edema fluid, or by components in aspirated amniotic fluid.

Affected foals have respiratory distress from the time of birth, an expiratory grunt or "bark," hypoxemia, and in some cases heart failure and/or convulsions and opisthotonos. The lungs are diffusely atelectatic, plum red, rubbery in texture, and sink or become partially submerged in formalin. Histologically, in addition to the thickened hypercellular alveolar septa expected in immature lung, hyaline membranes line the collapsed alveoli and sometimes the small bronchioles. Alveoli are edematous, and cellular debris is occasionally noted. **Bronchopulmonary dysplasia**, a chronic complication of prematurity, mechanical ventilation, and oxygen therapy in human infants, is characterized by alveolar hypoplasia, thickening of alveolar septa by type II pneumocyte proliferation and fibrosis, bronchiolar damage, and medial hypertrophy of pulmonary arteries; this complication is rare in domestic animals.

Meconium aspiration syndrome is described in human infants, neonatal calves, and rarely in other species. Affected lungs contain variable but usually low amounts of amorphous yellow-orange meconium, keratin, and/or squamous epithelial cells, associated with atelectasis, hemorrhage, and a mild but diffuse alveolar infiltrate of neutrophils, macrophages, and occasional multinucleate cells. Recent investigations of human neonatal mortalities have *questioned whether aspiration of meconium is a cause of the condition, or merely a frequent concurrent finding*. These studies suggest that chronic asphyxia due to placental insufficiency, placentitis causing neonatal sepsis, or acute asphyxia due to prolonged parturition may cause or at least exacerbate the pulmonary lesions and pulmonary hypertension that are characteristic of meconium aspiration syndrome.

Familial forms of neonatal respiratory distress are occasionally encountered but not documented in domestic species. Interstitial pneumonia caused by mutation of the surfactant protein genes are described in humans and rodents, and their manifestations vary between genotypes and species: SP-A deficiency is associated with bronchopulmonary dysplasia and/or increased susceptibility to bacterial infection; SP-B mutations result in alveolar proteinosis, failure of formation of tubular myelin, and/or diffuse alveolar damage; SP-C mutations in humans cause fibrosis of the alveolar septa with infiltration of mononuclear cells, similar to that seen in idiopathic pulmonary fibrosis; and SP-D-deficient mice develop alveolar lipidosis with type II pneumocyte proliferation. A familial form of neonatal respiratory distress is described in pigs, and may result from pulmonary dysmaturity due to congenital hypothyroidism. Affected piglets have diffuse alveolar damage with hyaline membranes and bronchiolar necrosis, and features suggesting hypothyroidism, including mildly prolonged gestation, fine hair coat, generalized edema, and thyroid follicular hyperplasia with lack of colloid.

Pneumoconiosis

Pneumoconiosis – lung disease ensuing from inhalation and retention of inorganic dusts – is uncommon in animals because they lack occupational exposures that are the basis for most human cases. In general, inorganic dusts are engulfed by and persist within macrophages, which secrete mediators that induce the *characteristic fibrosis and granulomatous inflammation*. Mild pulmonary **anthracosis** is a common incidental finding in city-dwelling animals or those cohabiting with cigarette smokers, in which carbon particles accrue within macrophages adjacent to airway bifurcations. **Asbestosis** is characterized by *asbestos bodies* – linear masses with globose ends formed of asbestos encrusted with ferritin – within granulomatous and fibrosing lung lesions. Sheep are used as an experimental model of the disease, but natural cases are rare. Asbestos-associated mesothelioma is rarely suggested in domestic animals.

Silicate pneumoconiosis in horses and, rarely, dogs is the only reported clinically important pneumoconiosis in animals, and occurs in certain geographic areas containing crystalline forms of free silica in the soil. Particles that are 0.5–5 μm in size are most likely to be retained in the distal airspaces, and filamentous particles are more likely to cause disease than amorphous ones. The clinical signs included weight loss, exercise intolerance, and dyspnea. Miliary lesions are distributed throughout the lung, and consist of extensive areas of fibrosis containing multifocal granulomatous infiltrates, often with necrosis and mineralization in the centers. Birefringent, eosinophilic, or brown crystals are indistinctly visible in the cytoplasm of the macrophages, or sometimes also free in the tissue, and are best detected by electron microscopy and identified by X-ray spectroscopy.

Lipid pneumonia and alveolar filling disorders

Lipid pneumonia *is a special form of aspiration pneumonia in which droplets of oil are aspirated into the lung.* Spectacular flooding of the lungs occurs when mineral oil is drenched through a stomach tube accidentally placed into the lung of horses or cattle with gastrointestinal disease, or more variable amounts may be aspirated if the oil is carelessly given per os. Cases in cats result from administration of laxatives containing mineral oil. Oily droplets may be noticed in the trachea and bronchi, or when sections of lung are immersed in formalin. The reaction is typically dominated by macrophages, but the appearance depends on the nature of the oil. In general, *vegetable oils* such as olive oil are not irritating and they are eventually resorbed with little reaction or fibrosis. *Oils of animal origin* are irritants and provoke early exudation of serofibrinous fluid and leukocytes. This is later replaced by foamy macrophages and giant cells that fill the alveoli; the alveolar septa are thickened by mononuclear cells and fibrosis. The oil is ultimately resorbed. The purest cellular response occurs to *mineral oil*, which is the usual offender in animals. Mineral oil can be identified by its permanence and by its failure to stain with osmic acid. The lipid is both extracellular and intracellular. Lipid-laden macrophages tend to fill the alveoli, and in time, they accumulate in the lymphatics that surround the bronchi and blood vessels. Fibrosis of alveolar septa and proliferation of alveolar type II epithelial cells are conspicuous, and the foamy macrophages tend to be incorporated into the alveolar septa by extension of the fibroplasia. Unless complicated by secondary bacterial infection, the lesions have a characteristic yellowish, homogeneous, or finely mottled appearance. The bronchial lymph nodes occasionally contain droplets of oil. *Pneumonias caused by aspiration of exogenous lipid must be differentiated from the so-called endogenous lipid pneumonias described below.* The most important distinguishing feature is that, in lipid aspiration pneumonias, there are extracellular globules of lipid. In paraffin-embedded sections, these appear as clear spherical spaces with distinct borders formed by the compressed cytoplasm of macrophages and giant cells.

Alveolar filling disorders *are a group of conditions characterized by accumulation of abnormal material within alveoli.* They are usually incidental findings but are occasionally responsible for clinical disease. In general, material may accumulate in alveoli because its clearance is impeded by obstructed airways, it is produced in excess, or its removal is impaired. These conditions are often overlapping, and include alveolar histiocytosis, endogenous lipid pneumonia, alveolar proteinosis, alveolar phospholipidosis, pulmonary hyalinosis, and alveolar microlithiasis.

Alveolar histiocytosis and **endogenous lipid pneumonia** (foam-cell pneumonia, cholesterol pneumonia) *are opposite ends of a spectrum characterized by focal accumulations of foamy macrophages in alveoli.* The condition is mostly encountered in laboratory rodents and mustelids. Endogenous lipid pneumonia is infrequently reported in cats, and minor lesions of alveolar histiocytosis are common in dogs. Many cases are idiopathic, but some are sequelae to obstruction of airways by exudates, bronchoconstriction, tumors, or anomalous bronchi, with the result that lipids such as surfactant accumulate within alveoli. Drug-induced alveolar phospholipidosis in laboratory rodents is a well-described sequel to administration of a group of cationic amphophilic drugs. Lipid storage diseases and injury to type II pneumocytes by particulates and irritant gases are additional causes described in humans. The lesions should be distinguished from the foamy macrophages encountered in *Pneumocystis*, *Histoplasma*, *Leishmania*, or environmental mycobacterial infections. Grossly, the lungs have irregularly distributed, often subpleural, yellow-white, firm foci that appear as sharply defined flecks or bulging nodules that may exceed 1 cm diameter (Fig. 5.39). Histologically, *lesions of alveolar histiocytosis consist of alveoli filled with foamy macrophages*, with only small amounts of interstitial fibrosis and accumulation of lymphocytes and plasma cells. The lesion is considered *endogenous lipid pneumonia* if lipids can be demonstrated within the macrophages by oil red O or Sudan black stains on frozen sections. In severe cases, there are intracellular and extracellular cholesterol crystals (but no extracellular lipid droplets), more severe interstitial fibrosis, accumulation of neutrophils and mononuclear cells, and type II pneumocyte proliferation. The large cholesterol crystals stimulate development of giant cells and intra-alveolar fibroplasia.

Alveolar proteinosis *(lipoproteinosis) is a rare but clinically significant disorder characterized by accumulation within alveoli of acellular eosinophilic material consisting of surfactant proteins and phospholipids.* The material is strongly periodic acid–Schiff (PAS)-positive and diastase-resistant, and ultrastructurally consists of lamellar and tubular myelin-like arrays. Alveoli may be lined by type II pneumocytes, but inflammation and fibrosis are usually minimal. The accumulation of surfactant lipids and proteins may result when they are produced in excess by type II pneumocytes, as occurs in rabbits and rats following inhalation of silica dust, surfactant protein (SP)-B deficient humans, or SP-D knockout mice. Alternatively, impaired degradation of these lipids and proteins by alveolar macrophages induces a similar lesion, as occurs in granulocyte–macrophage colony-stimulating factor

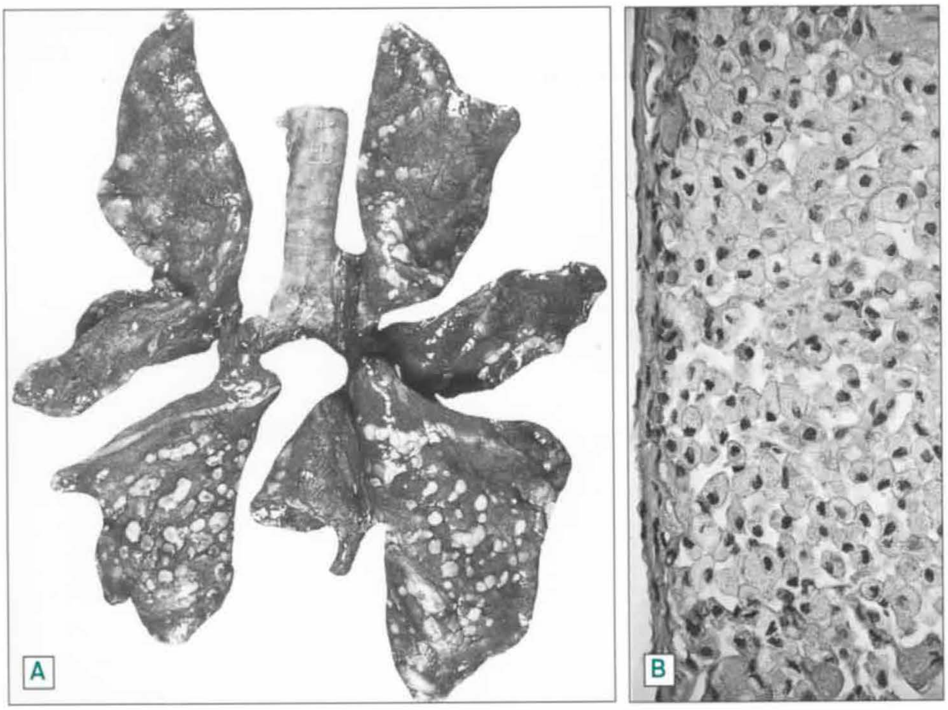

Figure 5.39 Endogenous lipid pneumonia in a cat. **A.** Multiple discrete pale subpleural nodules, consisting of (**B**) accumulation of foamy macrophages within alveoli.

(GM-CSF) knockout mice, humans with autoantibodies to GM-CSF, interleukin-10-induced inhibition of GM-CSF function, or inherited absence of the receptor. A similar lesion occurs in goats with pneumonia caused by *Caprine arthritis encephalitis virus*.

Pulmonary hyalinosis, *which consists of multifocal accumulations of macrophages and giant cells containing hyaline or laminated material*, is seen as an incidental finding in the lungs of old dogs. Histologically, the cytoplasm of macrophages and giant cells is greatly distended by amorphous or laminated, amphophilic, strongly PAS-positive material. This finding is in contrast to the extracellular deposits seen in pulmonary alveolar microlithiasis, discussed in the next section.

Pulmonary mineralization and alveolar microlithiasis

Metastatic mineralization of the pulmonary interstitium is a feature of uremic pneumonopathy in dogs with chronic renal failure, and similar lesions may result from hypercalcemia, hyperphosphatemia, or alkalosis. Mineralization occurs within the smooth muscle and connective tissue fibers in alveolar septa, pulmonary veins, and the walls of bronchioles. There are often no gross lesions, or the lung may be gritty and porous. Alveoli are edematous and contain increased numbers of macrophages, but other evidence of inflammation is minimal in dogs. Alveolar septa and pulmonary veins, like the gastric mucosa, may be predisposed to mineralization because of the alkaline microenvironment resulting from carbon dioxide excretion. Mineral deposits in the lung undergo *ossification* with time.

Pulmonary alveolar microlithiasis is characterized by *laminated and mineralized PAS-positive mineralized concretions* that form extracellular deposits in the alveoli and alveolar septa, and may become ossified. This condition is rarely reported in animals, but may be associated with clinical signs of respiratory disease if the lesions are extensive. An analogous condition in humans has an apparently familial basis in some cases, while others are sequelae to heart failure. Minor lesions of *focal ossification of the pulmonary interstitium* are occasionally encountered as incidental findings in dogs and cattle.

Toxic lung injury

The lung is the target of toxic injury by several mechanisms: inhalation of gases or fumes that are directly toxic to epithelial or endothelial cells, ingestion or inhalation of toxins that are metabolized to reactive intermediates mainly by Clara cells or type II pneumocytes, hypersensitivity reactions, effects of inhaled persistent fibers such as asbestos or fiberglass, and xenobiotic-induced carcinogenicity.

Severe lung injury from **inhalation of toxic gases** is rarely encountered in domestic animals because they do not have the occupational exposures that are usually responsible in humans. The anatomic location of injury by inhaled toxins depends on the dose, chemical reactivity, aqueous solubility, and particle size. Water-soluble gases such as sulfur dioxide and ammonia usually cause upper respiratory injury, whereas less soluble gases such as nitrogen dioxide are more widely distributed and may cause bronchiolar or alveolar injury. Poisoning of cattle, pigs, and chickens by nitrogen dioxide (silo gas) may cause massive mortality with lesions of pulmonary edema and congestion, necrosis of bronchial and bronchiolar epithelium, and alveolar hemorrhage and/or fibrin exudation. Acute pulmonary injury caused by **smoke inhalation** is seen in animals trapped in burning buildings. When asphyxiation is not immediate, the combined chemical and heat effects of smoke can cause widespread epithelial necrosis and exudation, and death within a few days.

Exposure to 85–100% **oxygen** damages capillary endothelium and type I pneumocytes, and causes serofibrinous exudation in alveoli or diffuse alveolar damage. In intensive care patients, it may be impossible to determine if diffuse alveolar damage was caused by the underlying disease, or hyperoxic or ventilator-induced lung injury. *Reactive oxygen species* (superoxide, hydroxyl radicals, and hydrogen peroxide) are currently favored as the active metabolites, and these cause cellular injury by lipid peroxidation, protein oxidation, and DNA strand breaks. Neutrophil-dependent lung injury and dysfunction of surfactant are additional proposed mechanisms of hyperoxic lung injury.

The toxicity of other compounds depends on their **conversion to reactive intermediate metabolites by phase I enzymes**, including the family of toxin-specific cytochrome P450 (CYP) isozymes. The CYP isozymes have a species-dependent distribution in nasal tissue, Clara cells, type II pneumocytes, and to a lesser extent in ciliated epithelial cells, type I pneumocytes, endothelial cells, and pulmonary macrophages. The reactive intermediates are further detoxified by phase II enzymes, including glutathione-S-transferases and glucuronyltransferases, to form water-soluble metabolites that are excreted. However, toxicity may develop when the phase II systems are inadequate (e.g., when glutathione is depleted or glutathione-S-transferase activity is impaired or absent) or overwhelmed by high concentrations of the reactive metabolite. In these situations, the electrophilic metabolite binds to essential proteins or nuclei acids, or leads to formation of oxygen radicals that damage cell membrane lipids. Thus, *the cellular susceptibility to toxic injury depends not only on cell-specific expression of the appropriate cytochrome P450 isozymes, but also on the adequacy of the antioxidants (glutathione, vitamin E, superoxide dismutase, and others) and phase II enzymes that protect the cell from injury.* Inherited polymorphisms in CYP genes and induction of CYP by glucocorticoids or other drugs may also influence the susceptibility of individual animals to pulmonary toxins.

3-Methylindole toxicity *causes acute bovine pulmonary emphysema and edema, or fog fever, in cattle.* L-tryptophan in grazed pastures is metabolized in the rumen (or the large colon of nonruminants) to 3-methylindole, and this is converted primarily by CYP to an electrophilic intermediate that alkylates cellular macromolecules, resulting in lipid peroxidation and membrane damage. The early ultrastructural changes are necrosis of nonciliated and ciliated bronchiolar epithelial cells and type I pneumocytes, and transient swelling of endothelial cells. Although type II pneumocytes have high CYP activity, the high levels of glutathione and phase II enzymes are thought to spare these cells from injury. The disease affects adult cattle in the autumn, within 4–10 days after they are moved from dry to lush pastures; younger animals are resistant to the toxic effects of 3-methylindole. Affected animals have acute onset of dyspnea with expiratory effort, tachypnea, open-mouth breathing, and froth in the mouth. The trachea is filled with foam, and the lungs contain striking alveolar and interlobular edema, resulting in heavy wet lungs that fail to collapse. Interlobular or bullous emphysema is prominent in the caudal lobes in less fulminant cases. Histologically, hyaline membranes line the edematous alveoli and alveolar ducts, and type II pneumocyte proliferation is extensive in the subacute stages. The alveolar septa are distended by edema, and may contain eosinophils and/or neutrophils in natural cases. Although bronchiolar lesions are often absent in natural cases, bronchiolar necrosis is described following intentional administration of 3-methylindole. The *differential diagnoses* for this histologic picture includes other toxins listed below; anaphylaxis, which causes pulmonary edema, congestion, emphysema, and rarely eosinophil infiltration, but usually not hyaline membranes; extrinsic allergic alveolitis, in which lymphocytes and granulomas form within alveolar septa; viral pneumonia, where bronchiolar and alveolar lesions are usually both present and syncytia may occur; and acute infection with *Ascaris suum* or *Dictyocaulus viviparus* larvae, which generally occur in younger calves and have many eosinophils with at least a few histologically visible larvae. In contrast to the predominantly alveolar damage in ruminants, experimental 3-methylindole toxicity in horses causes necrosis of Clara cells in the bronchioles, probably reflecting the species-dependent distribution of cytochrome P450.

4-Ipomeanol from moldy sweet potatoes induces a comparable condition in calves, of diffuse alveolar damage with or without bronchiolar injury following CYP-induced formation of a reactive intermediate. **Perilla ketone** toxicity (from perilla mint, *Perilla frutescens*) in cattle and horses follows a similar pattern. Other toxicants causing diffuse alveolar damage in cattle include stinkwood (*Zieria arborescens*, a small tree in southeastern Australia), moldy garden beans, *Brassica* (turnip tops or kale), and rape. **Carbolic dips** are reported to cause proliferative interstitial pneumonia in sheep. Pulmonary lesions are also produced in horses, pigs, sheep, and cattle by **pyrrolizidine alkaloids** (*Crotalaria, Trichodesma, Senecio*); the resulting vascular lesions are described in the section on Pulmonary vasculitis, pulmonary hypertension, above. **Crofton weed** (*Eupatorium adenophorum*) is a poisonous plant that produces chronic interstitial pneumonia in horses. Ingestion of the flowering plant causes multifocal or diffuse chronic interstitial pneumonia in which proliferation of alveolar epithelial cells and fibroplasia are the prominent features.

Paraquat *is a herbicide that causes acute diffuse alveolar damage*, and is most often encountered in dogs and cats. Paraquat undergoes reduction-oxidation (redox) cycling in alveolar type II pneumocytes, which depletes the cell of NADPH and glutathione and results in uncontrolled generation of superoxide anion. Cases of malicious poisoning are more likely to cause fulminating pulmonary edema and hemorrhage because of the high dosage, whereas in accidental poisonings there is more often time for hyperplasia of alveolar type II cells and fibroplasia to be superimposed on the earlier exudative changes. In the acute intoxication with survival up to 2–3 days, the lungs are heavy, dark, and rubbery, and the alveolar spaces are filled with fluid and blood with much fluid in the hilar connective tissue. Thin hyaline membranes are present in alveolar ducts. With longer survival, profuse fibroplasia and type II pneumocyte proliferation thicken the alveolar septa. Extrapulmonary lesions are often present and include patchy necrosis of the adrenal zona glomerulosa and of renal tubular epithelium. Poisoning by the rodenticide α-naphthylthiourea (ANTU) also causes respiratory distress but it causes pulmonary edema and pleural effusion without the tendency to epithelial hyperplasia and fibroplasia.

Drug reactions are important causes of acute or chronic pulmonary injury in humans, manifesting as pulmonary edema, asthma-like disease, bronchiolar necrosis, diffuse alveolar damage, eosinophilic pneumonia, pulmonary vascular disease with hemorrhage, or pleural effusion. Pulmonary drug reactions are poorly described and apparently rare in domestic animals.

Embolic pneumonia

Pulmonary abscesses usually arise either from chronic bronchopneumonia or from septic emboli lodging in the pulmonary vessels (Fig. 5.40). A cranioventral location and associated bronchiectasis are evidence of origin from bronchopneumonia. Multiple, widely distributed abscesses usually indicate hematogenous origin and are often associated with an obvious source of septic emboli elsewhere in the body, such as endocarditis or hepatic abscesses with phlebitis of the hepatic vein in cattle. The occurrence of abscesses in other tissues supports a hematogenous route of infection. *Other causes* of pulmonary abscess include aerogenous fungal infections that often have a disseminated pattern, aspirated foreign bodies such as plant awns, direct traumatic penetration of the lung, and specific hematogenous infections such as caseous lymphadenitis and melioidosis. It is often impossible to determine the pathogenesis of isolated abscesses, if lesions are not identified in other tissues. Abscesses may erode through the pleura to cause empyema, through blood vessels to cause massive blood loss, or into a bronchus to cause fatal airway obstruction or fulminant suppurative bronchopneumonia.

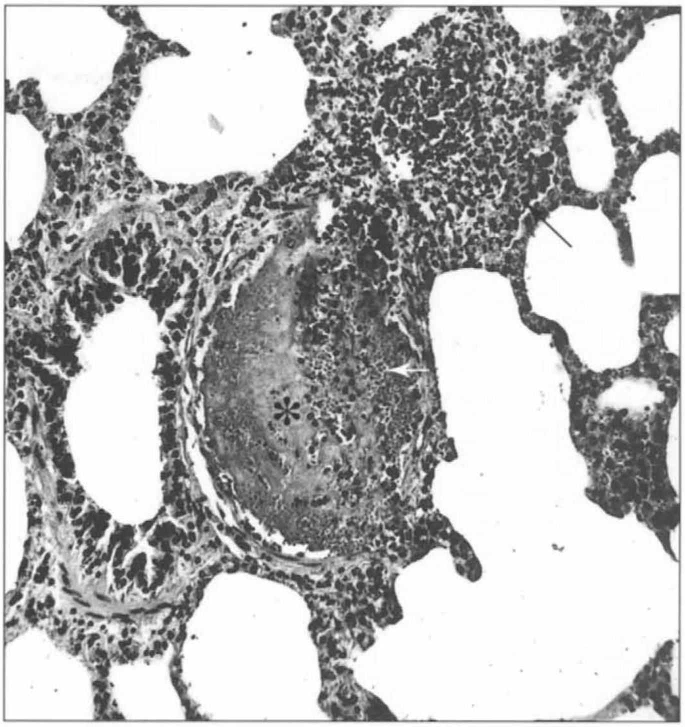

Figure 5.40 Suppurative embolic pneumonia in an ox. Thrombosis (asterisk) of a pulmonary artery with bacteria (white arrow) and neutrophil infiltration (black arrow) of the vessel wall and surrounding alveoli.

PLEURA

The relatively simple anatomy of the pleura belies the underlying complexity of the tissue. Mesothelial cells form a thin continuous layer and produce an underlying basal lamina. Although the thoracic mesothelial lining is contiguous, it is subdivided into *parietal pleura*, covering thoracic wall, diaphragm, and mediastinum; and *visceral pleura*, covering the lungs.

Mesothelial cells are flat cells with surface microvilli on their apex; tight junctions present between the cells have an important role in maintaining proper thoracic fluid balance. Mesothelial cells sample materials within the thoracic cavity using both pinocytosis to take in pleural fluid as well as phagocytosis to engulf particles such as bacteria. The cells participate in inflammation through production of cytokines and deposition of extracellular matrix; mesothelial cells are capable of producing large amounts of collagen and other extracellular matrix proteins. Both procoagulant and anticoagulant proteins are produced by the mesothelium, and an imbalance in these proteins, especially plasminogen-activator inhibitor, can promote pleural fibrin deposition.

Mesothelial cells normally have little baseline mitotic activity, and their ability to replace themselves following injury is not well understood. In response to pleural injury, mesothelial cells become cuboidal, and during long-standing stimulation often form villus projections into the pleural cavity covering a core of mesothelial-derived extracellular matrix and small capillaries.

The pleura has limited local defenses. *Kampmeier's foci*, found within the parietal pleura of the costal surface and mediastinum, are comprised of aggregates of lymphocytes and macrophages and are covered by a layer of modified mesothelial cells that are assumed to function similarly to mucosal-associated lymphoid tissues in the surveillance of the pleural fluid. Grossly, these aggregates may be seen as small white foci within the costal parietal pleura.

Pleural fluid is present in very small amounts (1–2 mL) in health. It provides for mechanical coupling between the lung and the chest wall in the negative-pressure environment of the thoracic cavity. Additionally, it acts as a lubricant between the lung and thoracic wall during respiration. Pleural fluid enters the thoracic cavity through stomata in the costal parietal pleura, following a hydrostatic gradient, and is pulled into the pleural space with the recoil of the lung during respiration. Pleural fluid is removed through visceral and parietal pleura through stoma, and to a lesser extent by transcellular means through mesothelial cells. **Pleural effusion** *occurs when filtration of fluid exceeds reabsorption*. Less commonly, pleuroperitoneal migration of fluid may result in fluid accumulation in the thoracic cavity through microscopic defects in the diaphragm when ascites is present.

Congenital anomalies of the pleura and mediastinum are of little significance. *Congenital cysts of branchial pouch origin* are most often encountered in brachycephalic dogs. They are found in the cranial mediastinum, often in close association with thymic tissues, and are lined by a single layer of cuboidal epithelium. *Bronchogenic cysts* are occasionally identified in the mediastinum. **Degenerative** changes in the pleura occur in uremia in dogs, with mineralization of elastin and collagen fibers in the parietal pleura of the intercostal spaces. *Pleural cysts* lined by keratinizing squamous epithelium are described in horses, but their cause is uncertain. Tetrathyridia of the cestode *Mesocestoides* sp. cause cystic lesions on the pleural surface.

Pneumothorax

Pneumothorax *refers to the presence of air or gas in the pleural cavities, and results in atelectasis because negative intrapleural pressure cannot be maintained*. In normal animals, the diaphragm moves caudally and an in-rush of air is heard when the diaphragm is pierced at necropsy; these features are absent in cases of pneumothorax. In small animals, where detection of this diaphragmatic movement and in-rush of air in normal animals may be challenging, pneumothorax can be detected by opening the chest under water and observing the escape of air bubbles.

Pneumothorax can be spontaneous or traumatic. *Spontaneous pneumothorax* is most commonly caused by rupture of emphysematous bullae. Other causes include rupture of a cavitated abscess or pyogranuloma that communicates with an airway, or of a parasitic cyst in paragonimiasis. *Traumatic pneumothorax* is usually the result of accidental puncture of the thoracic wall and/or visceral pleura. Traumatic pneumothorax can also be a complication of cardiac resuscitation or biopsy of the lung. Air that tracks through the pulmonary interstitium to the mediastinum (*pneumomediastinum*) does not usually escape into the pleural cavities unless there is traumatic rupture of the mediastinum.

Noninflammatory pleural effusions

Hydrothorax *is the accumulation in the pleural space of transudate, which is clear, watery, colorless, or light yellow, and has a low protein and cell content*. Chronic hydrothorax causes pleural opacity because of reactive hyperplasia of mesothelial cells, which produce fibrous thickening of the underlying pleural connective tissue. Hydrothorax is caused by increased venous pressure, lymphatic obstruction, and rarely hypoproteinemia; or by extension from a peritoneal effusion. It is particularly common in cats with cardiomyopathy, and occasionally develops from congestive heart failure in other species. Hydrothorax is also a feature of specific diseases such as "mulberry heart disease" in swine, black disease in sheep, African horsesickness, and ANTU poisoning.

Chylothorax *is the accumulation in the pleural space of lymph, which appears milky and has a high triglyceride and lymphocyte content* (Fig. 5.41). The diagnosis is confirmed by measurement of a higher triglyceride concentration in the fluid than in serum, or a reduced cholesterol-to-triglyceride ratio. Chylothorax is seen in cats and occasionally dogs, and *most cases are idiopathic*. Recognized causes include cardiomyopathy and right-sided heart failure, where increased central venous pressure prevents emptying of lymph from the thoracic duct into the vena cava; thoracic masses such as lymphoma, thymoma, or granulomas that cause thoracic duct obstruction; or infrequently dirofilariasis, lung lobe torsion, diaphragmatic hernia, or congenital anomalies in Afghan Hounds. Traumatic rupture of the thoracic duct is a well-known but exceedingly rare cause. *Chylous effusion causes atelectasis and stimulates noninflammatory pleural fibrosis*. Repeated removal of the effusion may induce dehydration, electrolyte disturbance, depletion of lipids and fat-soluble vitamins, hypoproteinemia, and lymphopenia.

Hemothorax *is the presence of blood in the pleural cavity*. It is most often the result of traumatic rupture of blood vessels, but it can also be caused by coagulopathies such as anticoagulant rodenticide toxicity, rupture of highly vascularized tumors such as hemangiosarcoma, lung lobe torsion, or erosion of the wall of a vessel by an inflammatory or neoplastic process. Chronic hydrothorax or chylothorax may lead to the development of well-vascularized papillae on the pleura, and rupture of these may result in a blood-stained effusion.

Pleuritis

Infectious agents most often reach the pleura from the blood or from lesions of bronchopneumonia, aspiration pneumonia, or abscesses in the underlying lung. Other routes of infection include perforation of the chest wall, penetrating foreign bodies from the esophagus or reticulum, perforating esophageal ulcers, lymphatic permeation from the peritoneal cavity, or direct extension from a mediastinal abscess. *Pleural defenses against microorganisms are much weaker than those of the lung*, and even a few organisms reaching the pleural surfaces are apt to have serious consequences. The appearance varies depending on the species affected, cause, magnitude of infection, and chronicity. Fibrinous exudates often form loosely adherent strands or veils of elastic material on the pleural surface. In more florid fibrinous lesions, the prosector is greeted by voluminous serofibrinous exudate when the chest is opened, and lakes of watery clear yellow fluid alternate with pockets of turbid and foul-smelling exudate. Creamy white suppurative exudate fills the pleural space in cases of **pyothorax** or **thoracic empyema**. Chronic lesions readily form adhesions between the parietal and visceral pleura, yet the functional impact of adhesions on lung function is usually minimal.

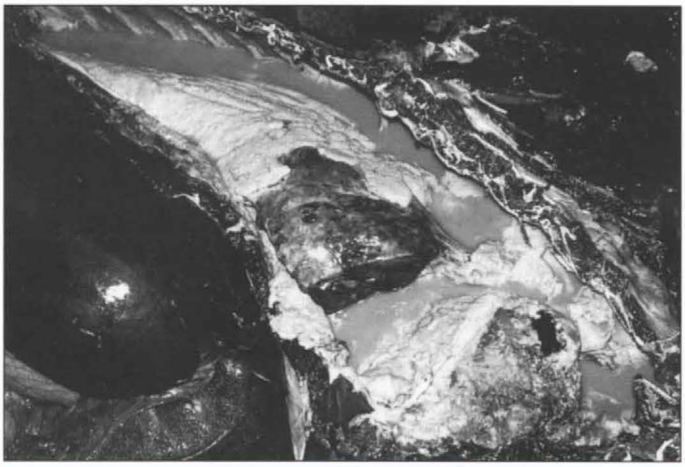

Figure 5.42 Severe fibrinopurulent pleuritis in a horse.

Pleuritis in **swine** may be an extension from obvious lesions of bronchopneumonia caused by *Actinobacillus pleuropneumoniae* or *A. suis*. *Streptococcus suis*, *Haemophilus parasuis*, and *Mycoplasma hyorhinis* are common causes of septicemia in swine, and the fibrinous or fibrinopurulent pleuritis caused by these agents is usually accompanied by exudates on other serosal surfaces, joints, or meninges. The causes in **cattle** include bronchopneumonia, direct extension from lesions of traumatic reticuloperitonitis, and septicemic *Histophilus somni* infection.

Pleuritis in mature **horses** often occurs with a recent history of travel, and is described later in the section on infectious diseases of the respiratory system (Fig. 5.42). The pleural exudate is unilateral or bilateral, and usually so florid that it masks the causative underlying lung lesion; but nearly all cases have either a focal area of consolidated lung that suggests aspiration pneumonia, or a bilateral lesion of necrotizing bronchopneumonia. *Mycoplasma felis* is an uncommon cause of pleuritis in horses without underlying lung lesions. Pleuritis occurs in neonatal foals with septicemia caused by *Actinobacillus equuli* or other gram-negative bacteria.

In **dogs**, pyothorax occurs mostly in hunting dogs or those with access to rural environments. The lesions are bilateral or occasionally unilateral, and pneumonia is absent or minor. The exudate is typically bloody and opaque, resembling tomato soup, or is more rarely creamy or darkly serofibrinous (Fig. 5.43). The pleural surfaces are usually thickened and velvety, red or gray-yellow, and fibrotic. *Actinomyces, Nocardia,* and *Bacteroides* spp. are the most frequently recovered organisms, and these are commonly associated with the presence of yellow "sulfur" granules amid the pus and a characteristic pyogranulomatous pleuritis and mediastinitis. Mixed infections are common, however, and a variety of other organisms can be present. Migrating grass awns or florets, usually impossible to find in the copious pleural exudate, are thought to be the source of infection in most cases.

In **cats**, feline infectious peritonitis is a common cause of pleuritis, and multifocal pyogranulomas are visible on the pleural surface. Pyothorax is fairly common in cats (Fig. 5.44), and *Pasteurella*

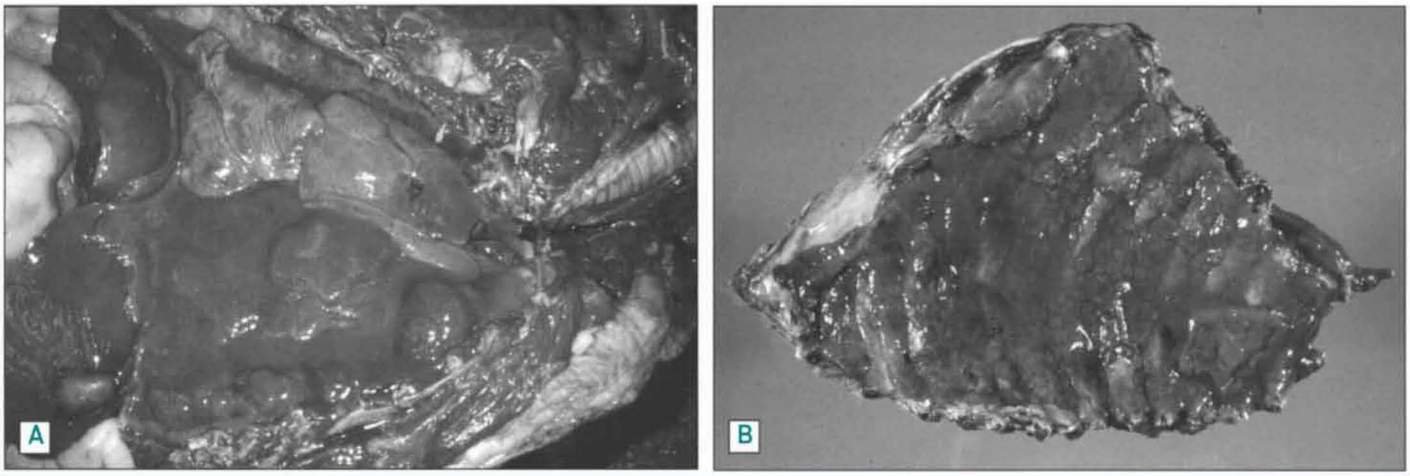

Figure 5.43 ***Nocardia* pleuritis** in a dog. **A.** The pleural cavity contains abundant thick red exudate. **B.** The parietal pleura is thickened and covered with exudate.

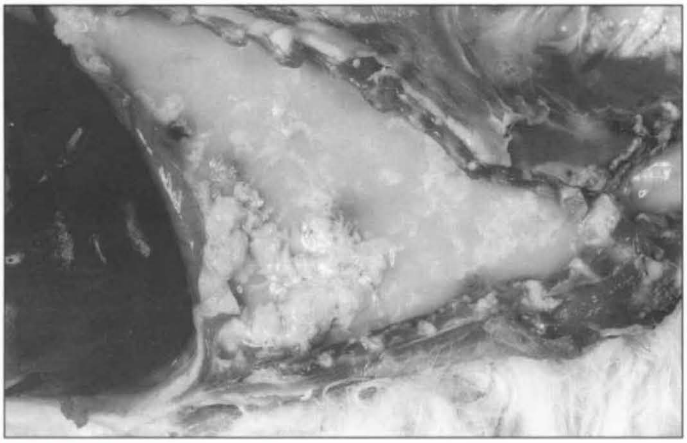

Figure 5.44 **Pyothorax** in a cat.

multocida, various gram-negative enteric bacteria, streptococci, and staphylococci are commonly isolated, often in mixed infection. Although most cases are idiopathic, penetrating bite wounds, migrating awns, extension from bacterial pneumonia, or penetration of a foreign body from the esophagus are likely causes.

Neoplastic conditions of the pleura

Mesothelioma arises from the pleura, as well as from the pericardium or peritoneum. Histologically, *epithelioid, sarcomatous, and biphasic patterns* are described. The epithelioid cells form nests, ribbons, acini, or papillary protrusions that resemble carcinoma, and the mesenchymal component may resemble fibrosarcoma. *Immunohistochemical detection of both vimentin and cytokeratin, and detection of acid mucins by Alcian blue stain, are useful in distinguishing mesothelioma from other epithelial or nonepithelial neoplasms.* Detection of the calcium-binding protein calretinin is used as a marker of mesothelioma in humans; its expression in a mesothelioma in a horse is described, but the reliability of this test in animals is unconfirmed. Pleural mesothelioma spreads and implants within the pleural cavity to cause persistent thoracic effusion, and often invades the underlying tissue or reaches the abdominal cavity via lymphatics.

In humans, the pleura is a primary site of pathology associated with inhalation exposure to asbestos fibers. While asbestos-induced mesothelioma is the best-known manifestation, benign pleural lesions include pleural effusion and focal or diffuse pleural fibrosis. *Ferruginous bodies*, which are asbestos fibers coated by ferritin and amorphous protein, have been detected with increased frequency in the lungs of dogs with mesothelioma, but further studies are needed to determine if this association is repeatable and causal.

Metastatic neoplasms localizing to the pleura are uncommon. Transpleural dissemination of carcinomas and sarcomas may occur by extension from the lungs, chest wall, or mediastinum, and carcinomas from the abdominal cavity can reach the pleura by pleuroperitoneal migration of fluid through the diaphragm. A fragment of hyaluron, a high-molecular-weight extracellular protein produced by mesothelial cells, has been shown to interact with CD44 receptors on neoplastic cells to effect pleura-specific colonization by carcinomas.

INFECTIOUS DISEASES OF THE RESPIRATORY SYSTEM

Infectious respiratory diseases of swine

Viral diseases

Porcine reproductive and respiratory syndrome

Porcine reproductive and respiratory syndrome (PRRS) was first identified in the late 1980s, and is now worldwide in distribution, with the probable exception of Australia and Sweden. It is an *important cause of reproductive failure and interstitial pneumonia*, and a predisposing factor for bacterial pneumonia and septicemia. The disease varies greatly in severity and clinicopathologic presentation depending on the strain of the *Porcine reproductive and respiratory syndrome virus* (PRRSV), the age of pigs affected, the level and distribution of immunity within the herd, and the presence of other pathogens.

On initial exposure, infection spreads slowly through the naive herd and causes a variety of clinical presentations: anorexia and lethargy of all age groups; reproductive failure characterized by late term abortion, stillbirth, mummified fetuses, and weak-born piglets; and interstitial pneumonia causing fatal hyperpnea, dyspnea, and lethargy in suckling pigs infected in utero or in the neonatal period, in weaned pigs, and to a lesser extent in grower-finisher pigs. "Sow abortion and mortality syndrome" describes a devastating disease resulting from PRRSV infection of naive herds, in which up to half of the sows may abort and sow mortality may reach 10%.

Viral infection often persists and circulates within the herd indefinitely, the result of prolonged viral shedding from individual animals and continuous entry of naive animals. The disease in endemically infected herds is highly variable: many herds have stable infections in which virus continues to circulate but does not cause clinical disease; others have endemic respiratory disease or a failure to thrive in nursery and grower-finisher pigs, or a PRRSV-induced increase in susceptibility to bacterial pneumonia and septicemia; and some herds have continuing losses due to abortion in gilts or dyspnea in neonatal or weaned pigs.

The PRRS virus is an enveloped, 50–65 nm diameter, positive-sense, single-stranded RNA virus in the family Arteriviridae. The viral genome includes 8 open reading frames (ORFs): ORF 1a and 1b encode proteins necessary for replication and transcription, ORFs 2–4 encode structural glycoproteins of uncertain function, ORF 5 encodes an envelope glycoprotein, ORF 6 encodes the integral membrane protein M, and ORF 7 encodes the nucleocapsid protein N. Genomic variability is an important feature of PRRSV, and may be attributed to the high mutation rate of RNA polymerase and perhaps recombination between viral strains. As a result, PRRSV isolates vary in terms of the severity of respiratory disease, reactivity in antigen- and nucleic acid-based diagnostic assays, and possibly in patterns of lesions in other organs, including brain and heart. These differences in virulence have not been shown to correlate with simple alterations in specific genes; rather, the virulence of particular strains is apparently determined by a combined effect of many genetic differences.

The pathogenicity of modified live vaccine strains of PRRSV is controversial. Vaccine strains of the virus can infect in-contact animals and persist in herds, but do not commonly cause clinical disease. However, as these vaccine strains circulate in swine herds, *mutation to a less attenuated form of the virus may result in disease caused by vaccine-derived strains*. Extra-label intranasal administration of modified live PRRSV vaccine has induced clinical signs and lesions typical of PRRS.

The common mode of *transmission* of PRRSV is direct nasal, oral, or coital contact with saliva, oropharyngeal mucus, urine, semen, serum, mammary secretions, or perhaps feces of infected pigs. Transmission of PRRSV by artificial insemination has been documented, and transmission by contamination of pharmaceutical preparations or needles with infected serum is a potential risk. Transmission by fomites may occur, but because the enveloped virus is rapidly inactivated in most environmental conditions, disinfection procedures should be effective. Aerosol transmission is apparently of limited importance, but can occur at low frequency over short distances.

The pathogenesis of PRRS centers on infection of macrophages at the site of nasal, tonsillar, or pulmonary infection, extension to associated lymphoid tissue, rapid viremia, and infection of macrophages throughout the body. Following experimental intranasal challenge, viral antigen is expressed within 12 hours of infection by nasal and tonsillar macrophages and epithelium, pulmonary alveolar, intravascular, and interstitial macrophages, bronchiolar epithelium, and endothelial cells of pulmonary arterioles. Viremia occurs rapidly, in some cases within 12 hours of infection, and leads to widespread infection of monocytes and tissue macrophages. Viral antigen may be detected in myocardial macrophages and endothelium, follicular macrophages and dendritic cells in lymph node, interdigitating cells in the thymus, macrophages and dendritic cells in the spleen and Peyer's patches, and macrophages in hepatic sinusoids, adrenal gland, interstitium of the kidney, and choroid plexus.

Persistent infection is a key feature of PRRSV. Virus has been detected in serum for 3 weeks; in nasal mucosa, pulmonary macrophages, and spleen for 4 weeks; and in oropharyngeal mucosa for up to 22 weeks after infection. Animals remain infectious for in-contact naive pigs for at least 22 weeks after infection. Persistent infections are of epidemiologic importance in the maintenance of PRRSV infection in endemically infected herds, yet the reasons for failure of the immune response to clear the infection and the role of cell-mediated immunity in protection and viral clearance are unknown. Following experimental PRRSV infection, serum antibody detectable by ELISA and virus-neutralizing antibody are first detectable at 7–14 days and 9–28 days after infection, peak at 5 weeks and 10 weeks, and remain detectable for 46 weeks and over 1 year, respectively. Antibody responses are directed against all proteins encoded by ORFs 2–7; the products of ORF 3, 4, and 5 may represent protective epitopes.

Infection with PRRSV impairs host defenses, and increases susceptibility to infection with *Streptococcus suis*, *Haemophilus parasuis*, *Salmonella choleraesuis*, and other opportunistic pathogens. Experiments to investigate this effect have been conflicting, and the ability of PRRSV to predispose to other agents is probably dependent on

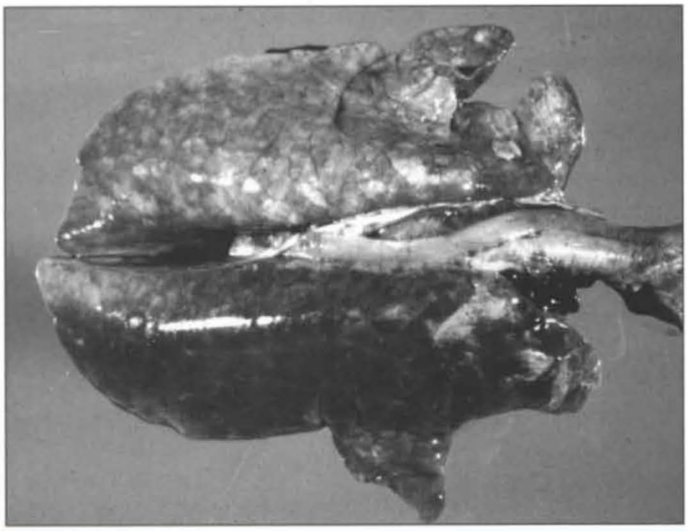

Figure 5.45 Porcine reproductive and respiratory syndrome. The lung is diffusely rubbery, fails to collapse, and has a lobular pattern of reddening.

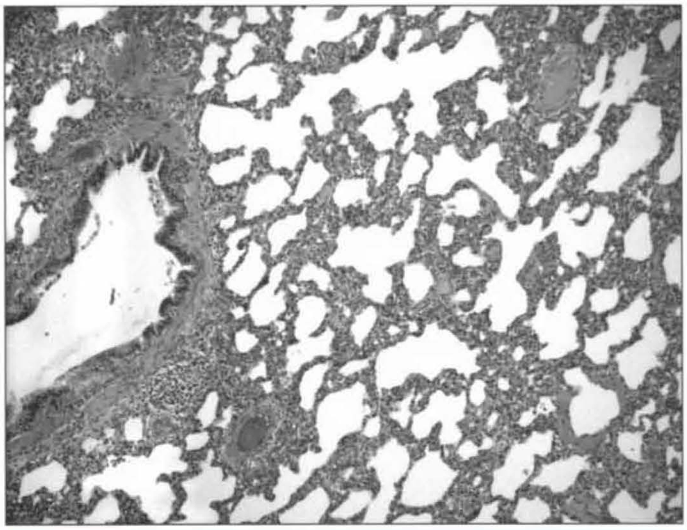

Figure 5.46 Porcine reproductive and respiratory syndrome. The alveolar septa are diffusely thickened by mononuclear cells. The bronchiole is normal.

the viral and bacterial strains examined and on the specific experimental conditions. The ability of PRRSV to infect and reduce the function of pulmonary intravascular macrophages is one mechanism whereby PRRSV predisposes to septicemia; a similar impairment of alveolar macrophage functions – including phagocytosis, oxidative burst, and cytokine secretion – may reduce lung defenses against bacterial bronchopneumonia. Subclinical or clinical infection with *Mycoplasma hyopneumoniae* exacerbates the clinical signs and lesions of PRRS, possibly because mycoplasma-induced proliferation and activation of macrophages enhance the replication or persistence of PRRSV. In contrast, infection with PRRSV has little effect on the severity of mycoplasmal lesions. This finding is of clinical importance, as control of *M. hyopneumoniae* is one strategy for minimizing the effect of PRRSV in endemically infected herds. The effect of PRRSV infection on immune responses to other pathogens has not been fully addressed, but a state of generalized immunosuppression is not a likely feature of PRRS.

Animals infected with PRRSV develop apoptosis of alveolar and pulmonary intravascular macrophages, and mononuclear cells in alveolar septa. Because apoptotic cells are more numerous than virus-infected cells, the mechanism of apoptosis may not represent a direct effect of viral infection. Similarly, although interstitial pneumonia is extensive in swine with PRRS, virus-infected cells are relatively infrequent, suggesting a role for host-derived factors such as cytokines in development of lesions.

The major **lesions** *of the postnatal form of PRRS include interstitial pneumonia, generalized lymphadenopathy, and lymphocytic infiltrates in multiple organs.* Gross lung lesions vary from undetectable to affecting the entire lung, and tend to be most striking in younger age groups. The lungs fail to collapse when the diaphragm is incised, occasionally retain impressions of the ribs, and have generalized, patchy, lobular, or diffuse distributions of lesions (Fig. 5.45). Affected areas of lung are discolored tan or red, and have a firm texture reminiscent of thymus, which contrasts with the crisp hard texture of bacterial pneumonia. A cut section reveals separation of lobules and oozing of edema fluid. In pigs that develop bacterial bronchopneumonia secondary to PRRS, lesions of cranioventral consolidation may be superimposed on the diffuse interstitial pneumonia. In these cases, the lesions of PRRS may be subtle, yet play a critical role in the development of pneumonia in the herd. Lymph nodes throughout the body – most notably the bronchial, mediastinal, cervical, and inguinal nodes – are enlarged, white or tan, solid, and rarely contain multiple clear cavitations on cut section. Periocular and subcutaneous edema, and mild serous effusions into body cavities, are variable findings.

Histologic *lung lesions are of interstitial pneumonia.* Alveolar septa are thickened due to infiltration of lymphocytes and macrophages (Fig. 5.46). This feature is easily obscured by atelectasis in routinely prepared samples, but can usually be confirmed by searching for areas of lung in which alveoli are not collapsed – where a single row of erythrocytes is visible in alveolar septal capillaries. Alveoli contain a cellular infiltrate of macrophages, lymphocytes, and fewer neutrophils, and scattered clusters of alveoli are filled with necrotic cells with pyknotic nuclei or karyorrhexis. *The latter is highly suggestive of PRRS, and probably represents clusters of apoptotic macrophages.* Type II pneumocytes are increased in number, but may or may not form a continuous layer of cuboidal epithelium lining the alveolus (Fig. 5.47). Bronchiolar epithelium is not affected by PRRSV, and a finding of bronchiolar necrosis should incite a search for an alternative or additional diagnosis.

Histologic examination of lymph nodes, tonsils, and spleens of pigs with PRRS may reveal *follicular and paracortical hyperplasia, and apoptosis of follicular lymphocytes.* Multinucleate cells, probably of histiocytic origin, may be present. Although this lesion is also common in *Porcine circovirus* type 2 (PCV2) infection, it has been described in PRRSV-infected pigs that have no evidence of PCV2 infection.

Perivascular infiltrates of lymphocytes, macrophages, and plasma cells occur in many organs in PRRS. Commonly affected sites include the nasal mucosa, heart, kidney, and brain. Severe neurologic disease occasionally occurs in association with other manifestations of PRRS, possibly related to the infecting viral strain, and lesions of the central nervous system include lymphocytic meningoencephalitis, lymphocytic perivascular cuffs, and focal gliosis. PRRSV may cause *vasculitis* in the lung and other organs, manifesting as necrosis

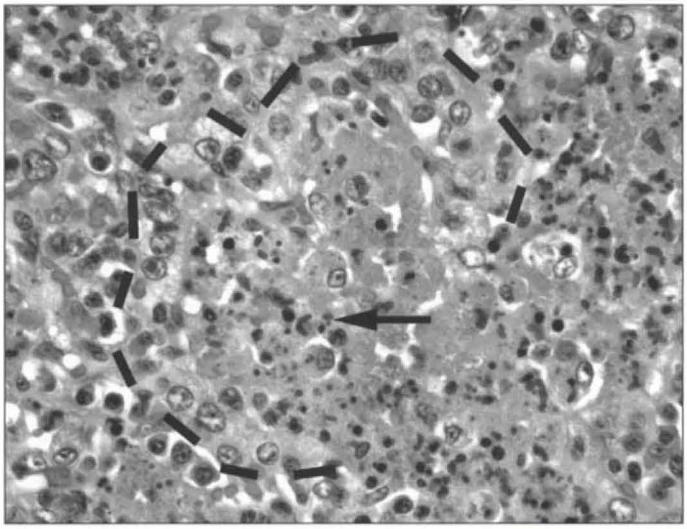

Figure 5.47 Porcine reproductive and respiratory syndrome. The alveolus is lined by cuboidal epithelial cells (outlined by dashed line), and filled with macrophages that often contain pyknotic nuclei or karyorrhexis (arrow).

of the walls of large and small blood vessels in addition to perivascular and mural infiltrates of lymphocytes and plasma cells.

Aborted fetuses usually lack gross or histologic lesions, and, when present, the lesions are often not specific for PRRSV. Infection may progress from one fetus to another, resulting in live, stillborn, and mummified fetuses in the same litter. Fetal lesions that suggest PRRS include segmental or diffuse hemorrhage of the umbilical cord due to fibrinoid necrosis and suppurative inflammation of the umbilical artery, mild interstitial pneumonia, pulmonary arteritis, lymphocytic myocarditis and encephalitis, and retroperitoneal and mesocolonic edema.

Diffusely firm lungs and histologic lesions of interstitial pneumonia are common findings at necropsy. In addition to PRRS, *a major differential diagnosis is septicemia.* Lesions of lymphadenopathy and mild proliferation of type II pneumocytes favor a diagnosis of PRRS, but differentiation requires ancillary testing. Porcine circovirus may cause a similar pattern of bronchointerstitial pneumonia, but granulomatous infiltrates and inclusion bodies are often present in lymph nodes and Peyer's patches. Proliferative and necrotizing pneumonia causes a similar alveolar lesion to PRRS, but bronchiolar necrosis is a feature of this disease that is absent in PRRS.

The arsenal of assays to confirm a **diagnosis** of PRRS in pathologic tissue specimens has recently expanded, and includes virus isolation, fluorescent antibody tests, immunohistochemistry, polymerase chain reaction (PCR), and in situ hybridization. Fluorescent antibody tests on frozen sections and immunohistochemistry on formalin-fixed paraffin-embedded sections of lung and tonsil are an economical approach to diagnosis, but because these assays are less sensitive than PCR, multiple sections should be examined. Virus isolation on chilled or frozen samples of lung, lymphoid tissues, serum, EDTA-treated blood, or pulmonary alveolar macrophages is a highly sensitive but laborious and slow method of diagnosis. Detection of viral nucleic acid by PCR is a rapid technique that is as sensitive as virus isolation and is becoming widely used in many laboratories. Serology is useful on a herd level to identify prior exposure to PRRSV in unvaccinated herds.

Results of diagnostic assays must be interpreted with caution in herds vaccinated with modified live viruses, as vaccine strains of PRRSV may circulate and persist in these herds and cause positive tests. An advantage of using PCR or virus isolation is the use of subsequent molecular analyses that assist in differentiating field and vaccine strains of virus in vaccinated herds. Identification of patterns of restriction fragment length polymorphisms (RFLP) in ORF 5 is commonly used to differentiate vaccine strains from some field strains; however, the RFLP pattern of vaccine strains may change to an intermediate pattern as they circulate in herds. A second strategy distinguishes vaccine and field strains by identifying glycine and arginine, respectively, in residue 151 of ORF 5.

Obtaining a diagnosis of PRRS in aborted fetuses can be frustrating, because lesions are usually absent or nonspecific and the agent often cannot be identified. Two techniques – the use of PCR assays on fetal lung and lymphoid tissue, and identification of antibody to PRRSV in precolostral sera – are currently recommended, but the low diagnostic rate remains a problem considering the importance of reproductive failure in swine herds.

Swine influenza

Orthomyxoviruses are pleomorphic, spherical to filamentous, 80–120 nm viruses containing negative-sense single-stranded RNA. Transcription of viral genes occurs in the nucleus, viral proteins are produced in the cytoplasm, and virions bud from the plasma membrane. Three genera of orthomyxoviruses are described based on variation of the nucleocapsid proteins: (1) ***Influenza type A viruses*** cause influenza in swine, horses, humans, and other species; (2) *type B viruses* represent human isolates only; and (3) *type C viruses* are rare and cause mild or subclinical infections in humans and swine. Orthomyxoviruses readily develop genomic variants, due to *genetic drift* caused by point mutations and *genetic shift* due to recombination of genomic segments. *Identification of viral strains is based on antigenic variation of the 15 hemagglutinin (H) and nine neuraminidase (N) envelope glycoproteins*, which mediate virus entry into cells and release of virus from infected cells, respectively. Analysis of viral strains is of practical importance in epidemiologic tracking of outbreaks and changing disease patterns, and to ensure that vaccine strains are representative of those in the field to ensure protective immunity.

Influenza viruses are usually host-specific, and although several strains are known to cross species barriers, transmission rates are generally low and the foreign strains are probably not maintained in the population. Although of only moderate consequence for direct zoonotic potential, this phenomenon is important in the evolution of new viral strains. *Since swine possess cell-surface receptors for both avian and human viral strains, it is postulated that swine are hosts for reassortment among avian, porcine, and human strains of influenza viruses, with the potential for human pandemics due to the introduction of novel pathogenic strains into immunologically naive human populations.*

Influenza viruses are transmitted by aerosol or by contact with secretions. Infection is usually restricted to the respiratory tract, although myocarditis, myositis, and encephalitis – probably as a consequence of viremia – are uncommon complications in horses and humans.

The principal lesion of influenza is necrosis of bronchiolar and bronchial epithelium, which represents cell lysis due to viral infection. Acute histologic lesions include attenuation of airway epithelium (Fig. 5.48), while hyperplasia of bronchiolar epithelium begins as early as 4 days after infection. Similar to the lesions of other viral lung pathogens, lymphocytes and plasma cells infiltrate the bronchiolar mucosa and encircle bronchioles and blood vessels. Neutrophils invade the mucosa and exude into the airway lumen in primary viral infection, but are particularly numerous if there is secondary bacterial pneumonia. Alveoli may be edematous and contain increased numbers of macrophages and neutrophils, but hyaline membranes or type II pneumocytes are not typical features of influenza. Viral infection is transient: in swine influenza, viral antigen is maximally expressed at 24 hours and often absent by 72 hours after infection. In all species, viral injury to airway epithelium predisposes to bacterial pneumonia, presumably due to failure of mucociliary clearance of opportunistic pathogens.

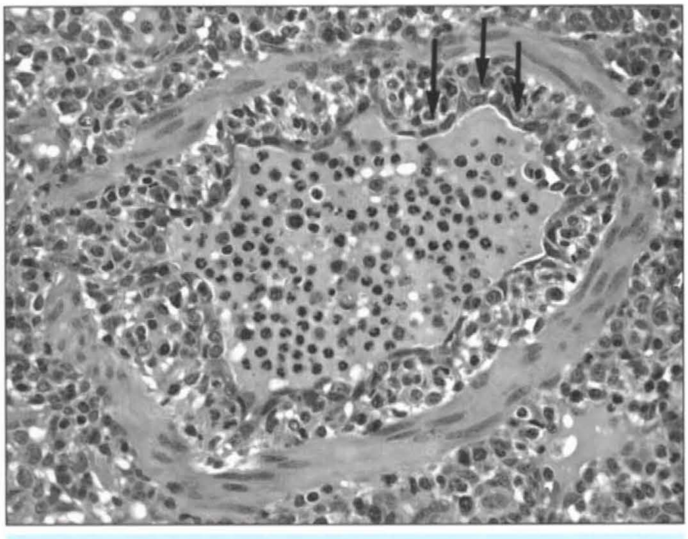

Figure 5.48 Swine influenza. The bronchiole contains neutrophils and is lined by markedly attenuated epithelium (arrows), and lymphocytes infiltrate the bronchiolar mucosa and surrounding tissue.

Swine influenza is an important form of respiratory disease, manifesting as rapidly spreading outbreaks of severe nonfatal disease or as endemic disease as part of the porcine respiratory disease complex. Disease outbreaks are most common in the winter in cool climates, or late summer in warm climates. Disease severity may be enhanced by stresses, climate change, PRRSV infection, or concurrent disease. Outbreaks of disease have a characteristic clinical presentation: the disease appears acutely and spreads rapidly to affect all ages of pigs, and despite severe clinical signs of coughing, fever, and stiffness, most pigs recover in 5–14 days and the mortality rate is low. An endemic form of disease is increasingly common, in which pigs develop bacterial bronchopneumonia secondary to subclinical infection with influenza virus. In this form of disease, the clinical picture is not specific for influenza and differentiation from other causes of porcine respiratory disease complex requires laboratory testing.

Identification of swine influenza virus (SIV) subtypes is important because there is limited cross-protection between subtypes; thus it is imperative that vaccines in current use are representative of circulating field strains. Subtype H1N1 is the common SIV in North America, and antigenic variants of this virus have been identified. H3N2 viruses have been detected more recently in North America. Avian-like H1N1 subtype as well as H3N2 subtypes are both isolated in Europe, and H1N2 viruses isolated in France and Japan probably represent genetic reassortment of these subtypes. SIV is transmitted by infected droplets, aerosol, or contact with infected secretions. After experimental infection, serum antibody titers are detectable in many pigs by 7 days and peak 2–3 weeks after infection, and mucosal immunoglobulin A (IgA) and IgG are maximal at 1 and 4 weeks after infection, respectively. Pigs shed virus for 5–7 days after infection, although viral antigen is often absent from lung as little as 72 hours after infection. Virus infection is probably maintained in swine populations by continuous infection of naive swine, as there is no evidence of a long-term carrier state or significant wildlife vector.

The **gross lesions** of swine influenza include a *cranioventral lobular distribution of atelectasis*, which is often sharply demarcated from normal lung tissue. Affected lobules are red, firm, and collapsed. Adjacent lobules are occasionally emphysematous. Generalized pulmonary edema may occur. Mediastinal and bronchial lymph nodes are enlarged and edematous, but usually not congested. The mucosa of the trachea and bronchi is often hyperemic and edematous. The development of secondary bacterial bronchopneumonia may obscure the gross lesions of swine influenza and cause red, firm, raised, lobular lesions in the cranioventral lung.

The **histologic lesions** reflect *necrosis of airway epithelium* and, to a lesser extent, alveolar epithelium, and include attenuation of bronchiolar epithelial cells, necrotic debris and neutrophils in bronchiolar lumens, atelectasis, and peribronchiolar, perivascular, and interstitial infiltrates of lymphocytes and plasma cells (Fig. 5.48). Vacuolation of bronchial and bronchiolar epithelial cells with loss of cilia occurs by 8 hours after experimental infection. By 24 hours, there is necrosis of bronchiolar and bronchial epithelial cells, and accumulation of sloughed necrotic cells in the lumen. Alveoli and airway lumens contain moderate numbers of neutrophils and edema fluid, and many alveoli are atelectatic. Mononuclear cell infiltration occurs by 48 hours after infection. Alveolar injury, manifesting as exudation of neutrophils and scant fibrin with thickening of alveolar septa, is described in experimental cases at 48 hours after infection, but is often inapparent or obscured by bacterial pneumonia in natural disease. Later lesions include hyperplasia of airway epithelium as regeneration occurs, and peribronchiolar and perivascular aggregation of lymphocytes and plasma cells as immune responses develop. Infection is, in most cases, restricted to the respiratory tract and associated lymph nodes, although viremia has been infrequently described in neonates.

The **diagnosis** is suggested by the characteristic clinical signs of severe, rapidly spreading disease with high morbidity and low mortality, and by the characteristic histologic lesions of bronchiolar necrosis. *Differential diagnoses* for the latter include *Porcine circovirus* type 2 infection, proliferative and necrotizing pneumonia, pseudorabies, *Nipah virus* infection, and airway injury due to inhaled toxic gases. The diagnosis is confirmed by inoculation of embryonated eggs, with subsequent identification of virus by detection of hemagglutinating activity. More rapid methods of obtaining a definitive diagnosis include immunohistochemistry on fixed tissues using monoclonal antibodies to conserved type A nucleoproteins, fluorescent antibody testing on frozen sections of affected lung, and polymerase chain reaction. Sample selection is critical for the diagnosis of swine influenza. Viral titers are highest 24 hours after infection, before gross lesions are obvious, and virus often cannot be identified by 72 hours after infection. Consequently, *selecting tissue from the cranioventral areas of the lung, from pigs early in the course of the disease, is critical for both histologic and virologic diagnosis.* Pigs with a fever are the most suitable subjects for diagnostic investigation. The transient nature of the infection may complicate an investigation of the role of swine influenza in herds with endemic respiratory disease. In these cases, herd-level serology may be useful, as most pigs develop hemagglutination inhibition titers of greater than 1:80 within a week of infection.

Porcine circovirus and postweaning multisystemic wasting syndrome

Porcine circovirus (genus *Circovirus*, family Circoviridae) has recently emerged as a common pathogen of swine. *Porcine circovirus* type 1 (PCV1) has been recognized for many years as a nonpathogenic cell culture contaminant. In contrast, *Porcine circovirus* type 2 (PCV2) was first isolated in 1997 from pigs with a novel disease, *postweaning multisystemic wasting syndrome* (PMWS). *Serum antibody to PCV2 is widespread in swine herds, and PCV2 infection is common in herds with no clinical evidence of PMWS.*

PMWS was originally described in high-health-status herds, but many herds with PMWS are infected with PRRSV or other pathogens. PMWS is usually a slowly progressive disease within the herd, with most cases developing in 5–12-week-old pigs. Morbidity is typically 5–10% but may be up to 20%, and most affected animals die or are euthanized. Pigs with PMWS lose weight or gain poorly, and have a variable combination of tachypnea, respiratory distress, diarrhea, pallor, and jaundice. Although uncommon, the finding of jaundice in swine should suggest a diagnosis of PMWS.

Porcine circoviruses are 17 nm diameter, nonenveloped, and contain circular single-stranded DNA. The number of encoded genes or open reading frames is controversial, and the function of each gene product is not yet known. Although isolates of PCV2 share 96% homology, the nucleotide homology of PCV1 and PCV2 is less than 80%.

Porcine circoviral antigen and nucleic acid are most consistently present in the cytoplasm of monocytes, macrophages, and dendritic cells throughout the body, and less often in the nuclei and cytoplasm of epithelial cells in bronchioles, pulmonary alveoli, liver, renal tubules, stomach and intestine, and pancreas. Vascular smooth-muscle and endothelial cells occasionally express circoviral antigen. Transmission is poorly characterized.

Current evidence indicates that PCV2 is sufficient to cause PMWS, as experimental infection of gnotobiotic or cesarean-derived colostrum-deprived pigs induces mild clinical signs and lesions of PMWS in the absence of other demonstrable pathogens. However, co-infection with PCV2 and other pathogens, including parvovirus or PRRSV, results in more severe disease. Immunostimulation itself, either as a consequence of viral infection or vaccination, precipitates more severe disease. Thus, *activation of the immune response may encourage replication of PCV2, resulting in more severe manifestations of PMWS.*

The role of PCV2 in other swine diseases remains controversial, in part because the virus can be isolated from many healthy pigs. In particular, although many pigs with dermatitis-nephropathy syndrome, proliferative and necrotizing pneumonia, sow abortion and mortality syndrome, congenital hypomyelination, and abortion with fetal myocarditis have evidence of PCV2 infection, definitive proof of their causal association is lacking.

The spectrum of **gross lesions** present and their severity are highly variable. Swine with PMWS are often thin, pale, and may be jaundiced. Lymph nodes throughout the body – particularly the inguinal, mesenteric, and bronchial nodes – are enlarged, soft, and white or gray-tan, and *this lymphadenopathy is the most consistent feature of PMWS.* Lung lesions, which are common, consist of interstitial pneumonia with generalized firm or rubbery texture, failure to collapse, and mottled color. Cranioventral bronchopneumonia is a frequent concurrent lesion. The liver may be atrophic and discolored yellow-orange. Kidneys may contain patchy pallor or obvious white foci. Lesions resembling dermatitis-nephropathy syndrome may also occur, including swelling and edema of the kidneys, and cutaneous hemorrhages and necrosis.

The characteristic **histologic lesions** of PMWS in many tissues are *granulomatous infiltrates and lymphoid depletion, with formation of distinctive inclusion bodies within the cytoplasm of macrophages.* Inclusions are usually multiple within a single macrophage, 1–3 μm diameter, round, and basophilic (Fig. 5.49). Inclusion bodies are most numerous and obvious in lymphoid tissues, including lymph nodes, Peyer's patch, tonsil, splenic periarteriolar lymphoid sheaths, and thymus. In these tissues, there is depletion of lymphocytes from B-cell follicles, with striking infiltration of macrophages into follicles and, to a lesser extent, T-cell-rich paracortical areas. Multinucleate histiocytes may be present amid the granulomatous infiltrates.

Histologic examination of the lungs of pigs with PMWS reveals diffuse or patchy *granulomatous interstitial pneumonia.* Epithelioid macrophages, multinucleated macrophages, lymphocytes, and fewer eosinophils or neutrophils infiltrate alveolar septa and may fill the alveoli. Lymphocytes and macrophages often encircle bronchioles and blood vessels (Fig. 5.49). Bronchiolar necrosis is a variable finding, and may progress to bronchiolitis obliterans in chronically affected pigs.

Liver lesions are highly variable, progressing from mild aggregates of lymphocytes in portal tracts, to single-cell necrosis of hepatocytes, periacinar necrosis, or widespread hepatocellular loss with condensation of hepatic stroma. Perivascular infiltrates of lymphocytes and macrophages may be present in other organs, including kidney, myocardium, leptomeninges, pancreas, adrenal, stomach, and intestine. Vasculitis, with necrosis of tunica muscularis accompanied by lymphohistiocytic infiltrates, and exudative glomerulonephritis are less common lesions.

Infection with PCV2 is usually identified using *immunohistochemistry or polymerase chain reaction.* The virus may be isolated in PK15 cells or identified by in situ hybridization, but these find more use in research than as diagnostic techniques. Serologic assays, including indirect immunofluorescence and immunoperoxidase tests, have been developed, but the high prevalence of antibodies to PCV2 in healthy pigs limits the utility of this test in disease diagnosis.

It is critical to recognize that demonstrating PCV2 infection does not in itself indicate a diagnosis of PMWS. A **diagnosis** of PMWS is mainly based on the demonstration of consistent clinical findings and gross and histologic lesions, and is supported by the demonstration of active PCV2 infection by immunohistochemistry or polymerase chain reaction. PRRS is the major differential diagnosis for lesions of interstitial pneumonia and lymphadenopathy in pigs. The following

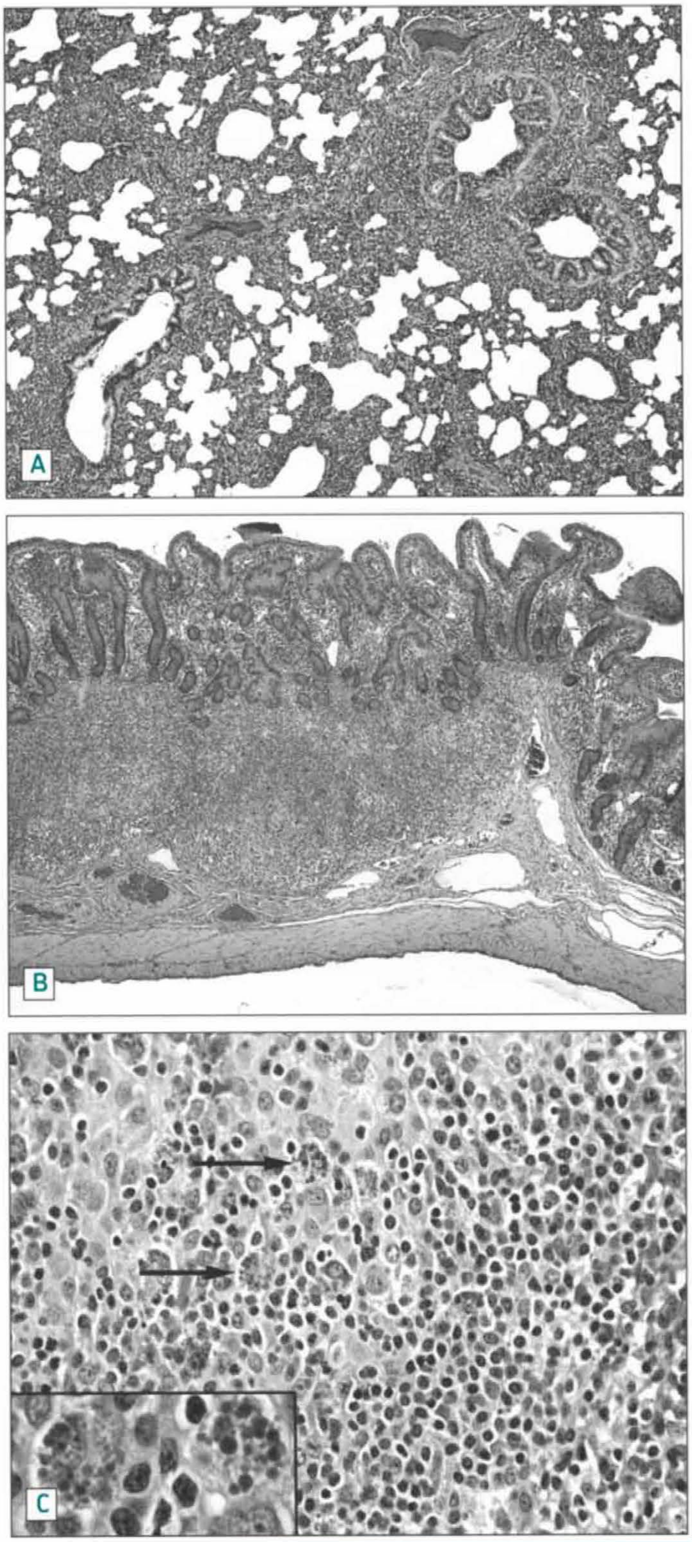

Figure 5.49 Postweaning multisystemic wasting syndrome in a pig. **A.** Lung, with diffusely thickened alveolar septa, and lymphocytes encircling bronchioles and blood vessels. **B.** Lymphoid depletion of Peyer's patch. **C.** Peyer's patch, with depletion of lymphocytes and infiltration of macrophages. Some macrophages contain numerous intracytoplasmic basophilic inclusion bodies (arrows, and inset).

are helpful differentiating features, but *the lesions of PMWS and PRRS may be difficult to distinguish, and many pigs are co-infected with PCV2 and PRRSV*:

- Multiple basophilic inclusion bodies in macrophages are a diagnostic feature of PCV2 infection, and support the diagnosis of PMWS.
- Bronchiolar necrosis is present in some cases of PMWS (and swine influenza), but is not a lesion of PRRS.
- Lung lesions of PMWS tend to be dominated by macrophages, whereas lesions in PRRS are more lymphocytic, although there is much overlap in the morphology of these diseases.
- Granulomatous infiltrates and multinucleate macrophages in lymphoid organs are more typical of PMWS than of PRRS, although both lesions may be present in PRRS.

Proliferative and necrotizing pneumonia

Proliferative and necrotizing pneumonia is a severe acute disease of weaner and grower pigs. Affected animals have acute onset of severe dyspnea, tachypnea, and fever. Gross lesions usually affect the entire lung, but may be restricted to the cranial and middle lobes. Lung lesions include remarkably increased firmness, failure to collapse, reddening, and edema. Generalized lymphadenopathy is usually present. Histologically, alveoli are edematous, contain macrophages and abundant necrotic cellular debris, and are lined by cuboidal type II pneumocytes. Alveolar septa are thickened by mononuclear cell infiltration. Although many of these lesions may be present in severe cases of PRRS, *bronchiolar necrosis is often present in proliferative and necrotizing pneumonia but absent in PRRS.*

The understanding of the cause of this lesion is evolving. When the lesion was first reported in the early 1990s, it was associated with an H1N1 influenza virus that was genetically and antigenically distinct from common North American swine influenza virus isolates. Later publications associated proliferative and necrotizing pneumonia with PRRSV infection, H3N2 influenza virus and, more recently, with PCV2. PRRSV can be detected in nearly all cases, whereas other pathogens are less consistently identified. It remains to be clarified whether this lesion is caused by particular strains of PRRSV or by combined infection with several agents, or if it represents a pattern of reaction shared by more than one pathogen.

Porcine respiratory coronavirus

Porcine respiratory coronavirus (PRCoV) is a minimally pathogenic virus that arose in the mid-1980s by deletion and point mutation of the *Transmissible gastroenteritis virus* (TGEV) genome. European and American isolates of PRCoV differ, and apparently developed independently from TGEV. Following experimental challenge, neonatal pigs develop viremia and respiratory infection, whereas in 5-week-old pigs, viral antigen is limited to the respiratory tract, particularly alveolar and bronchiolar epithelial cells and alveolar macrophages. Lesions of naturally infected pigs are not described. In experimental cases, there is necrosis of bronchiolar epithelium, mild proliferation of type II pneumocytes, mononuclear cell infiltrates in alveolar septa, and lymphocytes and macrophages in alveoli. Most field cases are subclinical, and the major importance is that *antibodies to PRCoV cross-react with those to TGEV, leading to false-positive serologic tests in swine herds that are expected to be free of TGEV.* Diagnosis at necropsy is based on isolation or indirect fluorescent antibody tests. Virus neutralization tests and some enzyme-linked immunosorbent assays (ELISAs) do not differentiate PRCoV from TGEV antibodies, but newer blocking ELISAs do differentiate these coronaviruses.

Inclusion body rhinitis – porcine cytomegalovirus

Porcine cytomegalovirus (PCMV) infections are ubiquitous and occur throughout the world, but clinical disease is much less frequent. *Inclusion body rhinitis is typically an acute to subacute disease of 3–5-week-old suckling piglets.* Piglets exhibit fever, sneezing, catarrhal nasal exudate, shivering, and occasional dyspnea. Morbidity is high and mortality is low unless secondary bacterial infections develop. Systemic cytomegalovirus infections usually affect piglets less than 3 weeks of age. These may be found dead without premonitory signs, or exhibit sneezing, lethargy, and anorexia, subcutaneous edema of the jaw and tarsal joints, and dyspnea. Infection of naive pregnant sows induces mild lethargy, anorexia, and delivery of stillborn or weak piglets.

Inclusion body rhinitis is caused by PCMV, a β-herpesvirus. Piglets commonly shed the virus soon after weaning at 3 weeks of age, suggesting that infection is usually acquired by contact with nasal secretions of infected cohorts. Other pigs, particularly those that develop generalized disease, are probably infected from the sow in the neonatal period. The virus replicates in nasal submucosal and lacrimal glands. Viremia develops at 5–14 days after infection, depending on the age of the pig, and leads to infection of epithelial cells in renal tubules, liver, duodenum, and elsewhere. Pulmonary alveolar and splenic macrophages may be additional sites of viral replication. Virus is shed in nasal and ocular secretions, in the urine, and in vaginal secretions of sows.

Gross lesions in pigs infected with cytomegalovirus are usually only seen in piglets less than 3 weeks of age with generalized disease, and may include catarrhal rhinitis, hydrothorax, hydropericardium, pulmonary and subcutaneous edema, and renal petechiae. **Histologically**, *large 8–12 μm basophilic intranuclear inclusion bodies* are numerous in the epithelial cells of the nasal submucosal glands and their ducts (Fig. 5.50). Affected glands are not diffusely distributed but tend to occur in irregular clusters. As the inclusion forms, cytomegaly and karyomegaly develop. The nuclear membrane becomes indistinct and the inclusions appear as blue-gray smears, and the necrotic epithelium sloughs into the lumen. The developing immune response incites a lymphocytic infiltrate in the lamina propria, macrophages and lymphocytes cluster within degenerating glands, and there is squamous metaplasia of the surface epithelium.

Systemic lesions develop following viremia, with intranuclear inclusion bodies in epithelial cells of renal tubules and glomeruli; lacrimal, Harderian, and salivary glands; and less commonly in hepatocytes and sinusoidal lining cells, adrenal gland, esophageal submucosal glands, lymph nodes, spleen, renal medulla, lung, and elsewhere. *Inclusions are most numerous in epithelium but also occur in macrophages and endothelial cells*; this vascular disease accounts for the petechiation and edema. Inclusion bodies are often accompanied by cytomegaly, lymphocytic infiltrates, and occasionally focal necrosis. Focal gliosis with intranuclear inclusions in scattered glial cells occurs throughout the central nervous system. The viremic phase may last for 2–3 weeks and is followed by persistent infection in pulmonary macrophages.

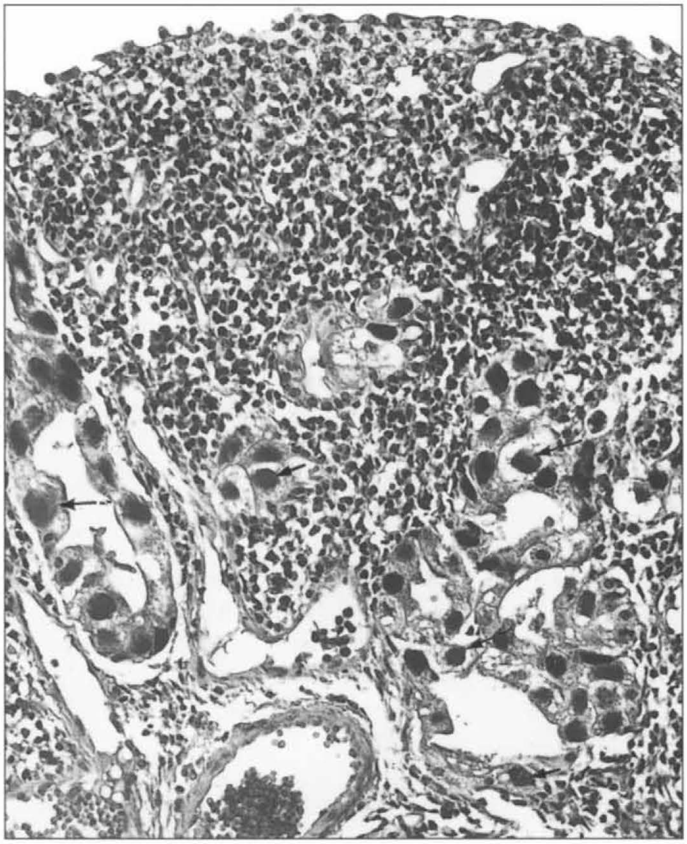

Figure 5.50 Inclusion body rhinitis in a pig. Large, basophilic intranuclear inclusions (arrows) in enlarged epithelial cells of the mucosal glands, with lymphocytic rhinitis.

Inclusion bodies, cytomegaly, and karyomegaly are pathognomonic when present. Adenovirus is the only viral agent likely to cause similarly large basophilic intranuclear inclusion bodies, but adenovirus does not induce cytomegaly and is usually restricted to intestinal epithelium in swine. The intranuclear inclusions of pseudorabies are eosinophilic, less obvious than those of cytomegalovirus, focal necrosis is more prominent, and lesions are most prominent in brain, respiratory tract, and lymphoid tissue. Confirmation of cytomegalovirus infection may be achieved by electron microscopy to search for herpesviral particles, or by virus isolation, immunofluorescence, or PCR on nasal scrapings, lung wash cells, or kidney homogenates.

Pseudorabies

Pseudorabies (Aujeszky's disease) is described in more detail in Vol. 1, Nervous system, for neurologic signs predominate in most cases of pseudorabies in young swine. However, *certain strains of pseudorabies virus tend to cause respiratory disease*, particularly following aerosol exposure of older pigs. The respiratory form is typified by high morbidity and low mortality, unless secondary bacterial pneumonia develops. Affected pigs are depressed, febrile, and display episodes of sneezing, coughing, and dyspnea. Gross lesions in the upper respiratory tract are most common, and include necrotizing rhinitis and laryngotracheitis, with foci of necrosis in the tonsils. Lung lesions are less consistent, but patchy areas of reddening and consolidation may be scattered throughout the lung, or target the cranioventral lung. Histologically, *bronchointerstitial pneumonia* is characterized by necrosis and sloughing of bronchial and bronchiolar epithelium, with *frequent intranuclear eosinophilic or faintly basophilic inclusions* in the early stages of disease. Alveolar lesions include multifocal necrosis, sloughing of necrotic alveolar epithelium, fibrinous exudate in alveoli, hemorrhage, infrequent inclusion bodies, and infiltration of lymphocytes, macrophages, and fewer plasma cells and neutrophils. Experimentally, necrotizing lesions develop within 3–6 days of infection, infiltration of lymphocytes is prominent by days 5–8, and repair occurs during days 6–10.

Nipah virus

Nipah virus emerged as an epidemic cause of nervous and respiratory disease in pigs and humans in Malaysia in 1998 and 1999 and in humans in Bangladesh in 2004. The disease also affects dogs and cats, and horses and goats develop an antibody response. Nipah and Hendra viruses are the lone members of the genus *Henipavirus* (family Paramyxoviridae). *Pteropus* fruit bats (flying foxes) are the reservoir and major source of infection; pigs are considered a major source of infection for humans and other pigs, while human-to-human transmission appears to be rare.

Gross lesions are nonspecific, but *the characteristic histologic findings are lymphocytic and/or fibrinoid vasculitis; lymphoid necrosis; syncytial cells affecting lymphoid tissues, endothelium, and perivascular cells; and intracytoplasmic eosinophilic inclusion bodies.* The lesions include lymphocytic meningitis and, to a lesser extent, encephalitis that is present throughout the brain but most severe in olfactory bulb; necrotizing, lymphocytic, and/or hyperplastic rhinitis, tracheitis, bronchitis, and bronchiolitis (Fig. 5.20); lymphohistiocytic bronchointerstitial pneumonia; necrosis of lymphoid tissues, particularly tonsil and submandibular and bronchial lymph node; and lymphocytic infiltrates in multiple organs.

Nipah virus is readily isolated from blood, tonsil, nasal mucosa, lung, and other lymphoid tissues. Viral antigen is demonstrated by immunohistochemistry in epithelial cells in tonsil, trachea, bronchioles, and alveoli; alveolar macrophages; meningeal connective tissue and possibly astrocytes; endothelium and muscularis of inflamed blood vessels; and areas of lymphoid necrosis.

Bacterial diseases

Actinobacillus pleuropneumoniae

Actinobacillus pleuropneumoniae (APP) causes contagious pleuropneumonia, an important cause of severe, often fatal, pneumonia in growing pigs. The disease is most common in 6-week to 6-month-old hogs. The severity is highly variable, but case fatality rates of 20–80% are common in acute outbreaks. Clinical signs in severely affected swine include fever, lethargy, severe dyspnea, cyanosis, bloody discharge from the nose, and occasionally vomiting or diarrhea. Convalescent pigs with chronic pneumonia may fail to thrive and display exercise intolerance and coughing.

APP is a gram-negative coccobacillus of the family Pasteurellaceae, and is classified based on requirement for an exogenous source of nicotinamide adenine dinucleotide (NAD) – biovar 1 is NAD-dependent, biovar 2 is NAD-independent. Twelve serotypes are defined by antigenic variation in capsular polysaccharide and cell wall lipopolysaccharide. Serotypes 1, 5, and 7 are most common in North America, serotypes 2 and 9 are prevalent in Europe, and serotypes 1, 7, and 12 are frequent in Australia. Serotypes 1, 5, 9, and 11 secrete both Apx I and II toxins and tend to cause more severe disease than other serotypes. Immunity to heterologous serotypes is only partially protective.

APP benefits from a rich spectrum of *virulence factors.* Three cytotoxins, named Apx I, II, and III, are members of the RTX (repeats in toxin) family of secreted toxins, along with *Mannheimia haemolytica* leukotoxin and *Escherichia coli* hemolysin. A fourth Apx toxin gene expressed in vivo but not in vitro is of uncertain significance. The Apx toxins are potent inducers of cytolysis in porcine neutrophils, alveolar macrophages, erythrocytes, and epithelial cells. Low concentrations induce an oxidative burst in porcine neutrophils. These toxins appear critical to development of disease, as Apx toxin-deficient mutants have reduced virulence, which is restored when the toxin genes are reintroduced. Lipopolysaccharide induces macrophage activation and secretion of neutrophil chemoattractants, procoagulant activity, and complement activation, similar to that described for *M. haemolytica*. The capsule impairs phagocytosis by macrophages and may prevent complement activation. Isolates with thin capsules may be less pathogenic. APP produces superoxide dismutase, catalase, and hydroperoxide reductase, which may protect against oxidative killing by neutrophils and macrophages. Other virulence factors include fimbrial adhesins, outer membrane proteins, iron-binding proteins, metalloproteinase, and urease.

Infection is acquired by direct contact with infected pigs or by spread of aerosol droplets over short distances. The bacteria may be carried in the nasopharynx of apparently healthy animals, and these carriers are the principal method of introduction onto a naive farm. In contrast to *Pasteurella multocida* and *Bordetella bronchiseptica* in pigs and *M. haemolytica* of cattle, APP often causes disease in the absence of predisposing factors. Nevertheless, disease severity is enhanced by *Mycoplasma hyopneumoniae* or pseudorabies infections, and by factors that cause ciliary stasis. The interaction between PRRSV and APP infections is controversial.

Following inhalation, APP rapidly binds to the epithelium lining terminal bronchioles and alveoli. Neutrophil infiltration and alveolar exudate develop as early as 90 minutes after infection. Neutrophil recruitment is primarily due to secretion of neutrophil chemoattractants by macrophages in response to infection, for bacterial products themselves do not directly induce neutrophil chemotaxis. *Leukocyte necrosis is a prominent feature of the histologic lesions*, and is presumably mediated by the Apx cytotoxins.

Immunity is conferred by mucosal IgA and serum IgG antibody responses, particularly to the Apx cytotoxins. However, heterologous infections impart only partial immunity, and this effect is not dependent on patterns of Apx toxin expression, implying that antibody against other bacterial antigens also contributes to protection. Antibody against surface components such as capsular polysaccharide greatly enhances phagocytosis of APP by neutrophils and macrophages, and neutrophils but not macrophages effectively kill these opsonized bacteria in vitro. In endemically infected herds, maternal antibody declines over the first 12 weeks of life, and active immune responses contribute to increasing titers thereafter. In experimental infections, serum antibody titers are detectable at 2 weeks and maximal at about 5 weeks after infection.

Gross findings in pigs that die of contagious pleuropneumonia are typified by *fibrinosuppurative, hemorrhagic, and necrotizing lobar pneumonia or pleuropneumonia.* Identical gross lesions may be caused by *Actinobacillus suis* and, less frequently, by *Salmonella choleraesuis*; these are important differential diagnoses in minimal-disease herds expected to be free of APP. The lesions commonly affect the *middle or caudal lung lobes*, and may be unilateral or bilateral (Fig. 5.51). Lesions are deep red, firm to hard, protrude above the surrounding lung, and cut crisply. The cut surface often exhibits sharply demarcated, irregularly shaped, 1–10 cm foci of coagulative necrosis that are friable and pale. In peracute cases, interlobular septa are expanded by fibrin and edema, and fibrinous exudate on the pleural surface ranges in appearance from a haze resembling ground glass to mats of elastic fibrin. The bronchi may contain frothy or bloody fluid, and blood may ooze from the nostrils. Bronchial and mediastinal lymph nodes are enlarged, edematous, and congested. The pericardial and peritoneal cavities may contain scant serosanguineous fluid. Lesions in chronic survivors include fibrous pleural adhesions, sequestra that develop from large foci of coagulative necrosis, and locally extensive pulmonary fibrosis or abscessation. Acutely affected pigs occasionally develop hyaline thrombi and fibrinoid necrosis of glomerular capillaries, afferent arterioles, and interlobular renal arteries, perhaps mediated by endotoxemia.

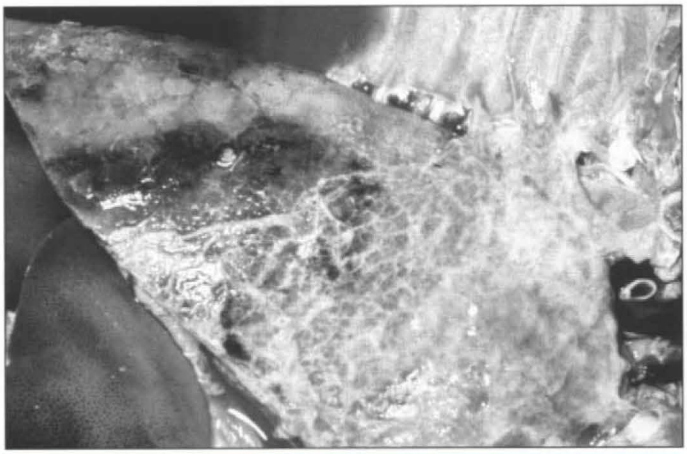

Figure 5.51 ***Actinobacillus pleuropneumoniae* pneumonia** in a pig. The cranial part of the caudal lung lobe is black and hard, and the pleura is covered by fibrin.

Microscopic investigation of these lesions reveals filling of alveoli and terminal bronchioles by fibrin, neutrophils, fewer macrophages, and many necrotic leukocytes that are probably neutrophils. The foci of necrosis, which are often centered on alveolar septa, are delineated by a basophilic band of intense neutrophil infiltration and extensive neutrophil necrosis. In the center of the necrotic areas, the exudate varies from protein-rich edema, to fibrin, to leukocytes. As in other areas of the lung, many of the leukocytes contain streaming, lightly basophilic, homogeneous chromatin debris similar to the "oat cells" of bovine pneumonic pasteurellosis. These neutrophils are in an apparent state of activation, and express tumor necrosis factor-α, IL-1, and IL-8 mRNA at high level.

The mucosa of bronchi and bronchioles may be invaded by neutrophils with fewer macrophages and neutrophils, and bronchiolar epithelium may be necrotic or sloughed. Nevertheless, a discovery of extensive bronchiolar necrosis should prompt a search for concurrent viral infection, such as influenza. Thrombi may develop in small venules and capillaries in the alveolar and interlobular septa, and fibrinoid vasculitis has been infrequently described. Lymphatics in the alveolar septa are distended by serofibrinous exudate with variable numbers of neutrophils. Extrapulmonary lesions are uncommon, but include renal glomerular thrombosis, renal vasculitis, or osteomyelitis.

Lesions of localized or locally extensive fibrinous and necrotizing pneumonia suggest APP, *A. suis* or, less commonly, *S. choleraesuis* as likely causes. *Definitive* **diagnosis** *depends on isolation of the agent, and microscopic identification of suppurative bronchopneumonia with neutrophil necrosis.* Isolation on blood agar requires a *Staphylococcus* streak or supplemented medium containing a source of nicotinamide adenine dinucleotide. Alternatively, bacteria in lung smears or primary cultures can be identified using antigen detection techniques such as ELISA or latex agglutination. Current polymerase chain reaction assays for APP cross-react with other *Actinobacillus* spp, and this assay is not commonly employed. Serologic identification of APP is particularly useful in the maintenance of minimal-disease herds; assays include the reference standard complement fixation test, which is recognized to have low sensitivity, and an ELISA that is useful but suffers from poor repeatability.

Bronchopneumonia caused by miscellaneous bacterial pathogens

The porcine respiratory disease complex is an exemplar of multifactorial disease causation. Although bacterial pneumonia is the final cause of death in many cases of porcine respiratory disease, its development is highly dependent on host factors, environmental influences, and other infectious agents. Important contributing environmental factors include elevated levels of dust and ammonia, temperature fluctuations and, to a lesser extent, extremes of temperature and humidity. In temperate climates, the incidence of swine pneumonia is maximal in the autumn and early winter, in part caused by fluctuating temperatures and the impact of cold weather on barn ventilation and air quality. Immunity to respiratory pathogens is dependent on patterns of pig flow through production units, vaccination practices, and alterations in innate resistance due to social and environmental stresses, nutrition, and management practices. Against this background of host and environmental factors, interactions between multiple pathogens are commonly identified in swine pneumonia. Thus, *effective control of disease requires that diagnostic investigations identify not only the immediate causes of fatal disease, but also the underlying infectious and noninfectious factors.*

Porcine reproductive and respiratory syndrome virus, *Mycoplasma hyopneumoniae*, swine influenza virus, and *Porcine circovirus 2* may all cause primary lung disease. In addition, all of these agents impair the normal pulmonary defenses against inhaled bacterial pathogens by, among other mechanisms, impairing mucociliary clearance and suppressing alveolar macrophage function. Swine are commonly exposed to the **opportunistic pathogens** *Pasteurella multocida*, *Streptococcus suis*, *Bordetella bronchiseptica*, and *Haemophilus parasuis*, and failure of lung defenses due to viral or mycoplasmal infection, poor air quality, or stresses are probably key factors in development of disease caused by these bacterial pathogens.

P. multocida serotypes A and D are important causes of fatal pneumonia in weaner and grower-finisher pigs. The massive doses of *P. multocida* needed for experimental induction of disease suggest that the predisposing causes listed above are necessary components of the natural disease. *Bordetella* is particularly noteworthy as a cause of fatal pneumonia in piglets less than 3 weeks of age, but may also cause bronchopneumonia in older swine.

Gross lesions of bronchopneumonia, in which cranioventral areas of lung are swollen, consolidated, reddened, and sharply demarcated from more normal lung, are typical of infection with these opportunistic bacterial pathogens. In many, but not all, cases, mucopurulent exudate may be expressed from airways on cut section. Fibrinous pleuritis may be present, but the massive serofibrinous exudate typical of *Actinobacillus pleuropneumoniae* is not present. Bronchial lymph nodes are often enlarged and mottled red and white. The predominant **histologic findings** are numerous neutrophils and macrophages filling alveoli and bronchioles. Fibrin exudation may occur but is usually minor. These lesions contrast with those of *A. pleuropneumoniae* and *A. suis*, where fibrinous exudate in the lungs and on the pleural surface is often prominent, most of the neutrophils are necrotic and have streaming basophilic chromatin, and focally extensive coagulative necrosis is often present. In cases of bronchopneumonia the bronchiolar epithelium is generally normal or mildly hyperplastic, but bronchiolar necrosis is usually absent unless there is underlying SIV or PCV2 infection. *M. hyopneumoniae* also causes a cranioventral pattern of bronchopneumonia, but in contrast to the red swollen lung of bacterial bronchopneumonia, the acute lesions of mycoplasmosis are red and atelectatic, while the subacute lesions are gray to tan and only mildly swollen to firm. Cranioventral bronchopneumonia superimposed on generalized or patchy lesions of interstitial pneumonia suggests underlying PRRSV or PCV2 infection, or septicemia.

While bacterial bronchopneumonia may be the immediate cause of death, viral or mycoplasmal pathogens should be considered as underlying causes. Microbiologic testing is commonly employed to identify the spectrum of pathogens causing pneumonia, but the plethora of currently available tests does not diminish the importance of morphologic examination of the lung. Determining the patterns of gross and histologic lesions allows the pathologist to narrow the list of differential diagnoses to select a panel of ancillary tests efficiently, to provide a tentative diagnosis when rapid therapeutic intervention is required or when ancillary microbiologic tests are negative, and to evaluate critically the contribution of particular pathogens, many of which are commonly present in healthy swine, to the case being investigated.

Atrophic rhinitis

Nonprogressive atrophic rhinitis (NPAR), caused by *Bordetella bronchiseptica* and other factors, causes mild transient sneezing and nasal discharge, and is *not usually of herd significance*. In contrast, **progressive atrophic rhinitis** (PAR) is caused by toxin-producing strains of *Pasteurella multocida*, often in concert with other bacterial pathogens, and is *a serious cause of production loss*. PAR affects pigs of at least 6–12 weeks of age, causing sneezing, mucopurulent nasal discharge, unilateral epistaxis, nasal deformity, failure to thrive, and

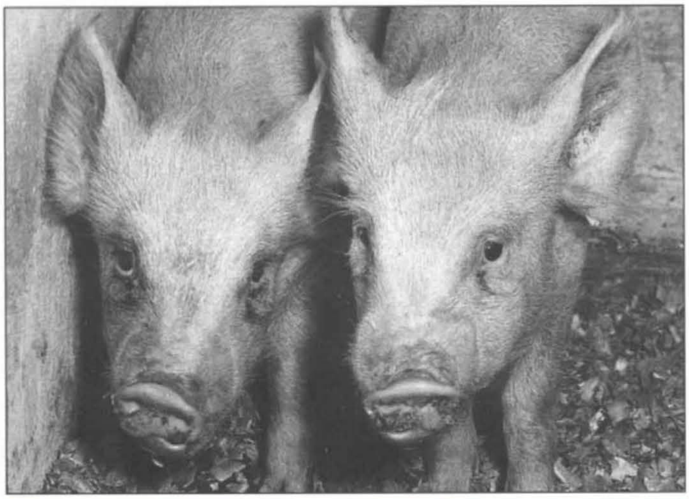

Figure 5.52 Atrophic rhinitis with deviation of the snouts of two pigs.

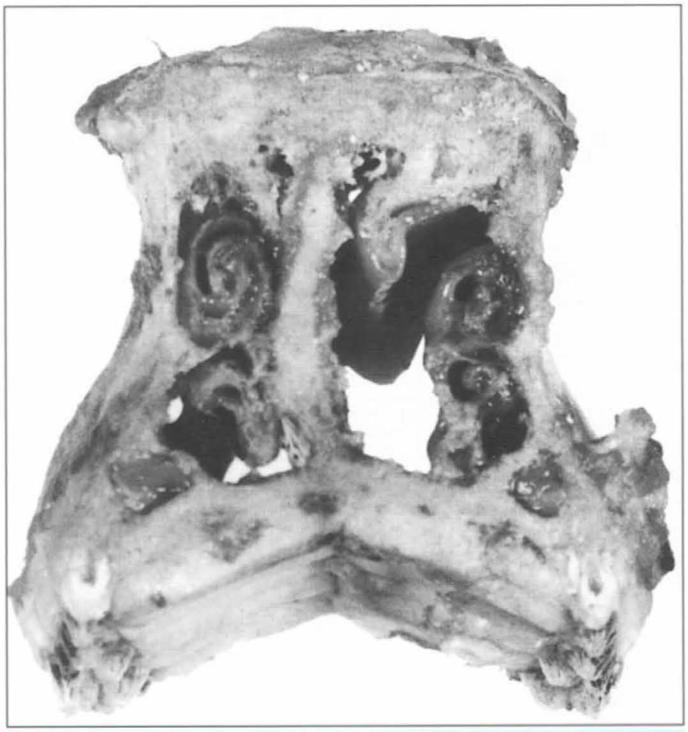

Figure 5.53 Atrophic rhinitis in a pig, with atrophy of turbinates and deviation of the nasal septum.

secondary bacterial bronchopneumonia. Freedom from PAR is a frequent requirement in minimal-disease herds, so *differentiation of PAR and NPAR is of substantial significance.* Toxigenic *P. multocida* infects rodents, cats, dogs, and ruminants, and may be of zoonotic concern.

Both NPAR and PAR are multifactorial conditions for which air quality and the presence of other pathogens influence the severity of disease. NPAR is primarily caused by strains of *B. bronchiseptica* that adhere to nasal cilia and tonsillar epithelium, and produce a toxin that causes mucosal edema, loss of cilia, and resorption of turbinate bone. Infection is acquired by inhalation of infected aerosol droplets.

Progressive atrophic rhinitis is caused by cytotoxin-producing strains of P. multocida type D or, less commonly, type A. Infection is acquired by inhalation following direct contact with infected pigs. Colonization of the nasal mucosa and tonsil is inefficient, but augmented by factors that harm the nasal mucosa, including *B. bronchiseptica* infection, ammonia, and dusts. The *cytotoxin*, also referred to as *dermonecrotic toxin*, is a secreted, heat-labile toxin encoded by the *tox*A gene. Intranasal or intramuscular administration of *P. multocida* cytotoxin has similar effects on the nasal turbinates, including epithelial hyperplasia, glandular atrophy, resorption of turbinate bone by osteoclasts, reduced formation of bone by osteoblasts, and fibroblast proliferation. The cytotoxin does not directly affect osteoclast function; rather, hyperplasia and increased function of these cells are apparently stimulated by soluble mediators secreted from nearby stromal cells in response to the cytotoxin.

Distortion of the snout is a prominent external finding in pigs with chronic atrophic rhinitis (Fig. 5.52). Brachygnathia superior occurs when the maxillary bones of the snout fail to grow. Lateral deviation toward the most severely affected side is common.

Atrophy and malformation of the nasal turbinates are the principal lesions of atrophic rhinitis, and are more severe in the ventral than the dorsal conchae. In cross-sections of the snout at the level of the first or second upper premolar teeth, the normally scroll-like turbinates are misshapen and form irregular or jumbled finger-like protrusions (Fig. 5.53). Turbinate atrophy may be partial or complete, leaving a hollow nasal cavity with an often-deformed nasal septum.

Histologic lesions in the nasal turbinates include *osteoclast hyperplasia, osteoclast-mediated resorption of bone, and replacement by fibrous tissue containing many plump fibroblasts.* Lymphocytes and fewer neutrophils infiltrate the nasal mucosa, and there may be squamous metaplasia of the ciliated epithelium.

The gross lesions of NPAR and PAR are qualitatively similar, although those of NPAR are generally less severe. Nevertheless, given the significance of a diagnosis of progressive atrophic rhinitis due to toxigenic *P. multocida*, definitive identification is usually warranted. *B. bronchiseptica* and *P. multocida* can be readily isolated from swabs of nasal mucosa or tonsil, but *definitive diagnosis of PAR depends on demonstrating P. multocida cytotoxin production using PCR or an ELISA.* Various necropsy-grading systems have been described to assess the severity of nasal turbinate atrophy. These grading systems are not intended to differentiate NPAR from PAR, but are useful in monitoring the herd response to management or therapeutic interventions.

Mycoplasmal diseases

General features of mycoplasmas

Mycoplasmas, which are members of the class Mollicutes, are the smallest self-replicating organisms, lack a cell wall, and have a protein- and lipid-rich plasma membrane. They are obligate parasites, and several species lack the ability to synthesize required amino acids, cholesterol, and fatty acids. The success of culturing mycoplasmas in vitro is highly dependent on the particular species: some mycoplasmas grow so readily that they commonly contaminate cell cultures, yet many of the pathogenic mycoplasmas grow slowly, have frustratingly fastidious growth requirements, and are easily overgrown by other agents. Mycoplasmas have a relatively small genome, 580–1380 kb for the species examined to date, which contains many repetitive elements and a propensity for genomic rearrangement through homologous recombination. Many mycoplasmas have highly specific host and tissue tropism, and are commonly commensals on mucosal surfaces. Nevertheless, spread of infection through the blood with subsequent localization in joints or serosal surfaces is a feature of some mycoplasmoses. *Most mycoplasmal pathogens of the respiratory tract adhere to ciliated epithelium*, mediated in some species by a specialized attachment organelle. A few mycoplasmas invade host cells, but this has not been demonstrated for mycoplasmal pathogens of animals.

High-frequency variation of surface antigens allows several mycoplasmas to evade the humoral immune response by changing their surface lipoprotein antigens as antibodies against these structures are formed. The mechanisms by which *Mycoplasma* infections result in disease remain poorly characterized. Mycoplasmas have not been shown to secrete exotoxins. *Pathogenic mechanisms* of respiratory disease include ciliostasis due to membrane alterations, alteration of host prostaglandin synthesis, induction of apoptosis in lymphocytes or other host cells, and nonantigen-specific stimulation of immune responses as a consequence of superantigens in the mycoplasmal plasma membrane. The latter is the likely factor that induces the *prominent peribronchiolar lymphocytic inflammation that is so characteristic of many pulmonary mycoplasmoses.*

Mycoplasma hyopneumoniae

Mycoplasma hyopneumoniae is the cause of *mycoplasmal pneumonia of swine*, also known as *enzootic pneumonia*. It is a common, chronic, usually nonfatal disease of young pigs. The disease may be endemic, or spread slowly but progressively through a facility over the course of weeks, and the morbidity rate may be as high as 70–100%. Although pigs as young as 5 weeks of age may develop disease, it is *most important in grower-finisher pigs* and may be a key component of fatal multifactorial pneumonia in 4–6-month-old hogs. Clinical expressions of the uncomplicated disease are coughing, unthriftiness, poor weight gain, and reduced feed conversion. Because there is usually low mortality associated with mycoplasmal pneumonia, the lesions are generally seen in slaughtered animals or those dying from other diseases. When deaths do occur, they are mainly due to superimposed bacterial infections.

Like other mycoplasmal pathogens, *M. hyopneumoniae* is a tiny bacterium that lacks a cell wall. The agent adheres to ciliated epithelium of the large airways and, in lower number, of the bronchioles, using 97 and 145 kDa outer-membrane proteins. Adherent organisms are closely associated with the cilia, and there is often extensive ciliary loss. In chronic infections, mycoplasmal antigen and nucleic acid are also present in alveolar and interstitial macrophages. The cell membranes of many mycoplasmas, presumably including *M. hyopneumoniae*, contain superantigens that induce polyclonal proliferation of lymphocytes and result in characteristic aggregates of lymphocytes around airways and blood vessels. Infection with *M. hyopneumoniae* is mainly transmitted by direct contact with nasal secretions from infected pigs, although aerosol transmission over short distances may occur. A common clinical scenario involves infection of a few young pigs by contact with an infected sow, followed by slow spread to in-contact pigs when groups are assembled in weaner or grower-finisher units.

Clinical disease is not an inevitable consequence of infection with *M. hyopneumoniae*. Rather, its development is highly dependent on other predisposing factors, including crowding, poor air quality, fluctuations in temperature or humidity, and the presence of other pathogens. Many infections are subclinical, and carrier animals are important sources of infection of naive herds. Primary *M. hyopneumoniae* infection is usually not fatal, but reduced mucociliary clearance and possibly impaired macrophage function may lead to fatal bacterial pneumonia caused by opportunistic pathogens such as *Pasteurella multocida, Streptococcus suis, Bordetella bronchiseptica*, or *Haemophilus* spp. The interaction of PRRSV with *M. hyopneumoniae* is particularly noteworthy: mycoplasmal infection exacerbates the severity and the duration of PRRS, although the effect of PRRSV infection on mycoplasmal pneumonia is apparently minor. As a result, new infections with *M. hyopneumoniae* may cause outbreaks of PRRS in herds with previously subclinical PRSSV infections.

The characteristic **gross feature** *of mycoplasmal pneumonia is red-tan-gray discoloration, collapse, and rubbery firmness affecting cranioventral regions of the lungs in a lobular pattern* (Fig. 5.54). Lesions often affect cranial and middle lung lobes, accessory lobe, and cranioventral portions of the caudal lobes. The mildest lesions resemble atelectasis, with a lobular pattern of reddening and collapse. More severe lesions evolve from dark red through gray-pink to more homogeneous gray as the lesion ages over the several-month course of disease. The rubbery or thymus-like texture of the lung contrasts with the more firm or

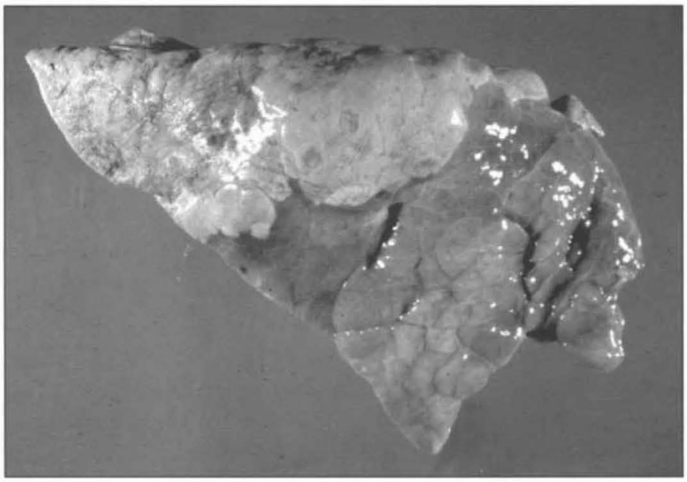

Figure 5.54 ***Mycoplasma hyopneumoniae* pneumonia** in a pig. The cranioventral lung (right) is dark, collapsed, and rubbery.

hard consistency of *Pasteurella* pneumonia, although this is often present concurrently. The cut surface of affected lung is edematous, and catarrhal exudate can be squeezed from bronchi. The bronchiolar orientation of the inflammation often results in a regular pattern of small gray nodules against a red background. *M. hyopneumoniae* rarely causes serofibrinous pleuritis or polyserositis, but this is more commonly due to *M. hyorhinis* or opportunistic bacteria. Pulmonary lymph nodes are enlarged and on cut surface are moist, usually bulging and sometimes hyperemic.

Histologically, subacute to chronic mycoplasmal pneumonia in swine is typified by lymphocytic infiltrates around airways, increased numbers of alveolar macrophages, and alveolar edema. In the fully developed mycoplasmal pneumonia, there is *extensive lymphoid hyperplasia* around bronchi, bronchioles, and their associated vessels; and lymphocytes infiltrate the lamina propria of the airway mucosa. The epithelium is often histologically normal or mildly hyperplastic. Although ciliary loss and exfoliation of ciliated epithelium may occur, this if difficult to detect by light microscopy. Goblet cells in the airway mucosa are increased in number and the bronchial submucosal glands are hyperplastic, reflecting the excessive mucus secretions seen grossly. The alveolar exudate consists predominantly of macrophages and protein-rich edema, but variable numbers of plasma cells, lymphocytes, and neutrophils are present. The alveolar septa are mildly thickened by lymphocytes and few plasma cells (Fig. 5.55).

Experimental studies of the pathogenesis of mycoplasmal pneumonia indicate that typical gross lesions do not occur until 2–4 weeks after infection. The rate of development of lesions is dependent on the dose and strain of *M. hyopneumoniae*, method of administration, and susceptibility of the pigs exposed. Young pigs naturally exposed to infectious aerosols soon after birth can develop lesions by the time they are 3–5 weeks of age. In the first week after experimental infection, neutrophils are present in airway lumens and, to a lesser extent, in alveoli. The numbers of neutrophils diminish and lymphoid cells increase over the subsequent several weeks to reach the fully developed stage of consolidation. After it has reached its peak some 5–6 weeks after infection, lesions of uncomplicated mycoplasmal pneumonia may persist or completely resolve within 2 months.

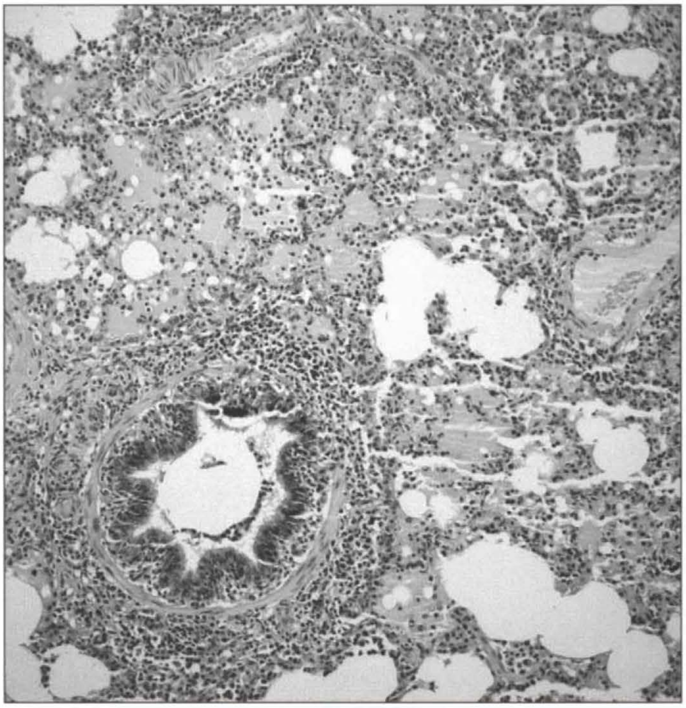

Figure 5.55 ***Mycoplasma hyopneumoniae* pneumonia** in a pig. The bronchiole is surrounded and invaded by lymphocytes, and the alveoli are edematous and contain increased numbers of macrophages.

The gross lesions of gray-tan discoloration and thymus-like texture are quite characteristic. However, many fatal cases are secondarily infected by *Pasteurella multocida* or other opportunists, resulting in red, firm or hard, cranioventral consolidation that appears identical to the bacterial pneumonia that complicates PRRSV, PCV2, or SIV. Similarly, the well-developed histologic lesions with thick peribronchial cuffs of lymphocytes are highly suggestive, yet lymphoplasmacytic peribronchiolitis – usually milder – is also often present in chronic PRRSV, SIV, or PCV2 pneumonia. In these cases, other histologic features can suggest a *tentative diagnosis*: *M. hyopneumoniae* also induces alveolar edema and increased numbers of plump alveolar macrophages, PRRSV results in diffuse lymphocytic infiltrates in alveolar septa, SIV and some PCV2 infections are accompanied in the acute stages by attenuation of bronchial epithelium, and granulomatous infiltrates in lymph nodes suggest PCV2 infection.

Establishing a definitive **diagnosis** in swine herds with pneumonia often requires laboratory support. *M. hyopneumoniae* is extremely fastidious in its growth requirements, and isolation in culture is not a useful method of diagnosis. More sensitive confirmation of a morphologic diagnosis can be obtained by identifying antigen in lesional lung tissue by immunohistochemistry or fluorescent antibody tests, or detection of *M. hyopneumoniae* DNA by polymerase chain reaction using lung tissue, nasal swabs, or transtracheal washes. Detection of serum antibody by ELISA is a useful method of confirming prior exposure, or validating the *M. hyopneumoniae*-free status of minimal disease herds.

Fungal diseases

Pneumocystis carinii

Pneumocystis carinii is a sporadic cause of acute or chronic dyspnea, usually without fever, in pigs, foals, dogs, and other domestic animals. Outbreaks of respiratory disease in pigs have been associated with *Pneumocystis* infection, but it is doubtful that *Pneumocystis* was the primary cause of respiratory disease. *Clinical disease due to Pneumocystis is unlikely without underlying immunosuppression*; identified causes include corticosteroid or other immunosuppressive therapy; severe combined immunodeficiency in foals, sometimes in association with adenovirus or *Rhodococcus* infection; common variable immunodeficiency of Miniature Dachshunds, demodicosis, or canine distemper in dogs; and perhaps PRRSV or PCV2 infection in pigs.

Although previously considered a protozoan, molecular analyses have conclusively determined that *P. carinii* is a *fungus*, probably in the class Ascomycetes. Isolates from different host species should be considered distinct species or subspecies, and there is little evidence that the fungus is of zoonotic importance. The life cycle is based only on morphologic evaluation, but involves a 1–4 μm diameter, thin-walled, *uninucleate, trophic form* that replicates by binary fission; and a 5–8 μm diameter, *thick-walled, multinucleate cyst form* that develops eight intracystic bodies, which may be daughter forms that are products of sexual replication. The latter are released, attach to type I pneumocytes, and presumably develop into trophic forms. The cell wall is composed of mannose-rich polysaccharides and the major surface glycoprotein. This glycoprotein A is the immunodominant antigen and mediates binding of *Pneumocystis* to type I pneumocytes and macrophages, surfactant proteins, and fibronectin. Both macrophages and cell-mediated immune responses are essential for controlling *Pneumocystis*; hence, clinical disease implies that there has been impairment of macrophage function or cell-mediated immune responses. In addition to the space-occupying effect of the fungus, *Pneumocystis* may alter lung function by interfering with surfactant homeostasis.

Gross lesions of *Pneumocystis* pneumonia are diffuse or patchy, red to yellow-brown regions of rubbery firmness or consolidation. The characteristic histologic finding is *foamy or "honeycomb" material filling alveoli*, due to the presence of numerous intra- and extracellular, 8-μm-diameter, round or crescent-shaped, clear fungal bodies, each containing one or more 0.5-μm-diameter, lightly basophilic bodies (Fig. 5.56). Foamy macrophages are present and contain the organisms, but the presence of lymphocytes, plasma cells, type II pneumocytes, and interstitial fibrosis is variable. *The diagnosis is made by identifying the fungi in histologic sections.* They are easily overlooked on hematoxylin and eosin-stained sections, but the wall of the cyst forms stains with methenamine silver or PAS. *Pneumocystis* cannot be cultured using conventional techniques, but novel cell culture systems have recently been described.

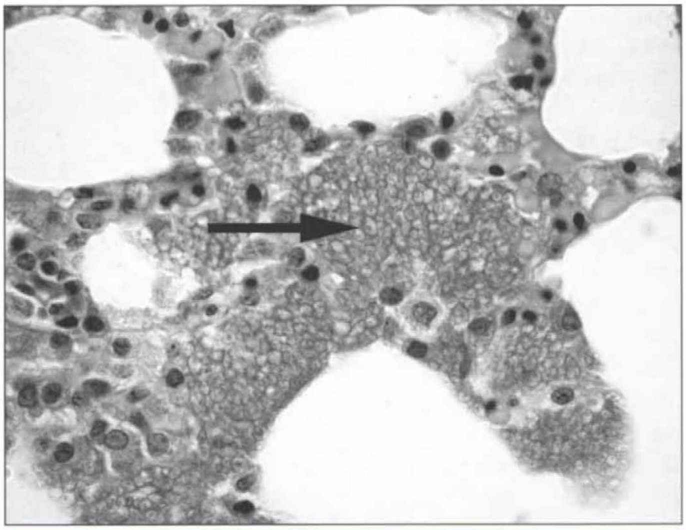

Figure 5.56 *Pneumocystis carinii* infection in a pig. The alveolus is filled with innumerable fungi, each with clear cytoplasm and a tiny dark nucleus (arrow).

Parasitic diseases

Ascaris suum, because of its tremendous biotic potential, may migrate in huge numbers and occasionally be fatal. The lesion is acute, diffuse, eosinophilic, interstitial pneumonia associated with the presence of large numbers of larvae. Rare parasitisms of the respiratory tract of pigs include ***Paragonimus*** spp. and **hydatid disease**.

***Metastrongylus** apri (elongatus), M. pudendotectus*, and *M. salmi* are all parasitic in the bronchi and bronchioles of pigs. They are nematodes of the superfamily Metastrongyloidea, family Protostrongylidae. Because the intermediate host is the earthworm, pulmonary metastrongylosis is now rare in housed swine, but it is common in wild boar. They are believed to be responsible for the occasional transmission of swine influenza virus. The adult worms are white, thread-like, and 14–60 mm in length. In heavy infections, which are mostly in young pigs, they may be found in all lobes of the lung. When there are fewer worms, particularly as occurs in older animals, the worms may be restricted to airways along the caudoventral borders of the caudal lobes. In histologic sections, the adults have polymyarian coelomyarian musculature, cuboidal multinucleate intestinal epithelium with an indistinct microvillus layer, and thick-shelled eggs or embryonated eggs in the uterus. Eggs are laid in the bronchi and a few of them hatch there, but most hatch after passing to the exterior in the feces. First-stage larvae are inactive and are capable of prolonged survival in moist conditions. Their further development depends on ingestion by earthworms, which are the intermediate hosts. The larvae develop to the third, infective stage in about 10 days, and then remain quiescent unless the earthworm is eaten by a pig. The larvae may survive for as long as 18 months in the earthworms and, by that time, thousands may be accumulated by a single worm. Migration within the pig is through the lymphatics from the intestine to the lungs. Some larvae pass through the liver and produce focal hepatitis, as is more commonly caused by *Ascaris suum*.

Even with heavy adult infestations, gross lesions are inconspicuous. The worms live in the smallest airways, and on superficial examination of the lungs the presence of the parasites is frequently only indicated by gray-pink nodules 1–3 mm in diameter and by hyperinflated lobules along the caudoventral margins of the caudal lobes. Histologically, the lesions are similar to those produced by *Dictyocaulus* spp. The initial lesions are multiple foci of intense accumulations of eosinophils surrounding larvae in alveoli. Subsequently, when reproduction is active, an eosinophilic and granulomatous response occurs to the eggs and larvae in the alveoli. The prepatent period for *Metastrongylus* spp. is about 25 days, after which the rate of egg production rapidly reaches a peak and then subsides to a low level. At this later stage, the adults persist mainly in the bronchioles and small bronchi and provoke goblet-cell hyperplasia and exudation of mucus, eosinophils, neutrophils, and mononuclear cells. The bronchiolar epithelium is mildly hyperplastic, and eosinophils, lymphocytes, and plasma cells permeate the lamina propria.

Infectious respiratory diseases of cattle

Viral diseases

General features of herpesviruses

Herpesviruses are 120–200 nm diameter, and composed of an icosahedral nucleocapsid surrounded by a proteinaceous tegument and an outer envelope. Herpesviruses have large genomes composed of double-stranded DNA. Viral infection of cells induces a highly regulated cascade of viral gene expression: preformed tegument proteins and the products of immediate-early and early genes regulate the host transcriptional machinery and viral gene expression, and late genes encode structural proteins of the virus. Viral glycoproteins often form peplomers that project from the surface of the envelope; in addition to being key targets of protective immune responses, these envelope glycoproteins mediate viral entry into target cells, cellular fusion to form syncytia, and spread of virus between cells without exposure of the virus to extracellular antibody. Some envelope glycoproteins act as complement C3b or immunoglobulin Fc receptors, and several herpesviruses encode chemokine or chemokine receptor homologues that modulate the immunoinflammatory response. Viral replication occurs in the nucleus, and virions acquire an envelope by budding through the nuclear membrane. Lysis of the cell releases the mature virions to the extracellular space.

Herpesviruses are classified into *α-*, *β-*, and *γ-herpesvirinae* subfamilies. *The* ***α-herpesviruses*** *are characterized by rapid growth in cell culture, lytic infection of cells, necrotizing lesions, the formation of syncytia in some instances, eosinophilic intranuclear inclusion bodies, latent infections, and narrow or broad host ranges.* Most α-herpesviruses establish latent infections in neurons of the trigeminal ganglia and other sensory ganglia, as well as other sites, including olfactory bulb, optic nerve, nasal turbinate, and cornea. During latent infections, gene expression is restricted to the so-called latency-associated transcripts, which have been utilized as markers of latent infection. Alpha-herpesviruses affecting the lung of domestic mammals include *Bovine herpesvirus 1* (infectious bovine rhinotracheitis), *Caprine herpesvirus 1; Suid herpesvirus 1* (pseudorabies), *Equid herpesviruses 1* and *4* (equine abortion, equine viral rhinopneumonitis), *Canid herpesvirus 1*, and *Felid herpesvirus 1* (feline viral rhinotracheitis).

The **β-herpesviruses**, including *Suid herpesvirus 2* (porcine cytomegalovirus) have a limited host range, and these cytomegaloviruses induce pathologic enlargement of infected cells and prominent basophilic intranuclear inclusion bodies. Replication of cytomegaloviruses is slower than that of α-herpesviruses, and disease is more chronic. As the immune response is generally effective, disease due to cytomegalovirus occurs principally in immunodeficient or immunosuppressed animals.

Infectious bovine rhinotracheitis

Infection with *Bovine herpesvirus-1* (BoHV-1, Infectious bovine rhinotracheitis virus) is widespread in cattle populations, but the disease infectious bovine rhinotracheitis (IBR) is uncommon in areas where vaccination is practiced. Although sporadic outbreaks of IBR still occur, the ability of BoHV-1 infection to impair lung defenses and predispose to bacterial pneumonia are probably of more importance to the beef industry. Feedlot calves usually develop IBR at least 3 weeks after entry to the feedlot, with an abrupt onset of fever, anorexia, tachypnea, mucopurulent nasal discharge, and dyspnea or open-mouth breathing. The nasal mucosa and muzzle are often hyperemic, suggesting the epithet "red nose," and white, loosely adherent plaques may peel from the surface. The mortality rate is low unless secondary bacterial pneumonia develops. Keratoconjunctivitis is common in calves with IBR, and affected cows or others in contact may abort. Vulvovaginitis and balanoposthitis are uncommon in calves with IBR. Calves that are infected in utero with BoHV-1 may be aborted, or may develop systemic disease in the neonatal or early suckling period up to about 1 month of age.

Affected calves are febrile, depressed, anorexic, and may display dyspnea or diarrhea.

Bovine α-herpesvirus infections cause infectious bovine rhinotracheitis, keratoconjunctivitis, bronchointerstitial pneumonia, abortion, encephalitis, systemic herpesvirus infection in young calves, and pustular vulvovaginitis or balanoposthitis. The factors that determine the manifestation are not fully understood, but include the following: route of infection (genital infection usually manifests as vulvovaginitis or balanoposthitis); strain of the virus (a distinct virus type, BoHV-5, is the usual cause of herpesviral encephalitis in calves); and degree of immunity (systemic herpesviral infection develops in young calves with low serum antibody titers to the virus).

BoHV-1 contains a large 136 kb genome that encodes 67 proteins. Ten envelope glycoproteins have been described. The glycoproteins gC and gD bind cell surface receptors, allowing virus entry into the cell by gB, gH, and gL. Fusion of cells, mediated by gB and gD, allows intercellular spread of virus and evasion of the immune response, and is the molecular basis of the epithelial syncytia that are occasionally noted histologically. The gC glycoprotein binds C3 component of complement and prevents complement activation, while gI and gE are Fc receptors for immunoglobulin that impair antibody-mediated neutralization of the virus.

BoHV-1 infects a wide range of animals, including cattle, sheep, goats, llamas, swine, water buffalo, mustelids, and rabbits, but *primary viral respiratory disease is only described in cattle.* Sources of BoHV-1 infection include clinically or subclinically infected cattle, and reactivation of latent infections. Wild ruminants may be subclinical reservoirs. Infection is transmitted by aerosol; direct contact with nasal, ocular, or vaginal secretions; or by indirect contact with fomites, semen, feed, or water. Systemic spread of the virus is a feature of the syndromes of systemic infection, abortion, and encephalitis. Viremia is not usually evident in cases of IBR, keratoconjunctivitis, vulvovaginitis, or balanoposthitis, although monocyte- or lymphocyte-associated viremia may occur at low level. In the latter conditions, virus spreads along mucosal epithelium, nerves, and lymphatics. *Latent infection of trigeminal or other sensory ganglia is common,* and probably follows axonal spread of infection rather than viremia. In latently infected neurons, viral DNA is present but, with the exception of a few "latency-associated transcripts," viral RNA or protein cannot be detected. Stress, glucocorticoid or epinephrine therapy, hyperthermia, or hypothermia trigger reactivation of the latent infection, and virus reaches the mucosal surface by retrograde axonal transport where mucosal replication leads to shedding of infectious virus. Reactivated infections are usually subclinical, but may act as a source of contagion to naive, in-contact animals.

Infection of the respiratory tract induces *clinical disease* after an incubation period of 2–6 days, and virus is shed in nasal secretions for at least 10–16 days. Clinical IBR is primarily an effect of lytic infection of nasal and airway epithelial cells. Functional abnormalities such as serotonin- or dopamine-induced bronchoconstriction may also contribute to clinical signs. Secondary bacterial pneumonia in calves with IBR is a consequence of the destruction of ciliated epithelium by lytic viral infection, and impairment of the ability of alveolar macrophages to phagocytose bacteria and secrete neutrophil chemotactic factors. These impairments of lung defenses are maximal at 4–5 days after viral infection.

Interferon-α and -β secretion is detectable within 5 hours of BoHV-1 infections, and peaks at 36–72 hours. These interferons mediate innate resistance to spread of the infection, in part by recruiting macrophages and natural killer cells to the sites of viral infection. Cell-mediated immune responses are detectable in the respiratory tract within 5 days of infection, and mediate lysis of virus-infected cells. Neutralizing IgG is first detected at 10 days after infection, and IgA responses develop later. Antibody prevents disease in calves exposed to the virus. In infected calves, antibody neutralizes free virus and may prevent mucosal shedding of virus following reactivation of latent infection. However, because the virus evades the humoral immune response by intracellular spread to adjacent cells, a combination of cellular and humoral immunity is probably necessary for recovery from infection.

Gross lesions of IBR are usually restricted to the *nasal cavity, larynx, and trachea.* Pustules erupt early after infection, but are fragile and rarely observed. Petechiae, a granular appearance of the mucosa, and serous exudate may be present in acute lesions. More commonly, there is intense hyperemia of the mucosal tissue, multifocal coalescing erosions with loosely adherent plaques of white debris, or diffuse ulceration covered by a mat of fibrinonecrotic and suppurative exudate forming a pseudodiphtheritic membrane (Fig. 5.57). When the exudate is peeled from the surface of the trachea or nasal cavity, dull granular eroded tissue remains. In contrast, in cases of bacterial pneumonia in which expectorated material accumulates on the tracheal or nasal mucosa, gentle removal of the exudate reveals a shiny intact mucosal surface. In severe cases, obstruction of the laryngeal or tracheal lumen by abundant exudate may prove fatal. Emphysema is a sequel to dyspnea in severely affected calves.

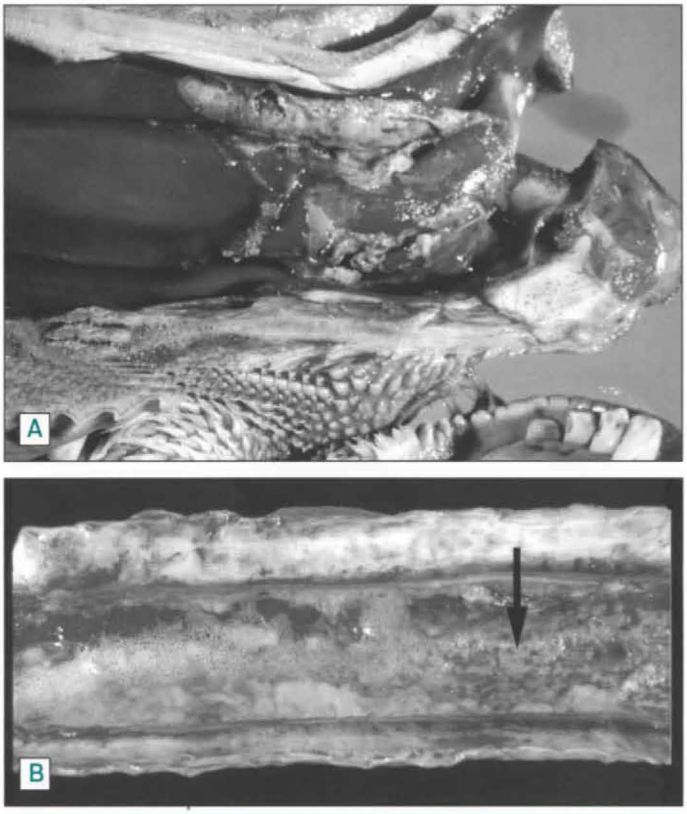

Figure 5.57 Infectious bovine rhinotracheitis. A. Fibrinous exudate adherent to the eroded mucosa of the rostral nasal cavity. **B.** Multifocal coalescing ulcers (arrow) of the tracheal mucosa.

The earliest **histologic lesions**, in the first 2 days after infection, include cytoplasmic vacuolation and pallor and nuclear pyknosis or karyolysis. Eosinophilic intranuclear inclusion bodies are present in the epithelium of the nasal turbinates, tracheal submucosal glands, and bronchi, but are rare in the tracheal surface epithelium. *Inclusions are absent in most diagnostic cases*, and the lesions at these later times include erosion or ulceration of nasal and tracheal mucosa, with necrosis and exfoliation of infected epithelial cells and exudation of neutrophils and fibrin. Neutrophils and mononuclear cells infiltrate the lamina propria. Mild perivascular infiltrates of lymphocytes may be detected in the trigeminal ganglion and brainstem.

Pulmonary lesions of primary viral pneumonia are uncommon, but *young calves may develop bronchointerstitial pneumonia without significant upper respiratory lesions*. There is erosion of bronchiolar epithelium and proliferation of type II pneumocytes. Epithelial syncytia may be numerous in alveoli, and eosinophilic intranuclear inclusion bodies are more common than is seen in IBR.

Systemic lesions of BoHV-1 infection in young calves include multiple, coalescing, 1–7 mm diameter, sharply demarcated foci of necrosis in the upper digestive tract, including the oral cavity, esophagus, and rumen. Necrotic foci are often covered by adherent debris and ingesta, which appears as caseous clumps of curdled milk. Multifocal, pinpoint to 1 mm diameter, white foci of necrosis are often present in the liver, and occasionally in kidney and spleen. The nasopharynx and larynx may contain erosive and exudative lesions, but tracheal and pulmonary lesions are not typical. Histologically, the foci of caseous necrosis affect the full thickness of the epithelium, and are accompanied by infiltration of neutrophils. Eosinophilic intranuclear inclusion bodies are usually apparent at the margins of the necrotic lesions. The injured mucosa may be secondarily infected with *Candida* sp. yeast. The lesions of herpesviral abortion are described in Vol. 3, Female genital system.

The gross appearance of IBR is highly suggestive of the causative agent. A casual observer may mistake loosely adherent expectorant for the tracheal ulceration of IBR; *Bovine parainfluenza virus 3* can cause nasal erosions, but aspiration or inhalation of chemical irritants, which is rarely encountered, is the only process likely to be confused with florid lesions of IBR. However, as subclinical BoHV-1 infection impairs pulmonary defenses, laboratory investigation to demonstrate this pathogen is often warranted in calves with bacterial pneumonia. The virus grows readily in cell culture and produces characteristic cytopathic effects. Thus, *virus isolation* from nasal swabs, nasal mucosa, trachea, or lung is an excellent means of definitive diagnosis, and has the advantage that novel strains may be identified and archived. Fluorescent antibody tests and immunohistochemistry are also useful for the diagnosis of BoHV-1 infection, and are advantageous when a rapid diagnosis is needed. A caveat is warranted when diagnosing BoHV-1 infection in the absence of characteristic lesions: *cattle with other diseases may experience stress-induced reactivation of latent herpesviral infections, leading to identification of the reactivated virus in any of these diagnostic assays.* Samples should be obtained early in the course of disease, as antibody in the exudate of subacute lesions may preclude isolation of the virus and block antigen–antibody interactions in antigen-based assays. Detection of seroconversion is useful to associate BoHV-1 infection with clinical disease.

Bovine respiratory syncytial virus

Infection with *Bovine respiratory syncytial virus* (BRSV) is common in North American and European beef and dairy herds. Seroprevalence studies suggest that about half of range calves are exposed to BRSV, and most nonexposed calves seroconvert within a month of entering feedlots. The seroprevalence of BRSV in adult cattle varies from 40 to 95%. *BRSV is an important cause of both acute outbreaks of respiratory disease and "enzootic pneumonia"* in 2-week to 5-month-old dairy and beef calves, with a peak incidence at 1–3 months of age. BRSV certainly causes *fatal bronchointerstitial pneumonia* soon after arrival in beef feedlots, but the role of BRSV in acute interstitial pneumonia in the late feeding period is questionable. Finally, *BRSV predisposes to bacterial pneumonia* in feedlot beef cattle by impairing lung defenses, and occasionally causes respiratory disease in naive adult dairy cows.

The disease is most prevalent in the autumn or early winter. *Clinical signs* in calves and cows are similar and include high fever, coughing, tachypnea, and variable nasal discharge and conjunctivitis. Some animals develop dyspnea with open-mouth breathing and increased abdominal effort. Calves often maintain a reasonable appetite in the face of severe respiratory distress, in contrast to the consistent depression of cattle with bacterial pneumonia. A biphasic clinical course is not present in all cases; when present, it is characterized by transient pyrexia and mild respiratory disease, temporary improvement for days to weeks, then rapid onset of severe respiratory distress.

BRSV, a member of the genus *Pneumovirus* in the family Paramyxoviridae, is pleomorphic, spherical or irregularly shaped, enveloped, 80–450 nm diameter, and contains negative-sense single-stranded RNA. The viral genome encodes 10 proteins, including the G glycoprotein which mediates attachment of viral particles to host cells, the F protein which induces fusion of infected cells, matrix proteins (M, M2 or 22 K), nucleocapsid protein (N), phosphoprotein (P), polymerase (L), small hydrophobic protein (SH), and nonstructural proteins (NS1(1C) and NS2(1B)). Subgroups of BRSV have been defined by antigenic and nucleotide differences of the G and F proteins, but their clinical significance is uncertain.

An understanding of the **pathogenesis** of BRSV pneumonia has been hindered by the difficulty of establishing experimental infections that are representative of naturally occurring disease. In general, experimentally infected calves develop less severe clinical disease and less extensive lesions than natural cases, in part because in vitro passage of the virus in cell culture rapidly attenuates virulence. As a result, descriptions of the pathogenesis of experimental infections are not necessarily representative of natural disease. *Airborne spread, probably by aerosol, is the common route of infection.* In natural cases, viral infection is restricted to the respiratory tract, and viral antigen is most abundant in bronchiolar epithelium of the cranioventral areas of lung. Alveolar type II pneumocytes and macrophages express lesser amounts of viral antigen, and infrequent virus-infected cells are present in nasal, tracheal, and bronchial epithelium. The virus infects but does not replicate in lymphocytes in vitro. Following experimental infection of naive calves, viral shedding was first detected on the second day after infection, was maximal at about 4 days, and was absent by 8 days after infection. This transient infection is consistent with the difficulty experienced in demonstrating virus in naturally occurring subacute or chronic cases.

Interactions with other agents may contribute to the severity of disease. Experimental BRSV infections result in more severe disease if calves are also infected with *Bovine viral diarrhea virus* or exposed to 3-methylindole. BRSV is an important predisposing factor in the development of bacterial bronchopneumonia in cattle, because the virus impairs alveolar macrophage function and destroys ciliated epithelium.

Calves with BRSV develop specific serum and mucosal antibody responses; however, most antibody is directed to the F and N proteins and is nonneutralizing, and serum titers are poorly correlated with protection from disease. Similarly, passively acquired colostral antibodies do not prevent disease. Although virus-neutralizing antibody is produced during infection, the role of humoral immunity in protection from disease requires further investigation. As for many viral infections, CD8+ T-lymphocyte responses may be important in recovery of calves following BRSV infection.

The role of the immune response in enhancing disease is controversial. It has been proposed that vaccination with inactive virus promotes a T-helper-2 immune response in which antiviral IgE exacerbates the severity of disease. Further, the biphasic clinical course, noted in some but not all natural cases, has been interpreted to represent a worsening of the disease as an immune response develops. Such comparisons have been used as a model to study human RSV infection, where children vaccinated with a formalin-inactivated vaccine developed more severe and prolonged disease course than nonvaccinates. However, attempts to reproduce this phenomenon in cattle have given conflicting results, and vaccinated calves developed milder disease than nonvaccinates in several studies. Recent investigations suggest that vaccination with inactivated vaccines results in a more rapid onset of disease following viral challenge, but a similar or milder clinical course and lung lesions compared to nonvaccinates. Similarly, it has been proposed that virus- or immune complex-induced activation of complement may contribute to bronchoconstriction or pulmonary lesions in calves infected with BRSV, but the significance of complement activation in infected calves remains uncertain.

Gross lesions *in lungs of calves with naturally occurring BRSV pneumonia often differ in cranioventral and caudodorsal areas of lung.* The cranioventral lung is atelectatic, collapsed, deep red or mottled, and rubbery in texture. In contrast, the caudodorsal areas fail to collapse and are edematous, heavy, and firmer than normal (Fig. 5.58). *Variations in these gross lesions occur commonly*: first, occasional cases have a generalized rubbery texture and red discoloration, with no difference between cranial and caudal lung; second, calves that die in respiratory distress may develop marked subpleural and interlobular emphysema with formation of bullae; and third, the raised, consolidated, firm to hard lesions of bronchopneumonia may obscure the aforementioned viral lesions in cases with secondary bacterial infection. Apart from hypertrophy and edema of bronchial and mediastinal lymph nodes, lesions in other organs are usually not noted. Chronic cases of viral pneumonia with bronchiolitis obliterans, including those caused by BRSV, may die of heart failure due to pulmonary hypertension, as a result of hypoxic vasoconstriction. Lesions in these animals include hypertrophy of the right ventricle of the heart, subcutaneous edema, and ascites.

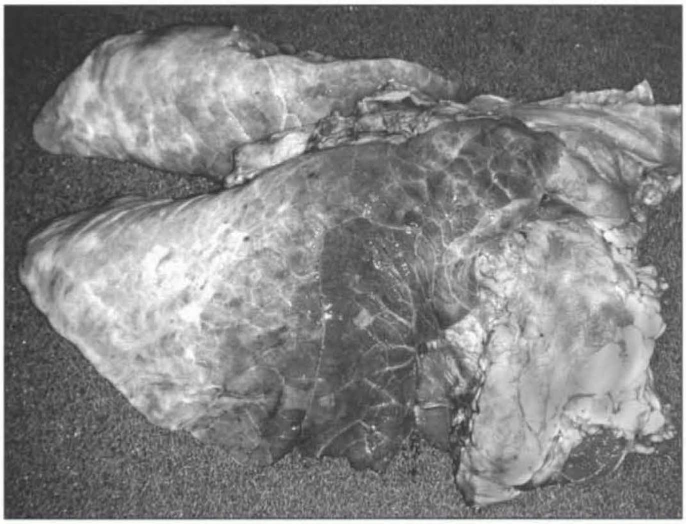

Figure 5.58 ***Bovine respiratory syncytial virus* infection** in a calf. The cranioventral lung is atelectatic and dark red; the caudodorsal lung is pale, emphysematous, and fails to collapse.

The **histologic hallmarks** of pneumonia caused by BRSV are *bronchointerstitial pneumonia, characterized by necrotizing bronchiolitis, formation of bronchiolar epithelial syncytia, and exudative or proliferative alveolitis.* The lesions and the presence of viral antigen are most obvious in the cranioventral areas of lung. In the acute lesions, from 1 to 8 days after infection, bronchioles are lined by flattened epithelium, bronchiolar lumens contain necrotic epithelial cells and modest numbers of neutrophils, and lymphocytes infiltrate around bronchioles (Fig. 5.59). Alveoli contain moderate numbers of neutrophils and macrophages, and alveolar septa may be mildly thickened by mononuclear cells, but hyaline membranes are infrequent. Syncytia are prominent at this stage, and appear as multinucleate cells closely associated with the bronchiolar epithelium, sloughed into bronchiolar lumens or, less commonly, in the alveoli. Alveolar syncytia may closely resemble the multinucleate macrophages that clear fibrin from alveoli in cases of fibrinous pneumonia; but the presence of bronchiolar syncytia is a more reliable indicator of viral infection. *Intracytoplasmic eosinophilic inclusion bodies* are occasionally present in syncytial cells and uncommonly in bronchiolar and alveolar epithelium.

The *subacute lesions* of BRSV infection – beginning at about 8 days after infection – represent *early repair of the above lesions following lymphocyte-mediated lysis of virus-infected cells.* The bronchiolar

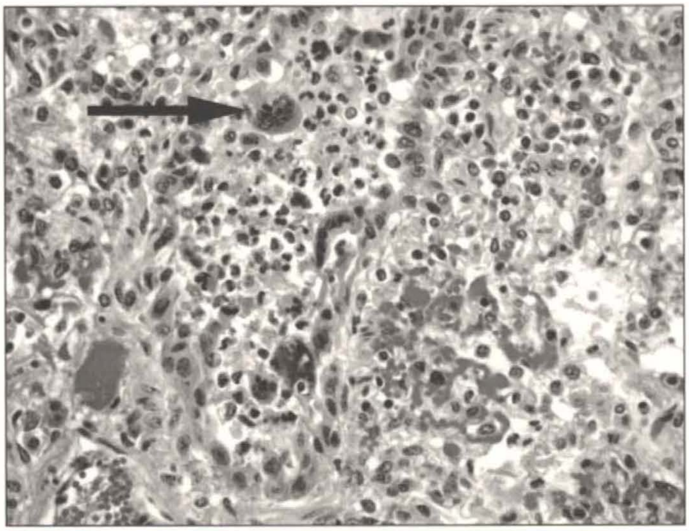

Figure 5.59 ***Bovine respiratory syncytial virus* infection** in a calf. The epithelium lining the bronchiole has a ragged appearance, and epithelial syncytia (arrow) are present. The lumen is filled with neutrophils and sloughed epithelial cells.

epithelium becomes hyperplastic, and there is disappearance of syncytial cells as viral antigen is cleared. Proliferation of type II pneumocytes appears as scattered tombstone-like cells or complete cuboidal epithelialization of the alveoli. Lymphocytes and plasma cells encircle bronchioles and blood vessels and thicken alveolar septa, and are most numerous 10 days after infection. Bronchiolitis obliterans may occur as early as 10 days after infection, and consists of plugs of fibrous tissue covered by epithelium that partially occlude bronchiolar lumens. Medial hypertrophy of pulmonary arterioles may be prominent in calves that develop pulmonary hypertension secondary to bronchiolitis obliterans.

The histologic lesions of necrotizing bronchiolitis with syncytial cells should be highly suggestive of BRSV infection, but two caveats should be considered. First, *Bovine parainfluenza virus 3* infection may also induce the formation of syncytia with intracytoplasmic inclusion bodies. Second, alveolar multinucleate macrophages are a common finding in fibrinous bronchopneumonia, and probably represent an attempt to remove the fibrinous alveolar exudate. This can present a diagnostic dilemma, since many calves with BRSV develop secondary bacterial pneumonia. Thus, if alveolar but not bronchiolar multinucleate cells are present, a diagnosis of BRSV infection is not indicated unless ancillary laboratory tests support the diagnosis.

Various assays are available to confirm BRSV infection. Lung tissue from the lesional cranioventral areas of lung are the most profitable sites to detect virus; viral antigen or nucleic acid is rarely demonstrated in caudodorsal lung tissue. Virus isolation is not recommended for routine diagnostic use, since the development of an immune response interferes with virus isolation and the virus is easily inactivated by transport conditions. Because the development of an antibody response may also interfere with assays that identify viral antigen, detection of viral nucleic acid using the *polymerase chain reaction* may be more effective for subacute or chronic cases. Nevertheless, *identification of viral antigen using fluorescent antibody tests, immunohistochemistry, or antigen detection ELISA are useful and cost-effective methods of diagnosing BRSV infection.*

Bovine parainfluenza virus 3

Infection with *Bovine parainfluenza virus 3* (BPIV-3) is widespread in 2–8-month-old beef and dairy cattle, but *clinically significant disease due to primary BPIV-3 infection is rare.* Clinical findings in uncomplicated primary BPIV-3 infection include transient fever, nasal discharge, sporadic coughing, mild depression, and increased respiratory rate. The virus causes occasional outbreaks of nasal disease in mature cows, with nasal erosions, fibrinous casts, epistaxis, and submandibular edema. Seroconversion to BPIV-3 commonly occurs during periods of temperature fluctuations in the autumn, in association with shipping fever of feedlot calves and with enzootic pneumonia of dairy calves. The prevalence of positive serum titers to BPIV-3 varies from 2 to 67% on arrival in feedlots, but 23–91% of animals seroconvert within a month after arrival. There is a variable association between seroconversion to BPIV-3 and development of pneumonia, and BPIV-3 predisposes to bacterial bronchopneumonia in some, but not all, cases of shipping fever.

BPIV-3 is a member of the genus *Respirovirus* in the family Paramyxoviridae. Paramyxoviruses are pleomorphic, 150–200 nm diameter, and contain negative-sense single-stranded RNA. Structural proteins include hemagglutinin-neuraminidase glycoprotein (HN), fusion glycoprotein (F), high-molecular-weight protein (L), a phosphoprotein (P), nucleocapsid protein (NP), and matrix protein (M). The HN protein mediates viral attachment to and release from infected cells, and the F protein allows penetration and spread of the virus between infected cells. Both the HN and F proteins are necessary for formation of syncytia and pathogenicity of the virus. BPIV-3 causes subclinical, genetically stable infection of humans, and is of current interest as a vaccine vector for human parainfluenza viral antigens.

BPIV-3 infects ciliated and nonciliated epithelial cells of the upper and lower respiratory tract, alveolar macrophages, type II pneumocytes, and lymphocytes. The *virus reduces pulmonary defenses* by several mechanisms: injury to ciliated epithelium results in functional and structural impairment of mucociliary clearance, alveolar macrophages from infected calves have reduced capacity for phagocytosis and oxidative killing of bacteria, and infected alveolar macrophages induce contact-mediated suppression of lymphocyte responses.

The HN and F proteins are immunodominant antigens, and serum antibody titers to these antigens correlate with disease resistance. Serum antibody responses develop at 8 days after experimental infection and peak at about 12 days, and a strong anamnestic response occurs after later infections. Cytotoxic cell-mediated immune responses, which are probably important for clearance of virus-infected cells, are maximal at 6–9 days after infection.

The **gross lesions** in natural cases of primary BPIV-3 pneumonia are usually mild, and consist of a *cranioventral or generalized, lobular pattern of gray-red discoloration, firm, or rubbery texture, and mild swelling or atelectasis of lung tissue.* In calves that die in respiratory distress, there may be emphysema of the caudal lung lobes. *Bronchiolitis and mild bronchitis are the major* **histologic lesions** in natural cases of primary uncomplicated BPIV-3 pneumonia. Epithelial cells lining small bronchioles are rounded, occasionally vacuolated, and slough into the lumen, and the epithelial layer may be discontinuous, attenuated, or hyperplastic. In the acute stages, many bronchial, bronchiolar, and alveolar epithelial cells and alveolar macrophages contain prominent *eosinophilic intracytoplasmic inclusion bodies*. In experimentally infected calves, inclusions are most numerous from 2 to 4 days after infection, and less common from 5 to 12 days. *Epithelial syncytial cells may be present in alveoli*, but are fewer than in *Bovine respiratory syncytial virus* infection. Airways contain low numbers of neutrophils, and lymphocytes infiltrate the mildly edematous bronchiolar walls. Alveoli are atelectatic, edematous, and contain increased numbers of macrophages and neutrophils. Proliferation of alveolar type II pneumocytes and thickening of alveolar septa are described in experimental infections using high doses of virus, but are uncommon in natural cases. Fibroblasts and macrophages begin to organize the bronchiolar exudate at 7–12 days after experimental infections, and bronchiolitis obliterans may develop thereafter.

BPIV-3 infection should be considered in calves with necrotizing bronchiolitis. Confirmation of the **diagnosis** is based on *virus isolation or detection of viral antigen.* Virus isolation in cell culture from fresh or frozen lung tissue harvested from cranioventral areas of lung with lesions, with virus identification by hemadsorption of erythrocytes, is a useful method of diagnosis. Antigen detection tests are more rapid, and include a fluorescent antibody test on frozen lung tissue and immunohistochemistry on formalin-fixed lung tissue. These diagnostic methods are effective in acute cases, but may be unrewarding in the more common necropsy presentation of chronic bacterial pneumonia with concurrent bronchiolar necrosis or bronchiolitis obliterans. *Definitive diagnosis in these cases may be impossible*, because viral antigen may be cleared long before the bacterial pneumonia proves fatal. If acute and convalescent sera are available, then demonstration of a *rising antibody titer* using the hemagglutination inhibition assay supports the histologic diagnosis.

Bovine coronavirus

Bovine coronavirus (BCoV) is an important cause of enteric disease in young calves, and the same strains occasionally induce respiratory disease in 2–16-week-old calves. Clinical signs include serous nasal discharge, sneezing, and coughing. The virus replicates primarily in the nasal and tracheal epithelium, and occasionally in the lung. Experimental oral infection of calves with a virulent pneumoenteric isolate resulted in diarrhea and dyspnea, and pulmonary lesions of interstitial pneumonia and hemorrhage. BCoV may be isolated using specific rectal tumor cell lines, or viral antigen may be demonstrated by immunofluorescence.

Many calves shed BCoV in their nasal secretions and/or seroconvert to BCoV in the first month after arrival in feedlots, but the association between seroconversion or virus shedding and increased risk of respiratory disease has been variable in the studies reported. Lesions of bronchiolitis and alveolitis with bronchiolar syncytia have been described in a feedlot calves with concurrent BCoV infection and bacterial pneumonia, but the contribution of other viruses such as *Bovine respiratory syncytial virus* to these lesions is uncertain.

Bovine viral diarrhea virus

The contribution of Bovine viral diarrhea virus (BVDV) to pneumonia in cattle is a long-standing source of controversy. Virus can be isolated from the lung in primary (acute) infections and in persistently infected calves. Bacterial bronchopneumonia is often present in calves with natural or experimental primary BVDV infections, and BVDV infections are common during times of increased susceptibility to bacterial pneumonia. Although one must be cognizant of the role of other pathogens in such situations, *epidemiologic studies imply that BVDV-infected calves do indeed have a heightened susceptibility to bacterial pneumonia.* Mechanisms by which BVDV predisposes to bacterial pneumonia include reduced antimicrobial protein production by virus-infected airway epithelial cells, reduced function of alveolar macrophages, and virus-induced neutropenia. BVDV has also been shown to exacerbate *Bovine respiratory syncytial virus* and *Bovine herpesvirus 1* infections in experimental situations.

It has been proposed that some isolates of BVDV induce primary respiratory disease, independent of opportunistic bacterial pathogens. During primary BVDV infection, viral antigen is present in pulmonary alveolar macrophages and in airway epithelium. In addition, viral antigen may be demonstrated in the tunica muscularis of arterioles in the lung, heart, and occasionally in other tissues, often in association with lesions of lymphocytic arteritis. Calves or lambs challenged with certain isolates of BVDV develop fever and hyperpnea or, in other studies, nasal discharge and coughing. The lesions described are mild, consisting of peribronchiolar, perivascular, or interstitial aggregates of lymphocytes and macrophages, and/or mild suppurative exudate in bronchioles. However, other studies have found no lung lesions in calves infected with BVDV, and *the importance of BVDV as a cause of primary lung disease is probably minimal.*

Bovine adenovirus

Bovine adenoviruses are a recognized cause of hemorrhagic colitis, but their role in respiratory disease is more controversial. Epitheliotropic bovine adenoviruses are occasionally isolated from feedlot calves with bacterial pneumonia, and many calves seroconvert to a range of *Bovine adenovirus* (BAdV) serotypes within 5 weeks of entering feedlots. Adenoviruses may predispose to bacterial pneumonia by injuring ciliated epithelium and, for some strains, by impairing alveolar macrophages. However, compared to the roles of stress and other viral infections, *adenoviruses are probably minor contributors to bacterial pneumonia in feedlot cattle.*

Calves experimentally infected with BAdV generally develop only mild respiratory disease; the severity of primary adenoviral pneumonia is probably dependent on both the strain of the BAdV and the immune status of the calf. Experimentally infected calves developed lobular or patchy areas of atelectasis and reddening. *Histologic lesions* include proliferation of bronchial and bronchiolar epithelium, lymphocytic infiltration of airway epithelium, formation of *large basophilic intranuclear inclusions* in airway epithelial cells, and exfoliation or necrosis of virus-infected cells. In well-developed cases, there is extensive bronchiolar necrosis, occlusion of bronchiolar lumens by sloughed epithelium, and inclusions in intact or sloughed epithelial cells. Thickening of alveolar septa by mononuclear cells may occur, but proliferation of type II pneumocytes is uncommon. Other BAdV strains cause no clinical signs and few lesions after experimental infection of calves, and there is much interest in developing these minimally pathogenic BAdV strains as DNA-based vaccine vectors for cattle.

Bovine rhinovirus

Two serotypes of *Bovine rhinovirus* (BRV) are widespread in cattle populations. *BRV is generally believed to be of little importance as a cause of respiratory disease in cattle.* Virus isolation and serologic responses occasionally provide circumstantial evidence that it is involved in causing upper respiratory disease. Experimental infection has inconsistently induced bronchointerstitial pneumonia.

Bacterial diseases

Bacterial bronchopneumonia due to Pasteurellaceae: *Mannheimia haemolytica*, *Histophilus somni*, and *Pasteurella multocida*

Bacterial bronchopneumonia is a common and economically important disease of cattle, particularly in temperate climates, and is commonly caused by bacteria of the family Pasteurellaceae. *The most important clinical entities are enzootic pneumonia of young calves and shipping fever of feedlot cattle,* but bacterial pneumonia may occur in any age group, often as a complication of viral infection, stress, or other impairment of lung defenses.

Shipping-fever pneumonia has long been considered the most economically important disease of beef cattle in temperate climates. Recent years have seen considerable advances in understanding of pathogenesis and preventive strategies, with the result that, although the disease remains prevalent, mortality rates are often lower than in the past. The *classic presentation* of shipping fever is of pneumonia affecting multiple calves, 3 days to 3 weeks after being shipped from their farm of origin to a feedlot. Affected animals exhibit acute onset of depression, pyrexia, anorexia, rapid and shallow respiration, and mucopurulent nasal discharge. Coughing is variably present and dyspnea develops in later stages. Most cattle respond rapidly to appropriate antibiotic therapy if given early in the course of disease, but relapses are common. Most reports of shipping fever describe 15–45% morbidity, 1–5% mortality, and case fatality rates of 5–10% depending on the rapidity with which treatment is initiated. *Risk factors* for shipping fever include those associated with: (1) increased exposure of naive calves to animals shedding viral pathogens, such as mixing of calves from various sources; (2) stress, such as weaning, transport, crowding, deprivation of feed and water, handling, vaccination, dehorning, and pregnancy checking; (3) metabolic acidosis, such as rapid introduction to grain or corn silage; and (4) exposure of calves to adverse environmental conditions, such as changes in temperature and humidity, cool weather in the autumn months, snow or rain, or dusty environment.

Bacterial pneumonia is also common in 1–4-month-old dairy and veal calves, and less common in suckling beef calves. Although commonly referred to as "*enzootic pneumonia*," cases may be sporadic, enzootic, or occur in outbreaks. Affected calves are febrile, hyperpneic, variably dyspneic, depressed, and anorexic. *Risk factors* include those that: (1) affect air quality, such as indoor housing, poor ventilation, high stocking density, high levels of airborne droplets or dust, and humid conditions; (2) reduce lung defenses, such as failure of passive transfer of immunoglobulin and high environmental ammonia concentrations; (3) expose calves to viral or mycoplasmal pathogens, such as housing calves and adults together; and (4) cause stress, such as concurrent diseases.

The Pasteurellaceae are gram-negative coccobacilli that are common causes of pneumonia or septicemia in domestic animals. *Many inhabit the upper respiratory tract of healthy animals,* but cause pneumonia when pulmonary defenses are impaired by viral infections, stress, temperature fluctuations, or noxious gases, or cause septicemia in naive animals or those with reduced systemic defenses. In general, the defense against many Pasteurellaceae depends on a combination of innate resistance mechanisms and acquired humoral immunity. Most members of the family are shrouded in a polysaccharide capsule that mediates resistance to phagocytosis by macrophages and neutrophils, and several species secrete RTX (repeats in toxin) toxins that induce necrosis of leukocytes. Endotoxin incites inflammation in response to infection with members of the Pasteurellaceae family. The most common pathogenic Pasteurellaceae of domestic animals include *Pasteurella multocida* of swine, ruminants, and cats; *P. trehalosi* of sheep, *Mannheimia haemolytica* of ruminants, *Actinobacillus pleuropneumoniae* and *A. suis* of swine, *A. equuli* of horses, *Histophilus somni* of cattle and sheep, and *Haemophilus parasuis* of swine.

Mannheimia haemolytica (formerly *Pasteurella haemolytica* biotype A): 12 serotypes of *M. haemolytica* are discerned based on soluble capsular polysaccharide antigens. Serotype names were maintained when the species *P. haemolytica* biotypes A and T were reclassified as *M. haemolytica* and *P. trehalosi*, respectively; as a result, serotypes 3, 4, 10, and 15 are represented only by *P. trehalosi*. Serotype 2, and, to a lesser extent, serotype 1, is a sporadic isolate from the nasopharynx of healthy calves. Serotype 1 is the most common isolate from pneumonic lung, but other serotypes in addition to many untypable isolates regularly cause bovine pneumonia.

Virulence factors of *M. haemolytica* include leukotoxin, lipopolysaccharide, capsular polysaccharide, transferrin-binding proteins A and B, O-sialoglycoprotease, neuraminidase, IgG1-specific protease, outer-membrane proteins, and fimbriae. All serotypes secrete *leukotoxin*, a member of the RTX family of bacterial toxins, during the log phase of growth. The gene products of *lkt*A and *lkt*C represent the active leukotoxin, while *lkt*B and *lkt*D are necessary for toxin secretion. At high concentrations, leukotoxin induces lysis of ruminant leukocytes and platelets, mediated by binding to CD18 on the leukocyte surface and formation of pores in the cell membrane. In contrast, at lower concentrations, leukotoxin activates leukocytes and platelets. Although leukotoxin clearly plays a role in the pathogenesis of pneumonia, disease does develop in calves vaccinated against leukotoxin and in those challenged with *M. haemolytica* constructs that do not secrete leukotoxin.

Lipopolysaccharide is a major component of the cell wall, and the presence of O-polysaccharide side chains confers a smooth phenotype to most serotypes. Lipopolysaccharide from *M. haemolytica* stimulates alveolar macrophages to secrete inflammatory mediators, including tumor necrosis factor-α, interleukin-1, and the chemokines IL-8, ENA, and GRO-α. Other effects of *M. haemolytica* lipopolysaccharide on alveolar macrophages include triggering of oxidative burst, an important bactericidal mechanism that may also lead to oxidative tissue injury; expression of tissue factor, a mediator of the thrombosis characteristic of the disease; and secretion of nitric oxide, which may augment lung defenses but is also a potent mediator of vasodilation and hypotension. Other effects of lipopolysaccharide include activation of the extrinsic coagulation pathway, and complement activation. The mannose-rich polysaccharide capsule confers resistance of *M. haemolytica* to phagocytosis by macrophages and neutrophils, and may also block complement-dependent killing. Neuraminidase enhances adhesion of bacteria to mucosal epithelium by cleaving sialic acid from the surface of epithelial cells, and may reduce mucus viscosity to prevent mucociliary clearance.

Low numbers of M. haemolytica colonize the nasopharynx of normal calves, and there are several potential explanations for the shift from a commensal to a pathogenic relationship. First, stress or exposure to cold results in greater numbers of nasopharyngeal bacteria, so inhalation of droplets containing increased numbers of bacteria may overwhelm pulmonary defenses. The mechanisms whereby stress or exposure to cold induces expansion of the bacterial population, and whether these factors also alter expression of bacterial virulence factors, have not been defined. Second, some studies indicate that stress and cold exposure induce a shift from serotype 2 to the more pathogenic serotype 1. Third, viral infections or stress impair lung defenses. The lung is normally exposed to low numbers of aspirated *M. haemolytica*, but a combination of mucociliary clearance, antimicrobial function of secreted mucosal proteins, and phagocytosis by alveolar macrophages controls this infection without inciting an inflammatory response. *Bovine herpesvirus 1* (BoHV-1), *Bovine respiratory syncytial virus* (BRSV), and *Bovine parainfluenza virus 3* infect ciliated epithelium and reduce mucociliary clearance, and BoHV-1 and BRSV infect and impair the function of alveolar macrophages. In addition, preliminary evidence suggests that BoHV-1 infection causes upregulation of CD18 on the surface of bovine neutrophils. Since CD18 is a receptor of *M. haemolytica* leukotoxin, neutrophils in BoHV-1-infected calves may be more susceptible to the effects of this pathogen. Viral infections may also impair secretion of antimicrobial proteins by airway or alveolar epithelium. The mechanisms whereby stress impairs innate pulmonary defenses are poorly defined. As a result of one or more of these processes, it is likely that exposure of the lung to increased numbers of virulent *M. haemolytica* coincides with a reduction in pulmonary defenses, and these alterations lead to increased colonization of the cranial lung lobes.

Clinical disease is principally a consequence of the host response to infection of the lung with *M. haemolytica*, rather than a direct effect of bacterial toxins on lung tissue. Massive exudation of fibrin into alveoli is a prominent feature of severe pneumonic pasteurellosis, and is mediated in part by a direct effect of lipopolysaccharide on endothelial cells. However, other mechanisms of vascular leakage also occur, such as exposure of endothelium to macrophage-derived proinflammatory cytokines such as tumor necrosis factor-α. Phagocytosis of *M. haemolytica* by alveolar macrophages is limited unless the bacteria are opsonized by antibody or complement; the significance of other opsonins, such as pulmonary or serum collectins, remains speculative. Alveolar macrophages which have ingested *M. haemolytica*, or been exposed to bacterial products, secrete an array of neutrophil chemoattractants, including interleukin-8, ENA, GRO, platelet-activating factor, and leukotriene B4. Neutrophils migrate to the alveoli and terminal bronchioles within 3 hours of experimental challenge with *M. haemolytica*. Neutrophil migration to alveoli employs a β_2 integrin-independent mechanism, whereas neutrophil recruitment to airways is dependent on interactions between β_2 integrin and ICAM-1. In contrast to most bacterial infections, in which neutrophils phagocytose and kill the offending bacteria, neutrophils recruited to the sites of established infection with *M. haemolytica* are probably lysed by the effects of leukotoxin. Thus, *this disease is characterized by massive recruitment of neutrophils that are ineffective in killing bacteria, but nonetheless exacerbate the severity of clinical disease*. Infiltration of neutrophils and additional macrophages into alveoli is harmful in several ways: the physical presence of these cells precludes normal ventilation and gas exchange; the secretion of oxygen radicals, nitric oxide derivatives, and proteinases secreted by leukocytes may injure pulmonary cells and the interstitial stroma; expression of tissue factor by activated alveolar or intravascular macrophages promotes fibrin formation in the alveolus and thrombosis of blood vessels in the alveolar septa; and both macrophages and neutrophils secrete chemoattractants that perpetuate the recruitment of additional leukocytes.

Focal areas of coagulative necrosis are a characteristic feature of infection with M. haemolytica. Some represent infarcts due to thrombosis of intralobular blood vessels, but bacterial toxins or leukocyte secretions might also cause direct lung injury. These foci of necrosis are encircled by a dense band of leukocytes, many of which are necrotic, and these leukocytes are in a state of intense activation featuring prominent gene expression of interleukin-8 and inducible nitric oxide synthetase. Profound depression and "toxemia" are constant features of acute infection with *M. haemolytica*; although the basis for this systemic illness is unknown, tumor necrosis factor-α in the plasma of some cases may be responsible.

Immune responses to *M. haemolytica* occur rapidly following exposure, with alveolar IgM detectable by 48 hours after experimental infection, and detectable serum IgM and IgG by 5 and 7 days after infection, respectively. Animals that recover from disease or are vaccinated with live bacteria are immune to subsequent challenge, and serum antibody titers to leukotoxin, outer-membrane proteins, and capsule all correlate with resistance to naturally occurring disease. However, it is likely that an immune response to several antigens is necessary for protection, for the presence of antibody to individual antigens – including leukotoxin, capsular polysaccharide, lipopolysaccharide, or outer membrane proteins – does not confer complete protection.

Histophilus somni (formerly *Haemophilus somnus*) benefits from a similarly broad array of virulence factors. Resistance to complement-mediated serum killing is mediated by proteins that bind the Fc component of immunoglobulin, making these Fc receptors unavailable for complement activation. Lipooligosaccharide has many proinflammatory effects, analogous to lipopolysaccharide in other gram-negative bacteria. The lipooligosaccharide of disease-associated, but not commensal, isolates of *H. somni* undergoes structural and antigenic variation during the course of an experimental infection, and this variation may serve as a mechanism of immune evasion and resistance to complement-mediated killing. Transferrin-binding proteins enable the bacteria to use transferrin as an iron source for growth. *Histophilus somni* binds to and induces apoptosis in endothelial cells in vitro, and although this effect may contribute to the vasculitis that is characteristic of *H. somni* septicemia, these processes are as yet poorly characterized. Immune-complex deposition is apparently not the cause of vasculitis. *H. somni* is considered a facultative intracellular pathogen as it survives within monocytes, yet both intra- and extracellular bacteria are numerous in acute pneumonia. Finally, *H. somni* impairs the phagocytic function of neutrophils and macrophages, and induces degeneration of macrophages and apoptosis of neutrophils.

In contrast to the advances made in understanding other ***Pasteurella multocida*** infections, notably atrophic rhinitis and fowl cholera, the pathogenesis of pneumonia due to *P. multocida* is poorly described. Capsular serotype A is most commonly isolated from cases of pneumonia. As for *M. haemolytica*, the bacteria are carried in the nasopharynx of many clinically normal calves. An antiphagocytic capsule and a neuraminidase enzyme are described, but their importance and role in disease are uncertain.

The **gross lesions** of acute fulminant "shipping-fever" pneumonia due to *M. haemolytica* or *H. somni* include *cranioventral lobar or lobular fibrinous bronchopneumonia, foci of coagulative necrosis, and variable fibrinous pleuritis*. Lesions are most severe in the cranial and middle lung lobes, but may also affect the caudal lung. Acute fulminant cases often exhibit lobar fibrinous pneumonia and pleuritis and may die with as little as 30% of the lung affected, due to systemic effects of the infection rather than failure of lung function. Lesions are often sharply demarcated from less affected areas of lung, are discolored red or gray, and the filling of alveoli with fibrin bestows a firm or hard texture to the affected lung (see Fig. 5.29).

The cut section of the lung is purple-red, firm or hard, and moist. It is often not possible to express exudate from the transected airway, for the leukocytes are enmeshed in polymerized fibrin. Sharply demarcated, irregularly shaped, 0.5–5 cm diameter, pale, dry foci of coagulative necrosis are frequent in fulminant cases of *M. haemolytica* or *H. somni* infection (Fig. 5.60). Bronchi may contain suppurative material or hemorrhage, or may be free of exudate. Interlobular septa are distended with fibrinous or serofibrinous exudate, and this lends a marbled appearance to the cut surface (Fig. 5.61). In the most severe cases, fibrin forms a mat or lattice over the pleural surface of affected lung lobes, and the pleural cavity may contain serofibrinous yellow fluid that clots when the chest is opened. Fibrinous pericarditis may accompany the pleuritis.

The lung lesions of acute *P. multocida* infection are in many respects similar, but lack the focal coagulative necrosis and abundant fibrinous exudate seen in *M. haemolytica* and *H. somni* infections. As a result, suppurative exudate oozes from small bronchi when a cut section is compressed, and purulent or catarrhal exudate may line the mucosal surface of the large airways. *Necrosis of laryngeal epithelium at the point of contact of the vocal folds is commonly identified in cattle with severe pneumonia*, due to mucosal trauma induced by abrupt laryngeal closure in a dyspneic animal. Infectious thrombotic meningoencephalitis and septicemia usually occur independently of bronchopneumonia, and calves with *H. somni* pneumonia do not commonly have encephalitis or myocarditis.

Sequelae are common in survivors of acute fulminant disease, and include *sequestra, bronchiectasis, abscesses, and fibrous pleural adhesions*. Sequestra consist of a necrotic core of firm but friable tissue,

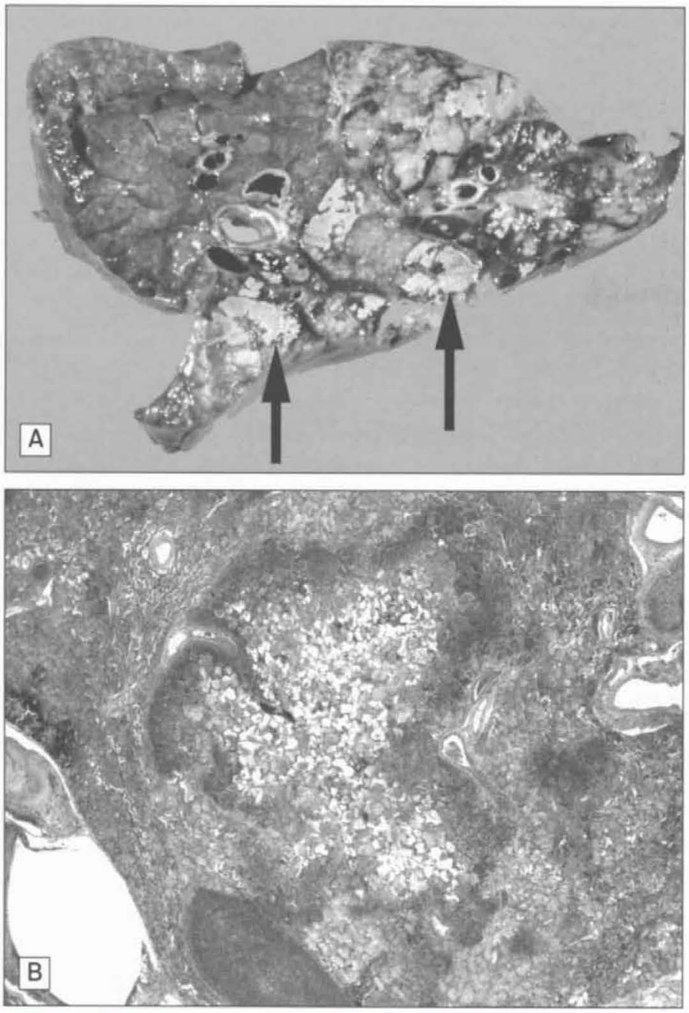

Figure 5.60 ***Mannheimia haemolytica* pneumonia** in a calf. **A.** Sharply demarcated, irregularly shaped foci of necrosis within the consolidated lung (arrows). **B.** Histologically, the foci of coagulative necrosis are delineated by a band of necrotic leukocytes.

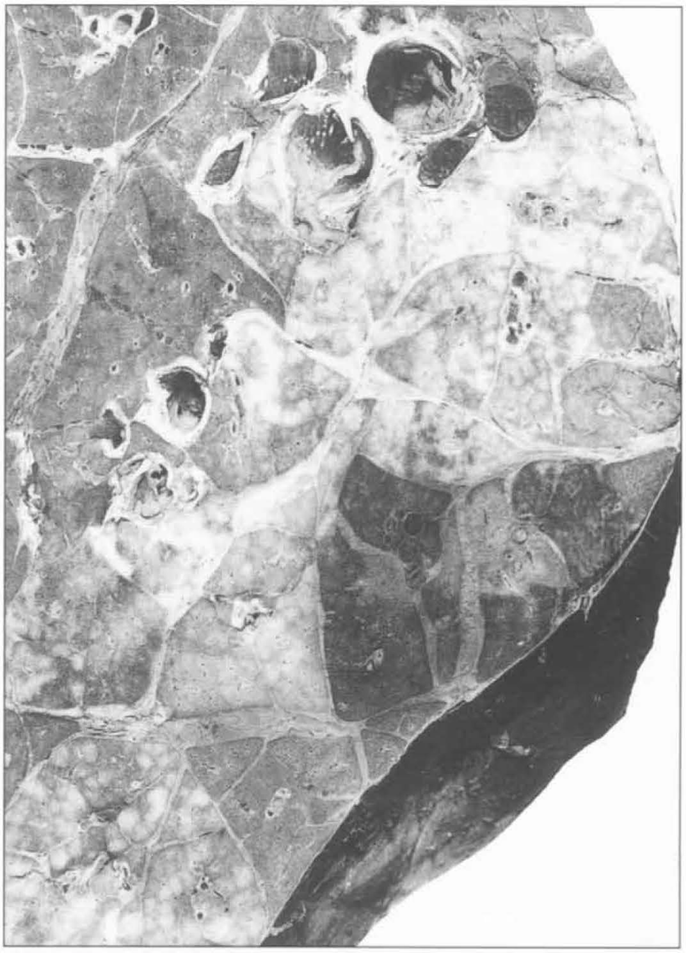

Figure 5.61 ***Mannheimia haemolytica* pneumonia** in a calf. Marbled pattern produced by differing degrees and stages of consolidation.

surrounded by fluid or caseous exudate, enveloped in a capsule of fibrous tissue. Bronchiectasis manifests as dilated airways that are filled with purulent exudate and thickened by fibrous tissue. The surrounding lung tissue is invariably atelectatic, and may be swollen due to persistent bronchopneumonia. Ectatic bronchi appear similar to abscesses, but bronchiectasis is typified by a regular distribution of purulent foci, the occasional presence of cartilage remnants on gross or histologic examination, and communication with a bronchus. Lesions of bronchiectasis and abscesses are often secondarily colonized by *Arcanobacterium pyogenes* or other opportunistic pathogens.

Subacute, less fulminant infection with Pasteurellaceae bacteria induces a lobular distribution of lesions, and most fatal cases have at least 60% of the lung affected. Compared to acute cases, subacute and chronic lesions may be pale red-tan or mottled red and gray, and the texture varies from hard to firm to rubbery. Mild cases with atelectasis and rubbery consolidation may be difficult to distinguish from lesions of viral pneumonia.

The **histologic lesions** of *acute fulminant "shipping-fever" pneumonia due to M. haemolytica or H. somni are characterized by fibrinous and suppurative bronchopneumonia with necrosis of leukocytes.* Alveoli and small bronchioles are filled with variable proportions of neutrophils and macrophages, fibrin, edema fluid, erythrocytes, necrotic cellular debris, and aggregates of bacteria. Necrosis of intra-alveolar leukocytes is a characteristic feature of infection with *M. haemolytica*, where leukotoxin is the likely cause of the neutrophil cell death. Leukocyte necrosis may also be present in *H. somni* infection, and this agent is capable of inducing apoptosis in neutrophils in vitro by uncharacterized mechanisms. The necrotic leukocytes are often lytic and exhibit a streaming pattern of pale basophilic chromatin, termed "*oat cells*" for their resemblance to grains of oats (Fig. 5.62). The nature of the necrotic leukocytes has long evaded definitive identification, but *it is likely that both neutrophils and macrophages are affected.* Larger airways may contain suppurative exudate, but neutrophil infiltration of the mucosa is often absent.

Necrosis and attenuation of bronchiolar epithelium, when present, should prompt a search for underlying viral infection. However, this lesion is present in some calves experimentally infected with *M. haemolytica* or *H. somni*, and may represent neutrophil-induced damage to the epithelium. Thrombi commonly occlude arterioles, venules, and alveolar septal capillaries. Interlobular septa are distended with serofibrinous exudate, and polymerized fibrin may occlude lymphatics in the interlobular septa. Sharply demarcated, irregularly shaped areas of coagulative necrosis are often apparent. In these, alveolar and bronchiolar lesions are as described above, but all cells within the lesions are necrotic, and karyolysis or karyorrhexis is prominent. A dense band of necrotic leukocytes encircles these foci of necrosis (Fig. 5.60), and thrombi occasionally fill blood vessels at the edge of or within the lesions. Suppurative phlebitis with fibrinoid necrosis may occur in pneumonia caused by *H. somni*, but is only common in acute fulminant cases.

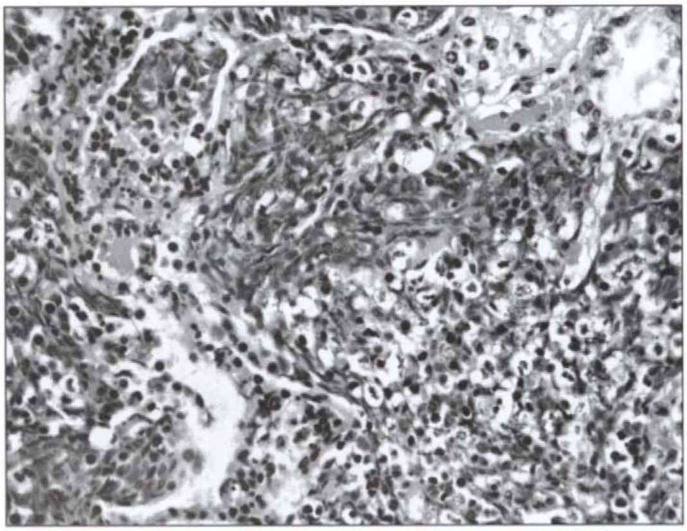

Figure 5.62 ***Mannheimia haemolytica*** **pneumonia** in a calf. Alveoli are filled with necrotic oat-shaped leukocytes with streaming chromatin.

Pulmonary changes in calves that survive an episode of fulminant shipping-fever pneumonia are poorly described in the literature. Macrophages and multinucleate histiocytic cells encompass the alveolar masses of polymerized fibrin; removal of fibrin by these macrophages and by fibrinolysis presumably occurs in some nonfatal cases. Otherwise, alveolar fibrin is infiltrated by fibroblasts and replaced by connective tissue, with two possible sequelae: incorporation of the re-epithelialized alveolar fibrous tissue into the alveolar septum to form a thickened alveolar septum and a "recanalized" alveolar lumen, or large expanses of pulmonary fibrosis. Chronic suppurative or lymphoplasmacytic bronchitis occurs regularly in calves with chronic pneumonia.

Less fulminant cases of *M. haemolytica* or *H. somni* infection, and the acute or subacute changes induced by *P. multocida*, tend to lack the fibrinous alveolar exudate, thrombosis, and interlobular fibrin that are typical of fulminant shipping-fever pneumonia. Rather, these lesions are dominated by exudation of neutrophils in alveoli and bronchioles, congestion of pulmonary vessels, but little other morphologic change in lung tissue. Whereas leukocyte necrosis is a constant feature of active *M. haemolytica* infection, lesions caused by *P. multocida* contain viable, nonnecrotic neutrophils.

The gross lesions of cranioventral bronchopneumonia are usually **diagnostic**. The swollen and hard nature of bacterial pneumonia aids in the differentiation from the atelectatic cranioventral lesions of *Bovine respiratory syncytial virus* pneumonia. A histologic finding of suppurative bronchopneumonia implies a diagnosis of bacterial pneumonia; the important challenge is to identify the underlying causes. Lesions of aspiration pneumonia may closely resemble bacterial pneumonia; however, necrosis of alveolar leukocytes is not expected, and focal or unilateral, necrotizing, and foul-smelling lesions containing histologically recognizable foreign material are more typical of aspiration. Differentiation of the foci of necrosis from those seen in *Mycoplasma bovis* pneumonia is discussed in the section on mycoplasmal disease.

The use of *aerobic and microaerophilic culture* to identify the specific etiology is commonly successful unless animals have been medicated with antimicrobial. Subacute or chronic cases may be colonized by opportunistic bacteria and the primary bacterial cause may no longer be present. Immunohistochemistry to identify *Mannheimia haemolytica* and *H. somni* has been described, and may be of use in antimicrobial-treated, autolysed, or archival tissues, or if fresh tissue is not available. Detection of serum antibody to *M. haemolytica* using a bacterial agglutination assay, leukotoxin neutralization assay, or leukotoxin ELISA is a common research tool, but finds limited use in field investigations.

Hemorrhagic septicemia of cattle

Hemorrhagic septicemia of cattle is caused by Pasteurella multocida types B or E. This disease was originally recognized in western Europe in the 19th century as a severe epidemic in deer which later spread to cattle, wild and domestic pigs, and horses. Sheep, bison, camels, and buffalo may also be affected. *Hemorrhagic septicemia is now limited largely to tropical countries from Egypt to the Philippines, and in these regions is primarily a disease of buffalo.* Outbreaks in tropical climates occur particularly during the rainy season. In intervening periods, the organism is apparently maintained in the nasopharyngeal regions of carrier cattle or buffalo. The start of an outbreak depends on some stress disturbing the balance in a carrier animal. This results in extensive proliferation and dissemination of the organisms to susceptible contact animals.

Approximately 10% of animals survive subclinical infections and become immune, but once clinical signs are apparent, the mortality is almost 100%, even with appropriate antimicrobial therapy. This, together with the immense proliferation of organisms in the clinical disease, suggests that bacterial toxins (particularly endotoxin) are important in causing death.

Hemorrhagic septicemia is a peracute disease and many animals die without clinical signs. Less fulminant cases exhibit high fever and rapid prostration, with profuse drooling. The saliva and feces contain large numbers of bacteria. Petechial hemorrhages are present on the serous membranes and in various organs, especially the lungs and muscles. Severe endotoxemia may cause *acute, fibrinohemorrhagic interstitial pneumonia*. Lymph nodes are swollen and hemorrhagic, and there may be blood-stained fluid in the serous cavities. Acute gastroenteritis, which can be hemorrhagic, is often present. The spleen is not greatly enlarged, which is a point of differentiation from anthrax.

There is a *peracute edematous form of hemorrhagic septicemia*, in which edema of the throat is unusually pronounced. The whole head, tongue, brisket, or a limb may also be affected. The swellings are produced by copious, clotted, straw-colored exudate. Although these lesions are caused by hemorrhagic septicemia, death is caused by asphyxiation.

Cilia-associated respiratory bacillus

Cilia-associated respiratory (CAR) bacillus is a recognized cause of chronic respiratory disease in rats, mice, and rabbits. The bacilli interdigitate between cilia and induce lymphocytic bronchitis and bronchiolitis, bronchiectasis, and lung abscesses. Morphologically similar bacteria colonize the tracheal epithelium of up to 83% of slaughter cattle and 46% of swine submitted for necropsy. The bacteria are of similar length and diameter as the cilia, but are visualized with Warthin–Starry silver stains (Fig. 5.63). In *calves*, there is an association between the presence of CAR bacilli and the presence of lymphoid follicles in the airway wall, but it remains unknown if this is a causal relationship. *Porcine* CAR bacilli are apparently nonpathogenic, for they are present in pigs with and without respiratory disease, and experimentally infected pigs have not developed clinical signs or lesions.

Tuberculosis

Bovine tuberculosis, caused by Mycobacterium bovis, is a chronic disease characterized by caseating granulomas in lung, lymph nodes, and other organs. Control programs have minimized the occurrence of bovine tuberculosis in many developed countries. The disease is rare in Canada, the USA, and Australia, although infected wildlife reservoirs remain and cases continue to occur in domestic livestock. Most recent reports of bovine tuberculosis in the USA and Canada have occurred in farmed cervids or in localized geographic areas. In most of Europe, fewer than 0.4% of herds are infected, but the prevalence is higher in Ireland, Spain, and Italy. In contrast, bovine tuberculosis is endemic in New Zealand and many, but reportedly not all, countries in Africa, Asia, Central and South America; 10–35% of herds are infected in many of these endemic areas.

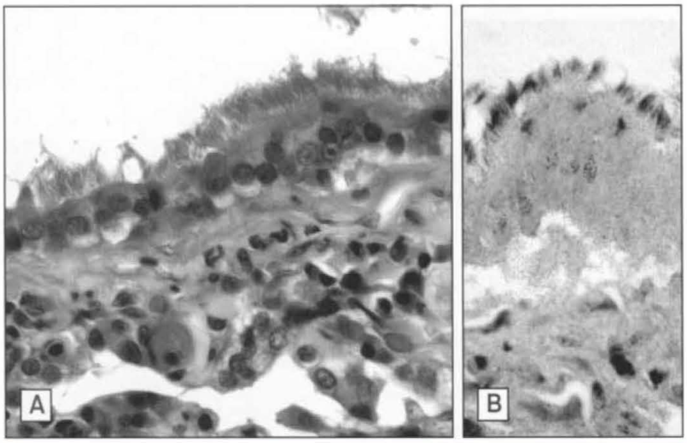

Figure 5.63 Cilia-associated respiratory (CAR) bacillus infection in a rat. **A.** The bacteria cause accentuation of the cilia on the apical surface of the bronchiolar epithelial cells. **B.** With Warthin–Starry silver stain, the bacteria stain black among the unstained cilia.

In many countries, the success of tuberculosis eradication schemes is complicated by *wildlife reservoirs*, which maintain infection and transmit disease to cattle. Probable wildlife reservoirs of *M. bovis* infection include European badgers (*Meles meles*) in Ireland and the UK, brush-tailed possum (*Trichosurus vulpecula* Kerr) in New Zealand, swamp buffalo (*Bubalus bubalis*) in Australian Northern Territory, Cape buffalo (*Syncerus caffer*) in Ruwenzori National Park in Uganda, bison (*Bison bison*) in Wood Buffalo National Park in western Canada, and various species of deer in the USA and New Zealand. In contrast, dead-end or spill-over hosts, including feral pigs, goats, wart hogs, cats, mustelids, and humans, may be infected with *M. bovis* but do not maintain infection in an area and rarely transmit infection to cattle.

Many mycobacteria persist in soil for prolonged periods, and the infectivity of *M. bovis* is likely maintained for several weeks in the environment. However, because oral infections require high doses of bacilli, the importance of environmental survival in the epidemiology of disease is likely limited.

The classical tubercle bacilli are *M. tuberculosis* (human), *M. bovis* (bovine), and *M. avium* (avian). Two other closely related species are *M. microti* from voles and *M. africanum*. Differing strains of *M. avium* are now commonly included with strains of the very closely related *M. intracellulare* as the *M. avium-intracellulare* complex. To avoid confusion surrounding the term **tuberculosis**, convention limits it to diseases caused by *M. tuberculosis* or *M. bovis*. Other conditions are referred to as **mycobacteriosis** or **atypical mycobacteriosis**.

Saprophytic mycobacteria are widespread in soil and water, on vegetation, and in mucous membranes of the oropharynx. These organisms typically cause disease in immunologically compromised hosts, and the manifestations are cervical lymphadenitis, pulmonary lesions similar to tuberculosis, or cutaneous lesions associated with local penetration of organisms through wounds. An example is *M. marinum*, which is abundant in pools in regions with temperate climates and causes tuberculous disease in fish and cutaneous ulcers in humans. This organism is grouped with the *photochromogens* (Runyon's group I) together with *M. kansasii*. The latter produces cervical lymphadenitis and pulmonary disease in humans, and has been isolated from cow's milk and from cattle in the USA and South Africa. *Scotochromogens* produce pigment without photoactivation (Runyon's group II) and include *M. scrofulaceum*, which is closely related to the *M. avium-intracellulare* complex. These organisms have been isolated from disease in cattle and tuberculoid lesions in dogs. Another member of the group, *M. aquae*, has been isolated from nodular lesions on the teats of cows. *Nonphotochromogens* (Runyon's group III) have organisms in the *M. avium-intracellulare* complex as the most important members. Some strains are virtually nonpathogenic and others produce generalized disease in calves and pigs.

Mycobacteria of Runyon's group IV grow rapidly at room temperature, are usually nonpigmented, and include many saprophytes.

Within this group, *M. smegmatis* is one of the organisms isolated from tubercle-like lesions in lymph nodes of swine and also causes bovine mastitis following its injection into the udder. Another member, *M. fortuitum*, was initially isolated from lesions in bovine lymph nodes and is an occasional cause of mastitis in cattle. Members of this group, particularly *M. fortuitum, M. chelonei*, and *M. phlei*, cause cutaneous mycobacteriosis in cats and dogs.

The three main species of tubercle bacilli, *M. tuberculosis, M. bovis*, and *M. avium*, occur most frequently in their respective hosts, but cross-infections do occur and various other species of animals are affected.

- **Bovine tuberculosis** refers mainly to disease in cattle caused by ***Mycobacterium bovis***, but the term is also used to describe the pathogenic effects of this agent in other hosts. The host range of *M. bovis* is broad, including cattle, deer, elk, bison, buffalo, goats, camels, llamas, swine, elephants, rhinoceros, dogs, foxes, cats, mink, badgers, and nonhuman and human primates. Natural disease is most common in cattle, cervids, humans, and swine.
- ***M. avium*** causes mycobacteriosis chiefly in birds and is occasionally found in cattle, swine, horses, sheep, and monkeys.
- ***M. tuberculosis*** is chiefly responsible for tuberculosis in humans, and occasionally infects pigs, captive monkeys, dogs, cats, cattle, and psittacine birds.

Human infections with *M. bovis* are well documented, but are much less common than *M. tuberculosis*. Immunosuppressed individuals, such as those with the acquired immunodeficiency syndrome (AIDS), are at particular risk. Ingestion of milk from cows with mammary tuberculosis is a major route of infection in humans, typically inducing cervical lymphadenitis or other nonpulmonary forms of disease. This pattern of disease is of great historical importance as the impetus for identification of the tubercle bacillus and the subsequent *pasteurization of milk*, but infection from raw milk continues to occur in regions where bovine tuberculosis is common. Transmission from cattle to humans by aerosol or by contamination of cutaneous wounds also occurs, most frequently in those in close contact with infected cattle.

Mycobacteria are nonmotile, nonspore-forming pleomorphic coccobacilli. They are gram-positive but almost unstainable by the simpler bacterial stains because of their high content of lipids. They are routinely stained with carbol-fuchsin, and then resist decoloration by inorganic acids. This property of acid-fastness of the stained bacilli depends on the amount and spatial arrangement of mycolic acids and their esters in the bacterial wall. They are also demonstrable by fluorescent dyes such as auramine. Sometimes, in cultures or in old lesions, the organisms have a beaded or granulated appearance. This beading is partly caused by the presence of lipid droplets within the bacteria and is an indication of an unfavorable environment for organisms in the postexponential growth phase.

In addition to the cell membrane and peptidoglycan layers found in other bacteria, *the mycobacterial cell wall contains a large hydrophobic layer of mycolic acids, which bestows hydrophobicity on the cell wall, conferring environmental and antimicrobial resistance.* The waxes and cell wall glycolipids are important inducers of the initial macrophage response and, together with peptidoglycan (muramyl dipeptide), are responsible for most of the adjuvant activity of mycobacteria that facilitates recruitment of antigen-presenting cells. Increased glycolipid content of mycobacterial cell walls, acid-fastness, and the amount of trehalose dimycolate (cord factor) in the cell wall are associated with increased virulence. Other glycolipids (mycosides) appear to form a barrier against lysosomal digestion and partly explain the ability of the organisms to survive after phagocytosis by macrophages. Intracellular survival is also facilitated by preventing fusion of phagosomes and lysosomes. The differing effectiveness of such mechanisms determines the relative ability of various mycobacteria to resist intracellular degradation.

Tuberculoproteins are the other major category of immunoreactive substances in mycobacteria. They provide most of the antigenic determinants, but the adjuvant activity of the lipids and polysaccharides in the mycobacterial cell wall is needed for an animal to produce an immunologic response to these tuberculoproteins. *Purified protein derivatives* (PPD) from mycobacteria are capable of eliciting delayed-type hypersensitivity once the animal is sensitized, however, and this is the basis of *tuberculin testing*. Both tuberculoproteins and the adjuvant lipids are present in infection, and the result is the development of both humoral and cell-mediated immune responses. Humoral antibodies can be demonstrated by serologic techniques, but do not participate in the development of lesions or in the production of immunity. Cell-mediated responses are responsible for both aspects of the disease.

The *method of transmission* influences the spectrum of lesions of bovine tuberculosis. Inhalation of droplet nuclei or dust particles containing *M. bovis* is the most common route of infection and leads to infection of the upper and lower airways. Oral infection requires a greater dose of bacilli than airborne infection to cause disease, and elicits lesions in the gut and associated lymph nodes. Transplacental transmission is a sequel of endometrial tuberculosis, and leads to fetal lesions in hepatic and portal lymph nodes. Less common routes of infection include percutaneous inoculation, genital transmission, and intramammary infusion of contaminated pharmaceutical preparations.

Important concepts in the pathogenesis of tuberculosis include the ability of mycobacteria to survive within macrophages, and the role of cellular immune responses in inciting granulomatous inflammation and enhancing the ability of macrophages to kill bacilli. Most animals that are infected with *M. bovis* do not develop clinical disease. The outcome of infection depends on bacterial factors, including the dose and virulence of infecting bacteria, but also on host factors, including the state of immune competence and heritable resistance to tuberculosis. Heritable variation in disease susceptibility has been identified in cattle and in deer. In humans and mice, mycobacterial resistance is partly related to allelic variation in the natural resistance-associated macrophage protein (Nramp) genes 1 and 2, which affect intracellular survival of pathogens by modifying lysosomal transport of divalent cations, including iron and manganese. Other forms of heritable resistance to *M. bovis* are unrelated to variation in Nramp genes.

There are several facets to immune-mediated control of tuberculosis, and most of this understanding is based on the study of *M. tuberculosis* infections in humans and laboratory animals. In the early phases of infection, bacilli are phagocytosed by macrophages and may be eliminated. Alternatively, infected macrophages may remain at the site of primary infection for prolonged periods before the disease progresses. An initial innate immune response develops at this site of primary infection, as macrophages secrete cytokines – particularly tumor necrosis factor-α and the C-C chemokines – that recruit additional macrophages and lymphocytes to the site.

Macrophages stimulated by exposure to mycobacteria secrete interleukin-12, which skews the immune response to favor secretion of interferon-γ and interleukin-2 by CD4+ T-helper-1 lymphocytes. These interferon-γ-producing T-helper lymphocytes signal the development of **cell-mediated immunity**, first detected at 14–28 days after infection by positive tuberculin skin test reactions. The arrival of these antigen-specific lymphocytes is crucial for host defense, activating macrophages and thus allowing them to overcome the block in phagosome maturation, and upregulate production of bactericidal products, including reactive nitrogen and oxygen intermediates and lysosomal enzymes, killing intracellular bacilli. Activated macrophages appear epithelioid, with abundant cytoplasm and indistinct cell borders, or form multinucleate giant cells.

The cytokines tumor necrosis factor-α and interferon-γ act synergistically to promote formation of the **tuberculoid granuloma**, a dynamic structure that prevents spread of infection to other sites in the lung, as well as animal-to-animal transmission, and represents a localized target for the immune response. Excessive tissue-damaging cell-mediated immune response, called **delayed-type hypersensitivity**, kills heavily infected macrophages, forming the caseous center of the granuloma. Matrix metalloproteinases released from activated macrophages are a likely cause of the characteristic cell necrosis and liquefaction of tissues in some lesions of tuberculosis. Bacilli within the caseous center do not multiply but may remain dormant as latent infections that may persist for years, until immunosuppression caused by diseases, drugs, hormones, or malnutrition, or other unidentified factors disturb the balance between host and agent, allowing proliferation of the pathogen and reactivation of the disease.

Whether the delayed-type hypersensitivity reaction is beneficial or harmful to the host depends on the circumstances. On the one hand, the reaction to relatively small numbers of bacilli causes accelerated tubercle formation that enhances the killing of the organisms, and helps prevent reinfection or dissemination from the initial site of infection. On the other hand, the delayed-type hypersensitivity response to large amounts of mycobacterial antigen causes extensive cell necrosis and tissue destruction, which is seriously detrimental. Liquefaction, brought about by hydrolytic enzymes of macrophages and possibly neutrophils, is the most harmful response. The bacilli multiply extracellularly in the liquefied material and are available in large numbers for dissemination through cavities, vessels, and airways. In summary, *the final determinants of the nature and intensity of lesions are the magnitude of the bacterial infection, the intensity and appropriateness of the immune response, and the modifying influences of the structure of the tissue involved.*

Gross or histologic lesions are absent in many cattle that react to tuberculin skin tests, and although *M. bovis* cannot be isolated from many of these cases, they are generally considered to be infected for the purposes of epidemiology and control. Thorough examination of lymph nodes throughout the body is necessary before declaring a carcass free of visible lesions; *only a single lesion is present in most cattle with gross lesions of tuberculosis.* The distribution of lesions of bovine tuberculosis depends on the mode of transmission. In most cases, gross lesions are restricted to the respiratory tract and associated lymphoid tissues. Tubercles or craterous ulcers in gut or mesenteric lymph nodes suggest an oral route of infection, or ingestion of infected sputum that has been coughed up from the lung. Generalized disease is less common but well described.

In **respiratory infections**, *lesions are most common in retropharyngeal, bronchial, and mediastinal lymph nodes*, and less frequent in mandibular and parotid lymph nodes and palatine tonsils. Lung lesions are detected in only 10–20% of cattle with gross lesions, and often affect the caudal lobes. *The classic gross lesion is the tubercle: a circumscribed, often encapsulated, 1–40 mm diameter, pale-yellow or white focus of granulomatous inflammation, often with caseous necrosis and/or mineralization* (Fig. 5.64). Larger lesions may contain liquefied or suppurative exudate and be mistaken for abscesses caused by pyogenic bacteria. Bacilli are released from expanding tubercles into the airways, and coughing up of infected sputum may spread the infection by ingestion to cause lesions in intestine or mesenteric lymph nodes, by adhesion to laryngeal or tracheal mucosa to incite ulcers or ulcerating tubercles, or by aspiration to seed secondary sites in the lung. Multiple, raised, yellow, 1–3 mm plaques on the mucosal surface of the nasal cavity and nasopharynx are early lesions following experimental intranasal infection. Erosion of pulmonary tubercles through the pleura may result in implantation of bacilli throughout the pleural cavity, with development of multiple granulomas on pleural surfaces (Fig. 5.65). Lymphatic spread has been suggested as an alternative route of pleural infection.

Generalized lesions are reported in about 1% of animals with gross lesions of tuberculosis, and probably result from hematogenous dissemination of bacilli following erosion of the wall of a blood vessel by an expanding tubercle. Embolic lesions are most common

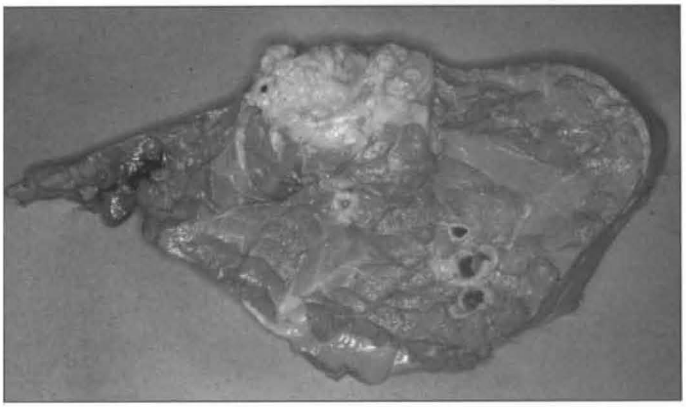

Figure 5.64 Tuberculosis in a cow. Pale bulging granuloma in the lung.

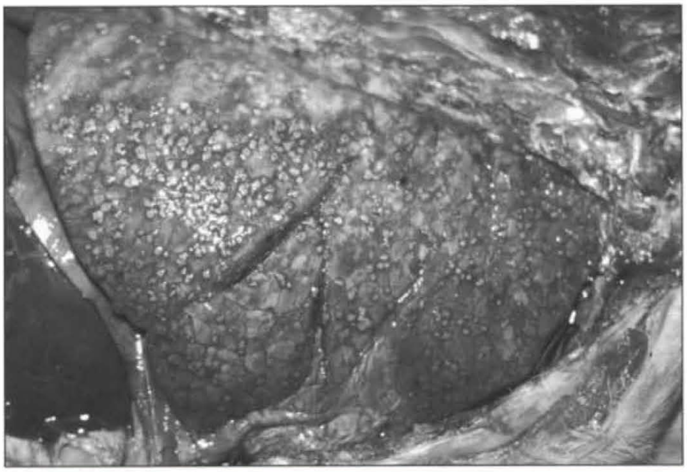

Figure 5.65 Tuberculosis in a cow. Granulomas disseminated throughout the pleura.

in lung, and may involve lymph nodes, bone, liver, kidney, mammary gland, uterus, pleura, peritoneum, pericardium, and meninges. Lesions are rare in salivary gland, pancreas, spleen, brain, myocardium, or muscle. In some instances, presumably following substantial release of bacilli into the blood, the presence of innumerable tiny white foci justifies the term "*miliary tuberculosis*." In contrast, other carcasses display generalized lesions that are variable in size and degree of caseation or fibrosis, and imply a less catastrophic but more prolonged bacteremia. Erosion through serosal or mucosal surfaces by expanding tubercles spreads the infection by implantation on pleural, peritoneal, pericardial, or meningeal surfaces or along the airways, intestine, or urinary tract.

Histologic features of the tubercle include: (1) a central coagulum of caseous necrosis, consisting of eosinophilic homogeneous material with scant nuclear debris and a variable degree of mineralization; (2) a mantle of macrophages and Langhans-type multinucleate giant cells; (3) a capsule containing lymphocytes, clusters of neutrophils in some cases, and a rim of collagenous connective tissue in chronic lesions; and (4) rare to numerous acid-fast bacteria within macrophages and giant cells of the mantle zone or extracellularly in the caseous core (Fig. 5.66). In experimentally infected cattle, the early lesions at 7 days after infection consisted of intra-alveolar clusters of macrophages, necrotic neutrophils, giant cells containing neutrophil remnants, and acid-fast bacteria. At 14 days after infection, corresponding to the onset of lymphocyte proliferative responses, tubercles contained central aggregates of neutrophils surrounded by epithelioid macrophages. In this study, necrosis in the center of the tubercles was noted at 21 days after infection, and the first mineralized lesions were at 35 days. The amount of fibrosis increases with time, and tends to be more prominent in individuals and species with greater resistance. The presence of neutrophils is highly variable, and their presence in large numbers is most common in cases with rapid multiplication of bacteria, numerous reactive lymphocytes, and easily distensible tissues.

In **cervids**, *M. bovis* causes a similar spectrum of lesions as in cattle, but several unique features are of note. As in cattle, lesions are most common in retropharyngeal lymph nodes, lungs, thoracic lymph nodes, and mesenteric lymph nodes. However, deer may develop superficial lymphadenitis and abscesses that drain to the skin surface. Disease progression may be more rapid in cervids than cattle; deer shed larger numbers of bacilli, and the disease may be more likely to remain subclinical. These features suggest that deer are less able to contain *M. bovis* infections than cattle, although limited evidence indicates they are not more susceptible to infection.

In elk (*Cervus elaphus* nelsoni), red deer (*C. elaphus* elaphus), and fallow deer (*Dama dama*), fibrosis and giant cells are less evident than in cattle, the presence of mineralization is more variable, and, importantly, *suppurative inflammation may be prominent*. Multifocal lesions of

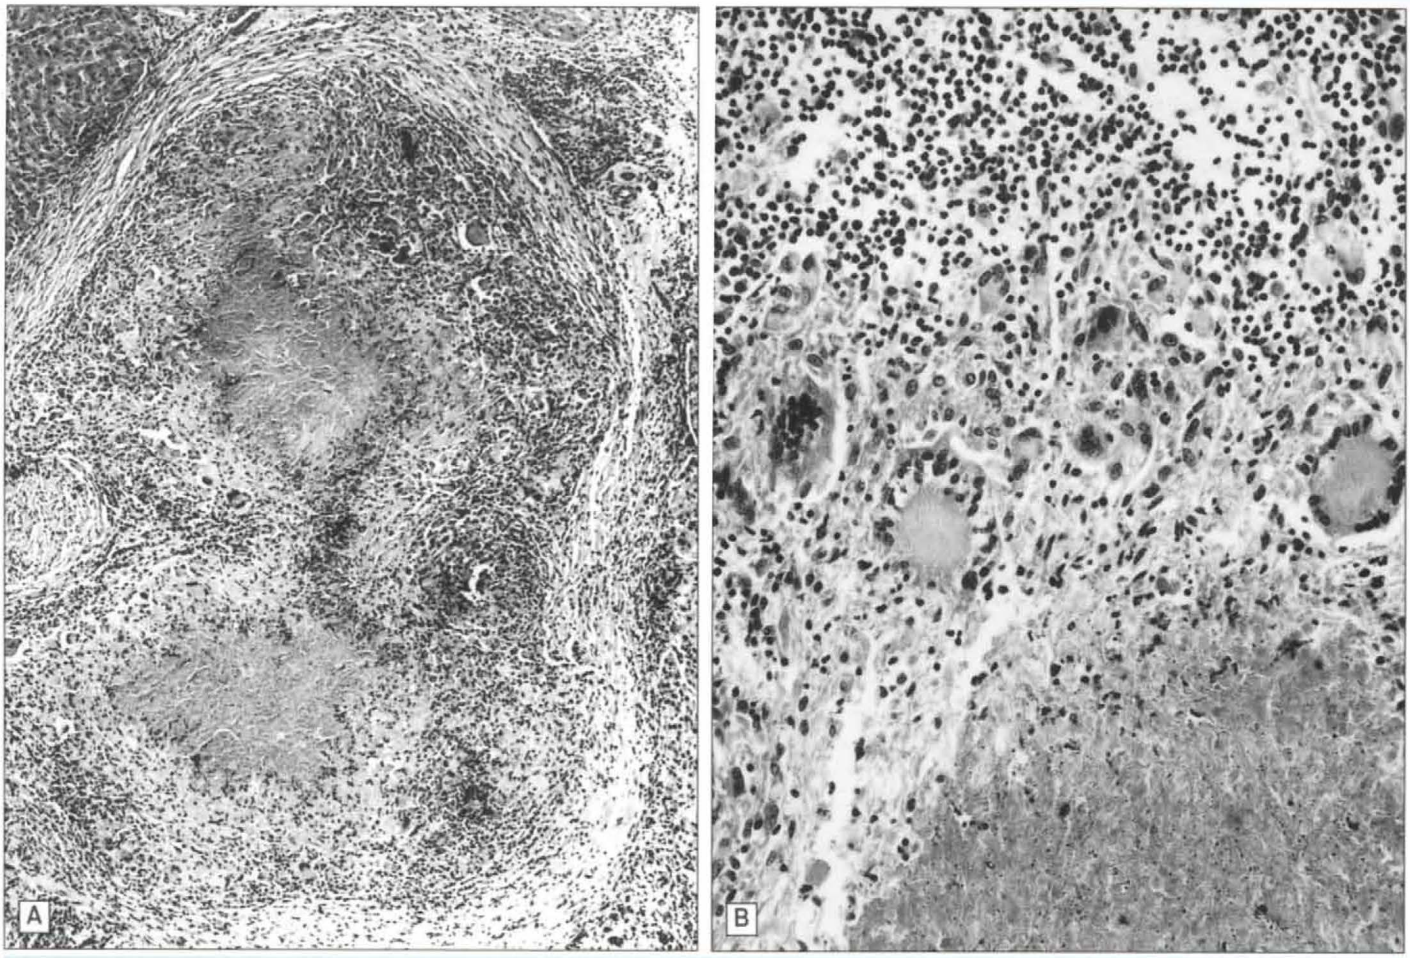

Figure 5.66 Tuberculosis. **A.** Caseous tubercles are encapsulated by fibrous tissue. **B.** Periphery of tubercle with giant cells and epithelioid cells bordering caseous necrosis.

caseous necrosis or suppurative inflammation in the lungs and lymph nodes of cervids are commonly caused by *Fusobacterium necrophorum* infection, and it has been recommended that these lesions be carefully examined for acid-fast bacteria as a routine procedure. Occasional cases of tuberculosis in these species may present concentrically laminated caseous abscesses reminiscent of caseous lymphadenitis in sheep. The lesions of tuberculosis in sika deer (*C. nippon*) are distinctive, consisting of nonencapsulated invasive accumulations of epithelioid macrophages and numerous irregularly shaped giant cells, few neutrophils, and minimal necrosis or mineralization.

Tuberculosis in **horses** is often *alimentary*, with lesions in *retropharyngeal and mesenteric lymph nodes and intestine*. Intestinal infection may cause localized ulcers or thickened mucosal lesions reminiscent of Johne's disease in cattle. Tubercles in horses are usually uniform, gray, smooth (lardaceous), with little caseation or mineralization but abundant fibrosis, and may resemble sarcomas. Tuberculosis in **small ruminants** is rare, but similar in most respects to the disease in cattle. Tuberculosis in **swine** is often *systemic*, and the morphology depends on the infecting pathogen. *M. bovis* produces caseous and mineralized tubercles similar to those that occur in cattle, and the lesions are often surrounded by a fibrous capsule. In the liver, there is a tendency for the caseous centers to liquefy. *M. avium* produces lesions that are proliferative in nature and consist of tuberculous granulation tissue resembling the lardaceous or sarcomatous lesions described in equine tuberculosis. The histologic appearance is of diffuse infiltration of macrophages, epithelioid cells, and Langhans' giant cells accompanied by extensive fibroplasia and numerous bacilli.

Tuberculosis in **dogs and cats** usually appears as *granulation tissue* in which macrophages are scattered at random and giant cells are rare. *Discrete tuberculous granulomas are uncommon*, and composed principally of epithelioid cells surrounded by narrow zones of fibrous tissue in which there are scattered small collections of lymphocytes and plasma cells. Necrosis is often present in the centers of larger granulomas. Giant cells are rare. The presence of central necrosis and fairly small numbers of acid-fast bacilli in lesions of cats helps to distinguish lesions of tuberculosis from those of feline leprosy. The primary foci in the lungs of dogs develop in most cases in the dorsal part of the caudal lobes. Dissemination within the lungs occurs quite rapidly and is predominantly intrabronchial with the production of tuberculous bronchitis and bronchiolitis rather than bronchopneumonia. Pleuritis or peritonitis often accompanies primary infections in the lungs or intestine, respectively, with diffuse or finely nodular pleural thickening by granulation tissue containing few macrophages and bacilli.

A thorough necropsy examination is the most sensitive method of detecting tuberculosis after death, as the likelihood of isolating M. bovis in culture is miniscule if gross lesions are not detected.

Gross lesions of focal caseous lesions in lymph nodes or lung, or histologic detection of granulomas, particularly with central areas of necrosis and/or mineralization, should prompt an extensive and thorough search for acid-fast bacilli. A finding of low numbers of bacilli is more suggestive of bovine tuberculosis than of mycobacteriosis caused by *M. avium*. However, *bacterial culture using egg-based or agar-based media enriched with serum or blood is the gold standard for definitive diagnosis of bovine tuberculosis*, particularly if the diagnosis is likely to have a serious impact. Specimens should be collected using sterile technique, to avoid contamination with environmental mycobacteria that may overgrow *M. bovis* in culture. Immunohistochemical identification of *M. bovis* has been described. This procedure is more sensitive than examining acid-fast-stained sections, in terms of number of animals detected, staining intensity, and ease of detection, but the antibodies in current use cross-react with other mycobacteria as well as some gram-positive bacteria and fungi.

Mycoplasmal diseases

Contagious bovine pleuropneumonia

Contagious bovine pleuropneumonia (CBPP), an OIE (World Organization for Animal Health) List A disease, is an important barrier to global trade, and a production-limiting disease in Africa. The disease is present in much of Africa except the Mediterranean and southeast African countries, and has recently occurred in southern Europe, central and eastern Asia, and the Middle East. CBPP caused devastating epidemics in cattle populations in the 19th century, but *sporadic disease is now more common in endemically infected countries practicing vaccination*. When the agent is introduced into naive populations, the effects vary from insidiously spreading disease to spectacular mortality affecting up to 50% of the animals.

The clinical signs and mortality rates are highly variable, depending on the strain of the pathogen, the age of the animal (adults are more susceptible than young stock), and the presence of other diseases, crowding, or stressors. Peracute cases die without premonitory signs. Acutely ill animals are febrile, anorexic, and depressed, with profound loss of milk production, open-mouth rapid breathing, mucoid nasal discharge, and occasional coughing. Chronically affected animals may be clinically normal or have an intermittent cough and fever, yet shed the organism intermittently. Calves less than 6 months old commonly develop polyarthritis affecting carpal and tarsal joints, rather than pneumonia.

CBPP is caused by Mycoplasma mycoides subspecies mycoides small colony type, which is different from the large colony type that causes pleuritis and pneumonia in goats in many countries throughout the world. There is marked strain-dependent variation in virulence, and the pathogenicity apparently declines as in vivo passage of the organism occurs during an outbreak. Galactan in the mucus capsule is correlated with virulence, and induces necrosis, thrombosis, and inflammation. The host range includes cattle (*Bos taurus*), zebu (*B. indicus*), water buffalo (*Bubalus bubalis*), bison, and yak, although *cattle are most commonly affected by clinical disease. Mycoplasma mycoides* is an obligate pathogen that survives poorly in the environment, so transmission usually depends on close contact with animals shedding the bacteria. Transplacental infection may occur. *The respiratory tract is the site of primary infection*, and bacteremia develops secondarily. The incubation period varies from 5 to 200 days, but is typically 20–40 days.

Gross lesions are often unilateral and restricted to the *caudal lung lobes*. In the acute stages, there are mats of fibrin and fluid exudate covering the pleural surface. Interlobular septa are remarkably distended with serous fluid, and the lobules vary from normal to consolidated and red or yellow-gray. The pattern of interlobular edema and lobular consolidation lends a *characteristic marbled appearance* to the lung. Focal areas of necrosis increase in size over time, and eventually develop into sequestra. Sequestrum formation and fibrous thickening of the pleura with adhesions to the ribs are typical of chronic CBPP. Pericarditis, peritonitis, and polysynovitis occur infrequently in adult cattle (Fig. 5.67).

Histologic examination of bronchioles and alveoli reveals serofibrinous or suppurative exudates with necrosis of neutrophils, and multifocal areas of coagulative necrosis in the lung parenchyma. Interlobular septa are expanded by edema and fibrin, and interlobular lymphatics contain fibrin. Thrombosis of arteries, veins, and lymphatics is common, and nonsuppurative arteritis may be evident. *Vasculitis* is central to the development of the necrotic lesions and sequestration of lung tissue (Fig. 5.67).

The **differential diagnosis** includes *Mannheimia haemolytica* and *Mycoplasma bovis*. The unilateral lesions, prominent inflammation in interlobular septa, and frequent development of sequestra should suggest a diagnosis of CBPP, although the latter two features do occur in shipping fever due to *Mannheimia haemolytica*. The lesions of *Mycoplasma bovis* lack the extensive fibrinous exudates in interlobular septa and on the pleural surface seen in CBPP.

Definitive **diagnosis** is based on *culture on special media*, which may take several weeks. *Frozen samples of lesional lung, pleural fluids, and lymph nodes are optimal for isolation of the agent*. Immunohistochemistry and the polymerase chain reaction are more rapid methods of diagnosis. Various serological assays are useful for screening of herds, but not for individual diagnosis. Development of improved methods to detect subclinical carriers is an area of intensive research, as current serologic assays lack sensitivity.

Mycoplasma bovis

The role of *Mycoplasma bovis* as a cause of mastitis and of infertility of dairy cows is discussed elsewhere. The two principal manifestations of *M. bovis* in the respiratory system are as a component of *enzootic pneumonia of young calves*, and *chronic pneumonia and polyarthritis in feedlot cattle*. The latter is an emerging disease in intensively raised feedlot cattle in North America and Europe. In contrast to the appearance of shipping fever, calves with lesions of *M. bovis* pneumonia or polyarthritis usually die or are euthanized in the second or third month after arrival. These calves have often had prolonged antimicrobial therapy for nonresponsive or relapsing respiratory disease, which is indistinguishable from shipping fever in the early stages. Calves may be lame and have swelling of one or more joints, and many calves exhibit both respiratory disease and lameness.

The prevalence of chronic pneumonia and polyarthritis is often low, although up to 30% of calves may be affected in exceptional cases. Nevertheless, since the diagnosis is only made on fatal cases, the true prevalence of the disease is unknown. In contrast, the prevalence of infection with *M. bovis* has been reported to vary from 20 to 70%, and most calves seroconvert to *M. bovis* during the first month in the feedlot.

M. bovis may be carried and shed in the secretions of the respiratory tract, the genital tract, and the mammary gland. Infection of the respiratory tract probably occurs by direct contact with nasal secretions, or perhaps by inhalation of infected droplets. Contact with genital secretions or ingestion of infected milk may cause infection in neonatal calves. Infection may remain confined to the respiratory tract, or extend from the lung to cause bacteremia with subsequent infection of joints and other tissues.

M. bovis is seemingly well equipped to evade the immune response. The bacterium induces apoptosis of bovine lymphocytes, suppresses the proliferative response of lymphocytes to mitogens, and impairs neutrophil activation. The bacterial surface is decorated with a family of highly immunogenic variable-surface lipoproteins, encoded by at least 13 *vsp* genes containing multiple repeat sequences, which undergo high-frequency phase variation (turning expression on and off) and size variation. *M. bovis* seems to alter surface lipoprotein expression in response to binding of specific antibody, suggesting that rapid changes in surface antigen expression is a mechanism of evading the humoral immune response, in a manner analogous to *Trypanosoma* sp. In support of this hypothesis, although antibody titers develop 2–3 weeks after experimental infections, the cellular and humoral immune responses are not protective.

Assessing the antimicrobial susceptibility patterns of *Mycoplasma* sp. is problematic, but several recent reports indicate that many isolates of *M. bovis* are resistant to antimicrobials commonly used in feedlot medicine, including florfenicol, tilmicosin, oxytetracycline, and spectinomycin. The pathogenetic implications of this antimicrobial resistance are uncertain. However, one theory suggests that *M. bovis* may be one of several pathogens infecting calves as they enter the feedlot, but the ability of this bacterium to resist antimicrobials

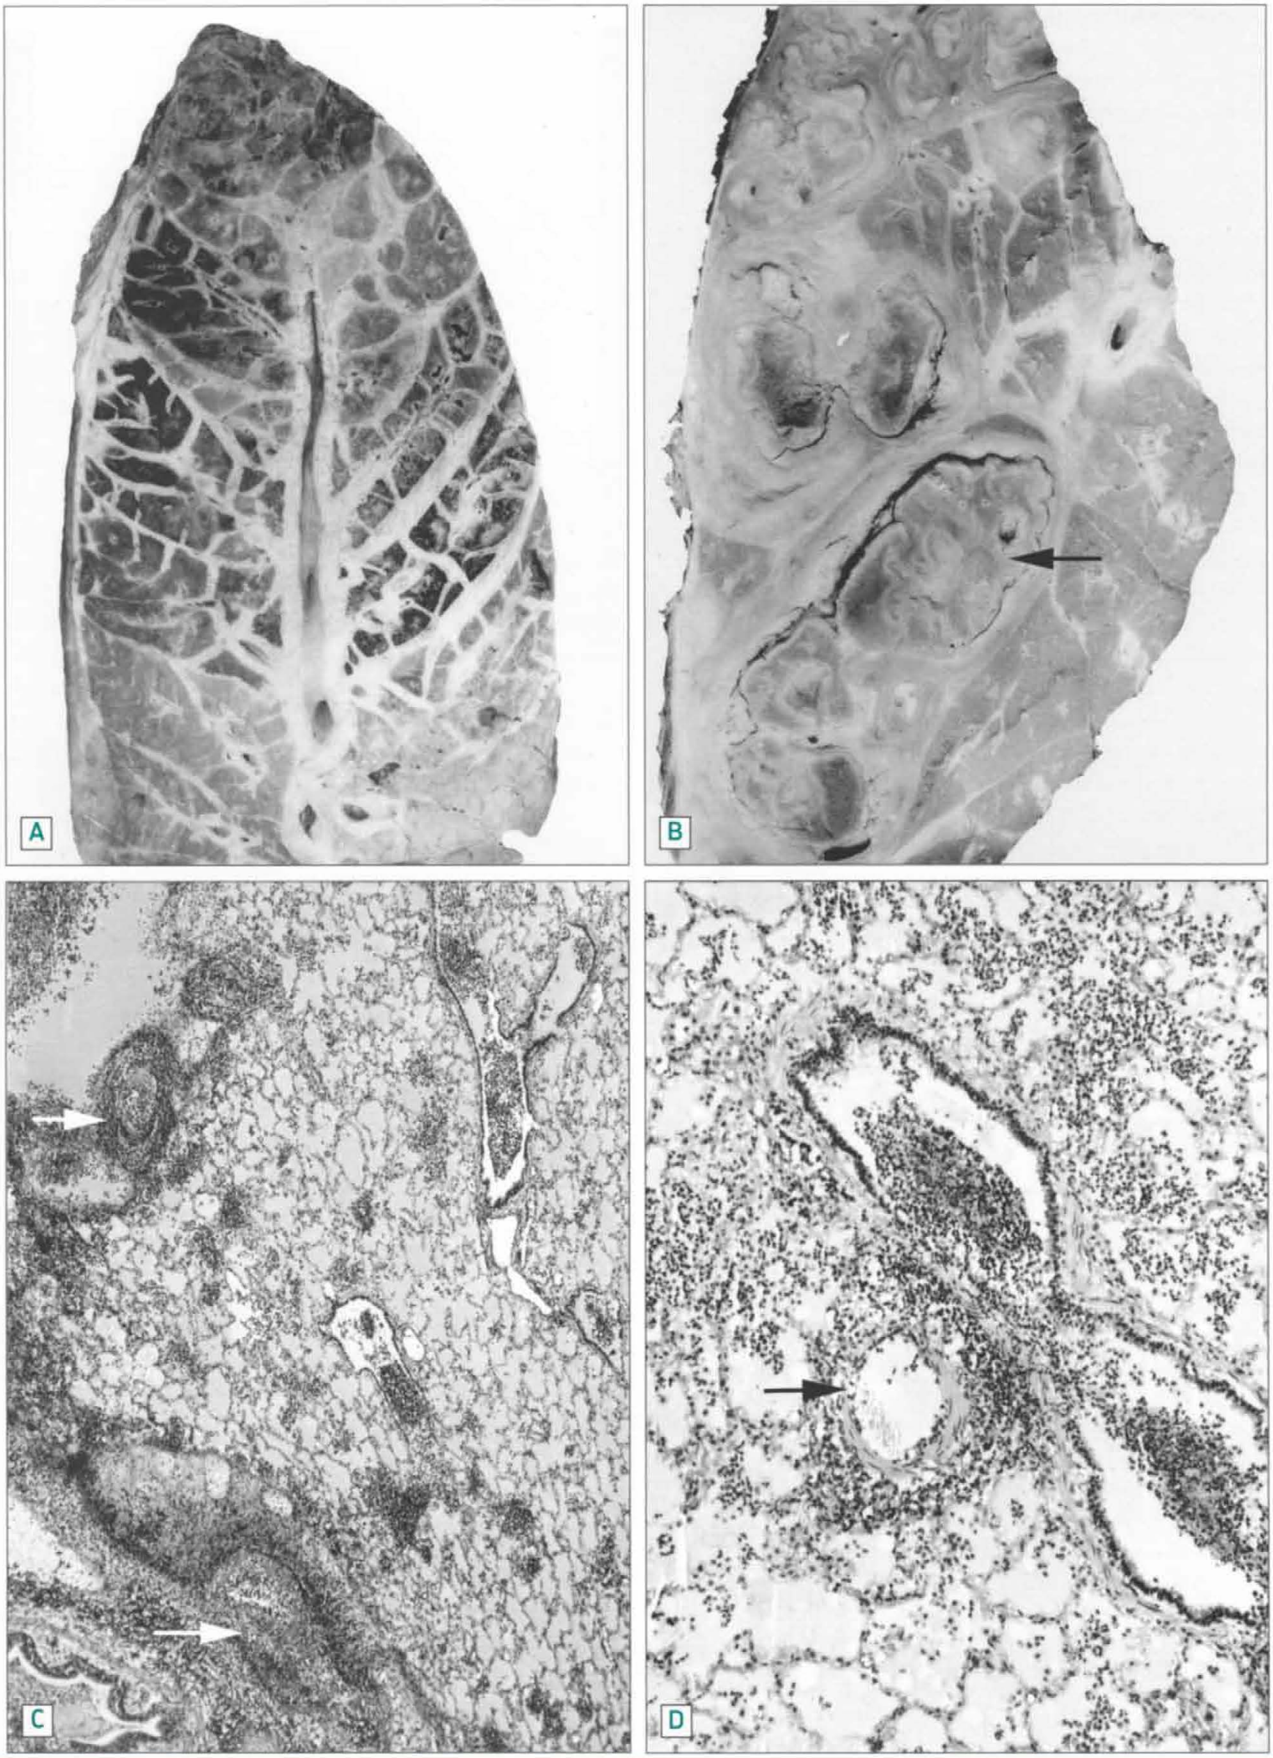

Figure 5.67 Contagious bovine pleuropneumonia. A. Distension of interlobular septa. **B.** Sequestra (arrow) with encapsulation of necrotic tissue. **C.** Acute fibrinonecrotic pneumonia with inflammation, arteritis, and necrosis in interlobular septa and peribronchial interstitium (arrows). **D.** Acute arteritis (arrow) affecting a peribronchial artery.

and evade the immune response leads to chronic disease that fails to respond to therapy.

Many calves with lesions of *M. bovis* pneumonia are also infected with *Mannheimia haemolytica*, and there is epidemiologic and morphologic evidence that the lesions of *Mycoplasma bovis* may evolve out of those of *Mannheimia haemolytica*. Most cases have concurrent infection with *Mycoplasma arginini*, suggesting possible synergy. The role of *M. bovis* in predisposing to bacterial pneumonia is uncertain, as *M. bovis* is reportedly less effective than *M. dispar* at impairing ciliary function.

The **gross appearance** of *M. bovis* pneumonia may be indistinguishable from suppurative bronchopneumonia of other causes: there is cranioventral reddening and consolidation, scant fibrin may cover pleural surfaces, and bronchial lymph nodes are enlarged and diffusely white. However, *the characteristic lesions are raised, white, sharply demarcated, friable foci of caseous necrosis within the consolidated areas of lung* (Figs 5.68 and 5.69). These foci of necrosis are often 2–10 mm in diameter, but occasionally enlarge to many centimeters diameter. The largest lesions may contain fluid pus rather than caseous exudate, presumably due to secondary or concurrent bacterial infection. These foci of necrosis form sequestra in some cases. Uncommonly, foci of necrosis and inflammation may be present in bronchial lymph nodes, and similar nodular masses are rarely encountered in the tracheal submucosa, along the dorsal tracheal ligament, or in other tissues.

Joint lesions are present in ~50% of calves with *M. bovis* pneumonia, and the lesions may vary considerably within the same animal. *Pneumonia is found in all calves with M. bovis arthritis.* Acute lesions consist of serofibrinous exudate within joint cavities and tendon sheaths, and the synovium is reddened and hyperplastic. Cartilage erosion is reported in experimental cases but is often absent in clinical material. Purulent or fibrinopurulent exudate is often florid in more established lesions. Foci of caseous necrosis, similar to those described in the lung, may be present in the synovium or joint capsule. Other joints have minimal lesions in the articular cavity, but extensive edema and foci of caseous necrosis in the tendon sheaths or the periarticular soft tissues.

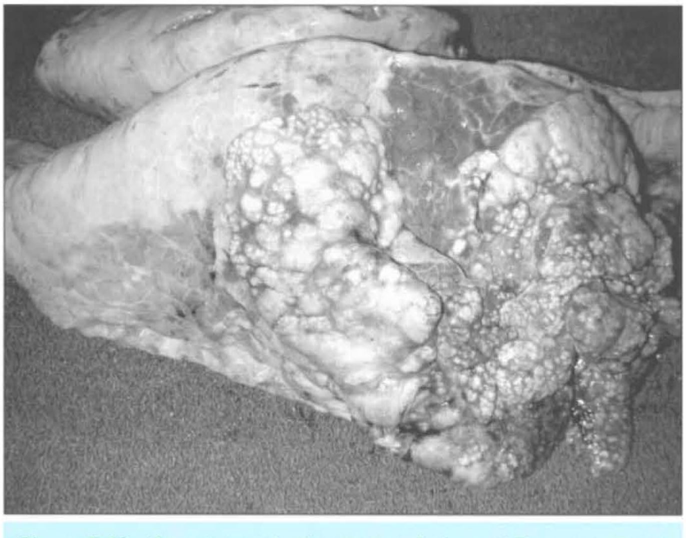

Figure 5.68 ***Mycoplasma bovis* pneumonia** in a calf. The cranioventral 60% of the lung is consolidated and contains innumerable white raised nodules.

Other manifestations of *M. bovis* infection include fibrinous, purulent, or caseating *otitis media* in young calves, which may be associated with feeding of mastitic milk; decubital abscesses; and a proposed association with *necrotizing myocarditis* of the papillary muscle that resembles *Histophilus somni* myocarditis.

The **histologic lesions** of suppurative bronchopneumonia are nonspecific, but the characteristic appearance of the foci of necrosis suggests a diagnosis of *M. bovis*. The lesions originate in small bronchioles, alveoli, and alveolar septa. The mildest, and probably earliest, lesion consists of suppurative exudate within small bronchioles, in which leukocytes have a characteristic appearance – they are necrotic but retain their cellular outlines, and have hypereosinophilic cytoplasm and inapparent or fragmented nuclei (Fig. 5.70). As the lesion progresses, there is erosion of bronchiolar epithelium, with expansion of the necrotic foci to incorporate peribronchiolar alveoli. Macrophages and lymphocytes infiltrate the margins, infrequent giant cells may be present, and immature fibrous tissue develops at the outermost edge of the lesion. Large lesions may contain coagulative necrosis in their centers, with retention of the alveolar and bronchiolar architecture of the dead parenchyma. Mineralization of the necrotic tissue is frequent. Lesions affecting bronchi may progress to bronchiectasis.

Using immunohistochemistry, mycoplasmal antigen is most abundant at the periphery of the foci of necrosis and within the bronchiolar exudate. Lesser amounts of antigen are present at the apical surfaces of bronchiolar and bronchial epithelial cells, and within alveolar macrophages and neutrophils. Foci of necrosis or lymphoplasmacytic inflammation may be present in the liver, kidney, or other viscera.

The gross and histologic appearance of the foci of necrosis is distinctive. The foci of necrosis caused by *Mannheimia haemolytica* or *H. somni* are irregular in shape, nonfriable, delineated by a white rim, retain

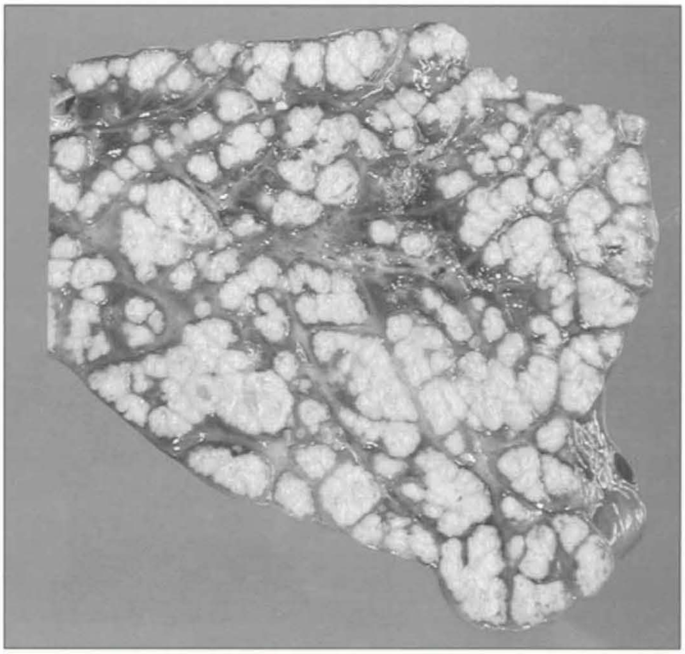

Figure 5.69 ***Mycoplasma bovis* pneumonia** in a calf. Consolidated lung contains coalescing white crumbly nodules of caseous necrosis, separated by atelectatic lung tissue.

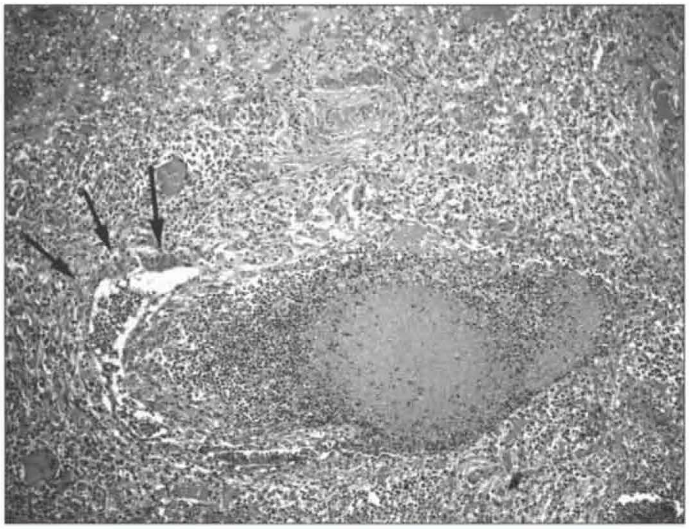

Figure 5.70 ***Mycoplasma bovis* pneumonia** in a calf. A bronchiole contains a few remnants of epithelium (arrows), and is filled with suppurative exudate containing a developing focus of caseous necrosis.

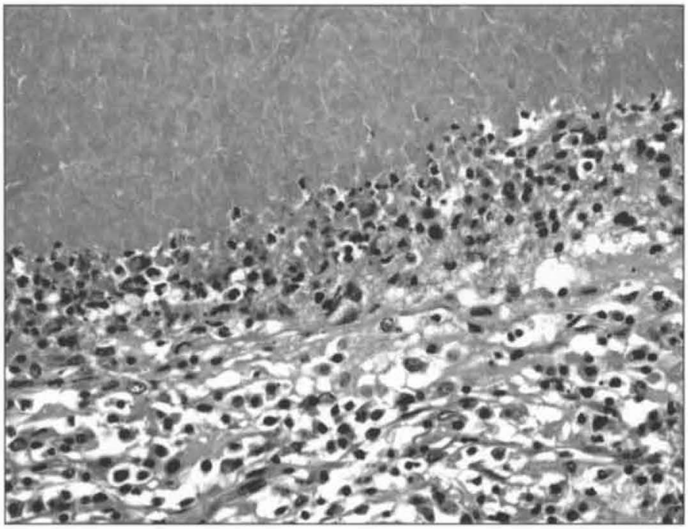

Figure 5.71 ***Mycoplasma bovis* pneumonia** in a calf. A well-developed focus of caseous necrosis containing an acidophilic coagulum (top), separated by a layer of necrotic neutrophils and macrophages from a fibrous capsule (bottom).

the histologically visible tissue architecture (coagulative necrosis), and contain streaming necrotic leukocytes. In contrast, the lesions of *Mycoplasma bovis* are usually circular and white throughout, and appear histologically as an eosinophilic coagulum exhibiting the ghost-like outlines of necrotic leukocytes (Fig. 5.71). Larger foci with fluid pus rather than crumbly content may be appropriately termed abscesses if a fibrous capsule can be demonstrated, and *M. bovis* may be isolated along with other bacterial pathogens such as *Arcanobacterium pyogenes*. Sequestra caused by *M. bovis* are indistinguishable from those caused by *Mannheimia haemolytica* or *H. somni*, unless typical foci of caseous necrosis are detected in the adjacent consolidated lung tissue.

Various techniques are available to confirm the tentative **diagnosis** of *Mycoplasma bovis*. It grows readily on *Mycoplasma* enrichment media, and is occasionally isolated on blood agar. However, many calves without apparent pneumonia are infected with *M. bovis*. Thus, *the diagnosis rests on identifying both infection with this agent and the presence of the characteristic lesions*. Immunohistochemistry is also advantageous for correlating the location of mycoplasmal antigen with the characteristic lesions. Seroconversion occurs in many healthy calves in the first month after entering feedlots, making this assay of dubious significance for diagnosis of individual cases.

Miscellaneous *Mycoplasma* spp. of calves

Mycoplasma spp. are regularly isolated from the lungs of calves with pneumonia, but their importance in disease is often difficult to interpret. Only *M. bovis* is likely to cause severe primary disease. Infection with ***M. dispar, Ureaplasma diversum***, and perhaps ***M. bovirhinis*** causes bronchiolitis and may contribute to development of acute or chronic enzootic pneumonia in young calves by predisposing to bacterial pneumonia. Experimental infections with ***M. bovigenitalium, M. arginini***, *and* ***M. canis*** induce mild lesions and no clinical signs.

Mycoplasma spp. attach to ciliated epithelial cells, on and between microvilli and covering the base of the cilia. *The typical lesion is chronic catarrhal bronchitis and bronchiolitis with prominent lymphocytic cuffs around airways*. Affected lungs contain patchy, cranioventral, purple-red foci of atelectasis. When secondarily infected by opportunistic bacterial pathogens, more confluent, meaty consolidation may also occur. Microscopically, accumulations of neutrophils and mucus are present in airway lumens and there is increased prominence of goblet cells. Moderate infiltrates of lymphocytes and fewer plasma cells encircle the airways and accompanying blood vessels. Inflammation of alveoli adjacent to terminal bronchioles occurs in experimental infections in colostrum-deprived, specific-pathogen-free calves and can probably occur in heavy natural infection. Alveolar lesions are not specific, and include atelectasis, accumulation of neutrophils and alveolar macrophages with occasional lymphocytes and plasma cells, and mild hypercellularity of alveolar septa. As the infection becomes chronic, lymphocytic peribronchiolar cuffs thicken, develop germinal centers, and extend to the lamina propria of the bronchiole. At this stage, the epithelium may be hyperplastic with goblet-cell hyperplasia and hypertrophy of bronchial submucosal glands.

Fungal diseases

Mortierellosis

Acute fatal mycotic pneumonia is a sequel to placental infection with *Mortierella wolfii, the most important cause of mycotic abortion of cattle in New Zealand*. This condition has rarely been reported elsewhere. Acute fibrinonecrotic pneumonia occurs in infected cows within a few days of abortion or parturition, due to extensive hematogenous dissemination of fungi when the placenta detaches. In the acute disease, the lung is diffusely firm, edematous, and red-yellow. Histologic lesions include serofibrinous and suppurative exudate in alveoli, with vascular necrosis, thrombosis, and coagulative ischemic necrosis of lung parenchyma. In the subacute and chronic disease, there is an embolic pattern of multifocal fibrinous and suppurative inflammation. Similar lesions may occur in the spleen. Fungal hyphae are present within the lesions, but may be inconspicuous in chronic lesions. The hyphae are periodic acid–Schiff-positive, nonseptate, branching, and vary from 2 to 12 μm in diameter.

Other fungi such as *Aspergillus*, *Mucor*, and *Rhizopus* are occasional opportunistic invaders of lung, and cause nodules of caseous necrosis or granulomatous inflammation.

Parasitic diseases

Dictyocaulus viviparus

Dictyocaulus viviparus is a common and important cause of respiratory disease in cool, wet, seasonal climates. **Primary infections**, sometimes known as "husk," cause disease in calves during their first grazing season, and occasionally affect mature animals that have not had sufficient exposure to develop immunity. Although clinical disease may develop within 3 weeks of access to infected pastures, it is most common late in the grazing season when calves have been at pasture for 3–5 months. Affected herds usually have high disease prevalence, and mortality rates are variable depending on the degree of pasture contamination. A second manifestation, **reinfection syndrome**, occurs when partially immune adult cattle on endemically infected farms have access to pastures that are contaminated with large numbers of infective larvae. In these herds, there is a high prevalence of coughing, tachypnea, and depression about 2 weeks after exposure. Some animals develop fatal dyspnea without coughing.

D. viviparus, the only adult nematode known to infect the lung of cattle, is a member of the superfamily Trichostrongyloidea, family Dictyocaulidae. *Adult lungworms inhabit the large bronchi*. The eggs are embryonated when laid, and hatch rapidly. First-stage larvae are expelled from the lung by coughing, are swallowed, and then passed in the feces. Further development to infective third-stage larvae occurs on the ground over the next 5–7 days. Larval development is optimal in moist cool conditions; the larvae can develop at temperatures as low as 5°C, and their viability is prolonged at these temperatures. The third-stage larvae are ingested by cattle, penetrate the wall of the intestine, and migrate via the lymphatics to the mesenteric lymph nodes. In the lymph nodes, they molt to form fourth-stage larvae, and then go by way of lymph and blood to enter the lungs about 7 days after infection. Some larvae accidentally take the portal route and are destroyed in the liver, or rarely enter the systemic circulation to cause intrauterine infections in the fetus. The final molt to the fifth-stage larvae occurs in the bronchioles, and adults develop in the larger airways. Eggs are first detectable in feces at 21–30 days after infection; the infection is usually patent for another 1–3 months. However, a few egg-laying adults may persist in some animals over the winter months, and serve as a source of pasture contamination in the following grazing season.

The clinical and pathologic manifestations of *Dictyocaulus* infestation are dependent on the stage of infection, the level of immunity of the host, and the number of invading larvae. *The following description pertains to primary infections of naive animals*; reinfection of partially immune cattle is discussed subsequently. *Lesions differ in the prepatent period, the patent period, and the period of recovery*. During the **prepatent period**, from 7 to 25 days after infection, the principal lesions are eosinophilic bronchiolitis and/or alveolitis in response to the presence of larvae in the alveoli and bronchioles. Clinical signs include coughing and tachypnea, and calves infected with many larvae may die at this stage. Where the larvae emerge from pulmonary capillaries, they cause microscopic foci of necrosis and fibrin exudation, with an alveolar infiltrate of eosinophils and fewer neutrophils, macrophages, and giant cells. Mononuclear cells thicken the alveolar walls, and hyaline membranes or hyperplasia of alveolar type II epithelial cells may occur. The larvae, some of them dead, can be found in the alveoli. When the number of larvae is large, the foci of acute interstitial pneumonia may be visible grossly as lobular or smaller foci that are slightly depressed, purple, and widely distributed throughout the lungs.

By about the tenth day, many of the larvae have reached the terminal bronchioles. Frothy fluid is present in the bronchi and, in very heavy infestations, there is edema, atelectasis, and/or emphysema. Eosinophils invade the septal tissues in large numbers and pursue the larvae into the bronchioles. Most of the bronchioles contain plugs of exudate composed largely of eosinophils. Neutrophils, lymphocytes, and macrophages are present in smaller numbers in both the lumens and walls of the bronchioles. The early bronchiolar epithelial response is of degeneration and sloughing, but subsequently hyperplasia and metaplasia occur. At this stage, adult worms are not present in the airways, but larvae are detectable histologically or in a smear of exudate harvested from the smallest airways.

During the **patent period**, beginning 25 days after infection, the inflammatory response targets adult worms in the bronchi, and eggs and recently hatched first-stage larvae that have been aspirated into the alveoli. At this stage, calves may exhibit chronic coughing, increased respiratory rate, and weight loss, or develop severe dyspnea and death. Adult worms, which are slender, white, and up to 8 cm long, are most numerous in the dorsocaudal bronchi of the caudal lobes (Fig. 5.72). Infections may be missed if only the trachea and large cranial bronchi are examined, as *many infestations are restricted to the small branches of the caudal bronchi*. Patchy lobular atelectasis may be the only other gross finding in mild infestations. In more severe cases, there are wedge-shaped, red-gray, firm, depressed areas of consolidation at the caudal border of the caudal lung (Fig. 5.73). Examination of a cut section may reveal similar areas of consolidation in much of the pulmonary tissue surrounding larger bronchi.

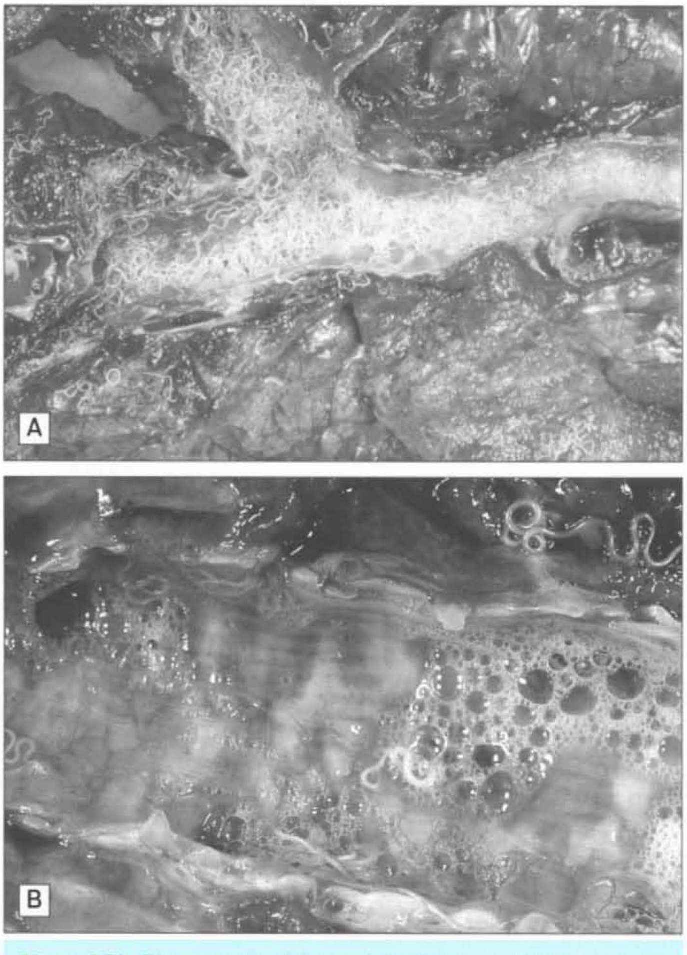

Figure 5.72 ***Dictyocaulus viviparus* infection** in a calf. Worms may be numerous (**A**) or few (**B**) within the frothy or catarrhal exudate in the lumen of caudal bronchi. (Courtesy of EG Clark.)

Histologic lesions in patent infections include eosinophilic catarrhal bronchitis, atelectasis, and eosinophilic granulomatous alveolitis. The bronchi and large bronchioles contain adult worms, eggs, and larvae mixed with mucus and numerous eosinophils. In histologic sections, adult worms have thick intestinal epithelium composed of a few multinucleated cells with indistinct microvilli, prominent lateral chords, and coelomyarian-polymyarian musculature, and the uterus may contain larvae or embryonated eggs. The airway mucosa contains infiltrates of eosinophils and mononuclear cells, the epithelium is hyperplastic and contains increased numbers of goblet cells, and the peribronchial lymphoid tissue is expanded. The accompanying alveolar lesions consist of atelectasis secondary to the obstructive bronchiolitis, and macrophages, giant cells, and lymphocytes encircling fragments of cuticle, aspirated eggs, or newly hatched larvae. It is complicated in some cases by bacterial bronchopneumonia. Alveolar septa are thickened by cellular infiltration, slight fibroplasia, and inconsistent proliferation of type II pneumocytes. At this stage, the infection may be diagnosed by gross observation of adult worms in the bronchi, examination of histologic sections of bronchi and alveoli, identification of all stages in wet mounts of airway mucus, and/or identifying larvae in feces by the Baermann technique.

During the **period of recovery**, *adult worms are eliminated.* However, gross lesions of consolidation may persist, and there is fibrosis of peribronchiolar alveoli with prominent lymphocytic cuffs around bronchi. Establishing a firm diagnosis at this stage may be impossible, as adults are not present and the feces no longer contain larvae. The distribution of lesions in the caudal lung helps to differentiate chronic parasitism from mycoplasmosis, which usually affects the cranioventral areas of lung. Acutely fatal exacerbations of the

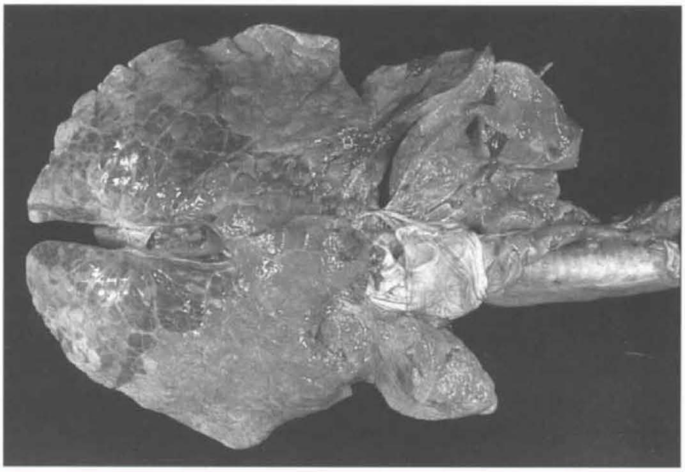

Figure 5.73 ***Dictyocaulus viviparus* infection** in a calf. Patchy areas of consolidation in the caudal lung lobes. (Courtesy of EG Clark.)

disease during the period of recovery, when larvae and adults are no longer present, have been described. These cases may be impossible to differentiate from toxic interstitial pneumonia, but acute exacerbation of a chronic illness is not typical of pulmonary toxicity.

Emphysema may be a prominent gross lesion in severe cases of *Dictyocaulus* infection, and is probably a consequence of forced expiration, due to severe dyspnea, in the presence of bronchiolar obstruction by exudate and bronchoconstriction. Cases in which emphysema is the major lesion at necropsy may be mistaken for acute interstitial pneumonia of toxic cause. This is particularly likely when the pulmonary damage is caused by massive invasion of larvae, and mature worms are not yet present for gross detection. Microscopic detection of larvae and immature worms usually provides the diagnosis.

The typical lesion in the **reinfection syndrome** – where partially immune adult cattle are infected with numerous larvae – are scattered, 2–4 mm diameter, gray nodules that often contain a green caseous center. The nodules represent dense accumulations of lymphocytes and plasma cells, encircling an eosinophilic and granulomatous response to a degenerating larva. As a result of this robust immunoinflammatory response, the larvae do not reach the large airways or develop into adults, and the infection does not usually achieve patency.

Miscellaneous parasites

Ascaris suum larvae are an occasional cause of severe interstitial pneumonia in calves housed in barns where pigs were previously kept. In these situations, infective eggs are ingested, larvae hatch within 18 hours, and migrate to the lungs 5–13 days after infection. The lesions are of severe acute interstitial pneumonia, in which the lungs are diffusely rubbery, wet, and heavy, and interlobular septa are distended with clear fluid. Migration of larvae through the liver may cause white streaks. Histologically, there is alveolar edema and hyaline membranes or type II pneumocyte proliferation, and numerous eosinophils infiltrate alveolar septa and exude into the alveoli. Larvae are readily identified in cases that die about a week after infection, but a diligent search may be required in calves that survive for 2–3 weeks after infection. Larvae cannot be consistently recovered from lung digests. The histologic appearance of the larvae is characteristic: they have lateral alae, large lateral chords, and an intestine (the only internal organ present) composed of few uninucleate cells.

The trematodes ***Fasciola gigantica*** and ***F. hepatica*** occasionally invade the lungs accidentally from the liver. Since they are large parasites which wander extensively, a small number in the lungs can produce extensive cavitations. ***Schistosoma nasalis*** causes nasal granulomas in India. In cattle, lung is less common than liver as a site of hydatid cysts caused by ***Echinococcus granulosus***.

The **leeches** *Limnatis nilotica* and *L. africana* are taken in while drinking and attach to the mucosa of the pharynx and nasopharynx. They suck large quantities of blood, and their presence induces localized edema that leads to dyspnea or asphyxiation. The **nematodes** *Mammomonogamus* (*Syngamus*) *nasicola* and *M. ierei* are found in the nasal passages of ruminants in tropical countries, and *M. laryngeus* causes lymphocytic polypoid hyperplasia in the pharynx and larynx of cattle in tropical Asia and South America.

Infectious respiratory diseases of sheep and goats

Viral diseases

Ovine respiratory syncytial and parainfluenza viruses

Many aspects of the pathogenesis, lesions, and role of these viruses in predisposing to bacterial pneumonia are similar to those described for the bovine viruses. Ruminant respiratory syncytial viruses have been divided into bovine and ovine subgroups based on nucleotide and antigenic differences in the G protein. Sheep are susceptible to infection and disease with both ovine and bovine subgroups, and ovine strains infect cattle and deer.

Adenovirus

Adenoviral infections are common in sheep, but primary adenoviral pneumonia is rare. *Ovine adenovirus* (OAdV) serotype 6 exacerbates disease caused by experimentally inoculated *Mannheimia haemolytica*, and adenoviruses are occasionally isolated from outbreaks of bacterial pneumonia in lambs. These findings suggest that adenoviral infection may predispose to development of bacterial pneumonia in some groups of lambs. Lesions in experimentally infected lambs are similar to those described for calves. A noteworthy feature of the lesions caused by at least one strain of OAdV is the enlargement of both nucleus and cytoplasm of inclusion-bearing bronchiolar and alveolar epithelial cells, which could be mistaken for cytomegalovirus infection. Adenoviruses have been isolated from goats, but their role in causing disease appears minor.

Peste des petits ruminants

Peste-des-petits-ruminants virus (PPRV) (see Vol. 2, Alimentary system) is closely related to *Rinderpest virus* in the genus *Morbillivirus*. Sheep and goats with PPR commonly have clinical signs and lesions affecting the respiratory system, in addition to enteric lesions that resemble those of rinderpest. The gross lesions usually affect the cranioventral lobes of the lung, which are firm, reddened, and may have fibrinous exudate on the pleural surface. Histologic lesions are of *bronchointerstitial pneumonia*, and resemble the lesions of canine distemper, another morbillivirus. There is necrosis and attenuation of epithelial cells lining the trachea, bronchi, and bronchioles; proliferation of alveolar type II pneumocytes; and formation of epithelial syncytia in the alveoli. Infected epithelial cells often contain eosinophilic inclusion bodies in the cytoplasm or the nucleus. As the virus is difficult to isolate in culture, definitive diagnosis depends on immunohistochemistry or serology.

Lentiviral pneumonia: maedi-visna (ovine progressive pneumonia) and caprine arthritis-encephalitis viral pneumonia

Lentiviral infections are common in sheep and goats worldwide, with the exceptions of Iceland, where the disease was eradicated in 1965, and Australia and New Zealand, where ovine lentiviral disease has not been recorded. The seroprevalence varies greatly, for example from 1 to 70% in various areas of the USA. Most infected animals are not clinically ill, and infection may become widespread before diseased animals are noticed. *Lentiviruses cause slowly progressive pneumonia, encephalitis, arthritis, and mastitis; the various syndromes may occur independently or concurrently.* The descriptive terminology of the ovine disease is a colorful consequence of the history of the disease. The respiratory form in sheep, which is termed *maedi* ("dyspnea" in Icelandic) in much of the world and ovine progressive pneumonia in the USA, is the most common presentation, and manifests as inexorably progressive dyspnea, hyperpnea, and weight loss in sheep greater than 3 years of age. Other outcomes in sheep are less frequent and include encephalitis, arthritis, and mastitis. Encephalitis – *visna* ("fading away" in Icelandic) – was common in the original Icelandic description but is now a rare expression of the disease, and results in ataxia, trembling, and profound weight loss. Mastitis and arthritis are uncommon in sheep, and manifest as agalactia and a hard udder, or lameness and swollen joints (particularly carpal joints) respectively.

Caprine arthritis encephalitis virus (CAEV) causes two common clinical diseases. The first, *arthritis in adult goats*, results in acute or chronic lameness and swelling of carpal or tarsal joints. The second manifestation, *neurologic disease* in 2–4-month-old kids or less commonly in older animals, is characterized by progressive ataxia and weakness beginning in the hindlimbs. *Pneumonia*, which is less frequent than arthritis and neurologic disease, may occasionally be the major presenting complaint in kids or adults, or occur concurrently with arthritis or neurologic disease.

Maedi-visna, ovine progressive pneumonia, and CAE are caused by closely related lentiviruses in the family Retroviridae, genus *Lentivirus*; these share more homology with feline immunodeficiency virus than with other lentiviruses. The extreme genetic diversity created by replicative infidelity of the lentiviruses has blurred the concept of distinct viral species: although distinct viral clades can be identified, ovine and caprine isolates are represented in each, and French ovine lentivirus isolates have greater homology to CAEV than to *Visna/maedi virus* (VISNA). These findings suggest interspecies transmission; however, the identification of CAE but not maedi-visna in Australia implies that a species barrier exists for some strains. The comparative phylogeny of small ruminant lentiviruses remains an active area of research.

Small ruminant lentiviruses are enveloped, 100 nm diameter, and contain a dense nucleoid and a positive-sense single-stranded RNA genome. Viral genes include *gag*, which encodes group-specific nucleocapsid and matrix glycoproteins that are detected by antibody-based diagnostic tests; *pol*, which encodes reverse transcriptase and other enzymes; *env*, encoding the surface glycoprotein that mediates receptor binding and virus entry into cells, and is the target for neutralizing antibody; and the regulatory proteins encoded by *vif, rev, and tat*. Long terminal repeats that flank the encoding regions of the genome bind transcription factors and are necessary for replication.

Lentiviral diseases in sheep and goats are marked by their variability. Viral strains or quasispecies may differ in their virulence or their propensity to cause pulmonary, nervous, joint, or mammary disease. Disease manifestation is also influenced by host genetics, as certain breeds of sheep are more susceptible to disease than others. Finally, the local tissue microenvironment affects viral replication and development of disease; for example, proinflammatory cytokines generated in response to concurrent infection with other pathogens augment lentiviral replication and may hasten disease onset.

Transmission of small ruminant lentiviruses through colostrum or milk is the major method of disease spread. Inhalation of nasal secretions following prolonged close contact, as occurs in confined animals in the winter months, is a recognized mode of horizontal transmission. The virus is shed in semen, but infection by coitus or artificial insemination has not been documented. In utero transmission occurs rarely or never. Ovine lentivirus infects a variety of cell types, including choroid plexus epithelium, fibroblasts, endothelial cells, and monocytes. However, viral replication is restricted in these cells, and complete viral replication and assembly only occur in mature macrophages. Viral antigen is widespread, having been detected in lung, bone marrow, mammary gland, lymph node, spleen, synovium, brain, and spinal cord of sheep with maedi, and is most abundant in areas of lymphocytic inflammation. Similarly, viral nucleic acid is demonstrable in lung, liver, spleen, lymph nodes, brain, synovium, intestine, kidney, and thyroid gland of goats with CAE.

In contrast to primate and feline lentiviruses, *immunosuppression is not a feature of small ruminant lentiviral infection. Infection and shedding of the virus persist for life*, but the disease in sheep develops slowly and the incubation period usually exceeds 2 years. The mechanisms of persistent lentiviral infection are not clear, but may include proviral integration, lack of avidity of neutralizing antibody, or decoy viral antigens that are immunodominant but nonneutralizing. Integration of provirus into the host genome is a necessary feature for viral replication, occurs increasingly as the disease progresses, and may facilitate persistence of the virus. The development of serum neutralizing antibody responses during persistent infection is perplexing; the higher affinity of virus for macrophage receptors than for antibody has been suggested as a reason for failure of these antibodies to prevent cell-to-cell spread of infection in vivo.

The pathogenesis of the inflammatory infiltrates characteristic of small ruminant lentiviral infections requires further study. Infection of alveolar macrophages triggers production of proinflammatory cytokines that presumably directly or indirectly recruit and activate leukocytes in the area of infection, and may also incite fibrosis or smooth-muscle hyperplasia. Cytokine-dependent activation of macrophages stimulates lentiviral replication, which may in turn stimulate additional leukocyte recruitment. Whether lentiviral infection contributes directly to altered organ function, or whether this is an exclusive sequel to the immunoinflammatory response, remains enigmatic.

The lungs of **sheep** with maedi are remarkably heavy, pale gray or tan, and fail to collapse when the chest is opened. The lesions are generalized but most obvious in the caudal lobes, and vary from a diffusely firm or rubbery texture, to multiple coalescing gray and firm foci (Fig. 5.74). Mediastinal and bronchial lymph nodes are enlarged, white, and edematous. Lesions of cranioventral bronchopneumonia caused by *Pasteurella multocida* or *Arcanobacterium pyogenes* are commonly superimposed on the lesions of maedi. Lungworms – *Dictyocaulus* or *Protostrongylus* – are common in sheep with maedi, and an association between maedi and retroviral pulmonary adenomatosis has been described.

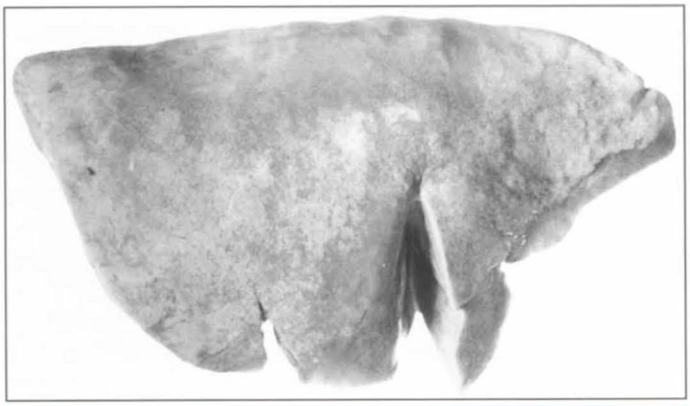

Figure 5.74 Maedi in a sheep. The lungs failed to collapse and have widespread gray-white mottled pallor.

The histologic pulmonary lesions are of interstitial pneumonia. Infiltrates of lymphocytes, plasma cells, and macrophages thicken alveolar septa and form cuffs around blood vessels and airways. The tendency for these cellular infiltrates to form *lymphoid nodules with germinal centers* is a characteristic feature of maedi. In addition to the cellular infiltrate, alveolar septa are thickened by *hypertrophy of smooth muscle* and by *mild interstitial fibrosis* (Fig. 5.75). Hyperplasia of type II pneumocytes is not prominent, in contrast to pulmonary adenomatosis and CAE viral pneumonia. Mild hyperplasia of bronchiolar epithelium is occasionally present.

Mastitis is an uncommon clinical presentation of VISNA infection, but is a frequent subclinical lesion. There is diffuse firmness and pallor of the mammary gland, and histologic lesions include follicular aggregates of lymphocytes, plasma cells, and macrophages in the mammary interstitium. Similarly, although clinical neurologic disease typical of visna is rare, histologic lesions of lymphocytic leukoencephalomyelitis, gliosis, demyelination, and meningitis are occasionally encountered in sheep with maedi, and tend to be most severe adjacent to the ependyma. Mesangial or proliferative glomerulonephritis is an uncommon lesion in VISNA-infected sheep.

The lung lesions of **goats** infected with CAEV are distinctive. The gross appearance is of multifocal coalescing pale firm foci throughout the lung. Histologically, these foci are abruptly demarcated from relatively unaffected areas of lung. In the lesional areas, alveoli are filled with densely eosinophilic fluid and lined by a continuous or patchy layer of cuboidal type II pneumocytes, and alveolar septa are thickened by lymphocytes.

Goats with *arthritis* due to CAEV commonly have unilateral or bilateral carpal lesions, but tarsal, fetlock, stifle, and atlanto-occipital joints may be affected. Histologic lesions include striking villus hyperplasia of the synovium, and synovial infiltrates of lymphocytes, plasma cells, and macrophages. Fibrosis, mineralization, and necrosis of synovium and joint capsule develop in chronically affected animals. The brain and mammary lesions of CAE are similar to those of sheep with maedi.

Serology has long been the mainstay of confirming a morphologic **diagnosis** of maedi, but is subject to several caveats. First, because the prevalence of infection is up to 90% in some geographic areas, serology may be more useful as a tool to detect infected flocks than to diagnose the cause of a respiratory disease problem. Second, although infection is lifelong, infected animals may become transiently seronegative, resulting in false-negative tests. Third, recently infected sheep may be seronegative, for development of an antibody titer may take several months. The agar gel immunodiffusion test is most commonly used, and has a sensitivity of 100% and specificity of 81% compared to the "gold standard" immunoprecipitation test. Recently developed enzyme-linked immunosorbent assays (ELISAs) have greater sensitivity, require less laboratory expertise, and may be more economical.

Assays that detect viral antigen or nucleic acid in tissues have been more recently developed for both maedi and CAE. Immunohistochemistry, using a panel of monoclonal antibodies to detect antigenic variants, has the advantage of associating the presence of viral antigen with the histologic lesion, but reagents are not yet widely available. In situ hybridization is a highly sensitive technique that also associates lesions with viral nucleic acid, but the cost and limited availability restrict its use as a diagnostic tool. Polymerase chain reaction (PCR) appears to be a promising method to detect proviral DNA or viral

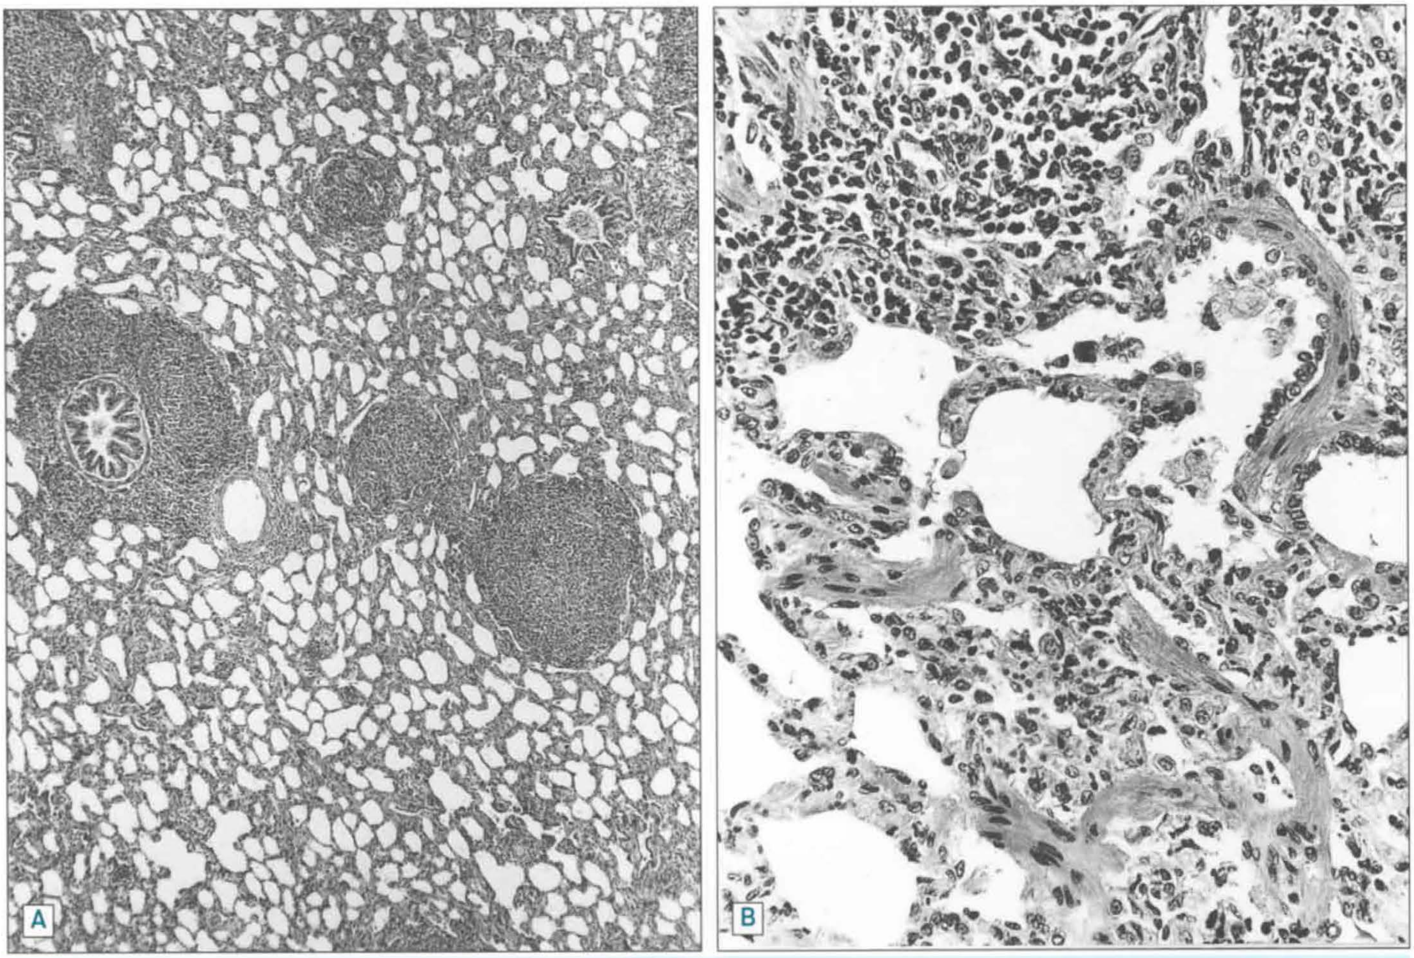

Figure 5.75 Maedi in a sheep. **A.** Prominent accumulations of lymphocytes around blood vessels and airways, with diffuse thickening of alveolar walls. **B.** Hyperplasia of smooth muscle of terminal bronchioles and alveolar septa.

RNA in blood mononuclear cells or lung tissue. Virus isolation from explant cultures of spleen, lung, or lymph nodes is as sensitive as current PCR assays, but is more costly and time-consuming.

Enzootic nasal tumor of sheep

Viral adenomas and carcinomas of the nasal cavity of sheep and goats are geographically widespread, but absent from Australia and New Zealand, and there are regions with greater prevalence, including sheep in the USA, Canada, France, Germany, and Spain, and goats in India, Spain, and France. The disease may be enzootic, with multiple animals affected in certain flocks. Clinical disease typically arises in adult sheep and goats, but lambs as young as 6 months have been affected. Clinical signs are insidious, progressive, and may include stertor, inspiratory dyspnea, open-mouth breathing, nasal discharge, nasal deformity, and weight loss.

Enzootic nasal adenoma and carcinoma are associated with and probably caused by a betaretrovirus, named "Enzootic nasal tumor virus" (ENTV-1 from sheep, ENTV-2 from goats), which is closely related to, but distinct from Ovine pulmonary adenocarcinoma virus. The disease has been transmitted to neonatal goats using cell-free nasal fluids from affected goats or preparations of concentrated virus, with an incubation period of

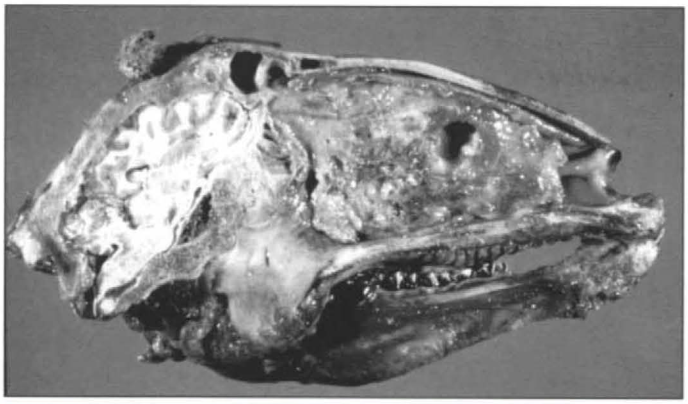

Figure 5.76 Enzootic nasal tumor in a sheep. A fleshy white tumor originating in the ethmoid region fills the nasal cavity.

12–24 months. The presence of multiple affected animals in some flocks suggests that the disease is contagious, presumably by contact with nasal secretions. The mechanisms whereby infection with ENTV leads to neoplasia have not been defined.

Tumors may be unilateral or bilateral and *usually originate from the ethmoid turbinates*, but fill much of the caudal nasal cavity before severe clinical signs develop (Fig. 5.76). In protracted unilateral cases, the entire nasal cavity is occluded by tumor, there is deviation of the nasal septum, and tumor may protrude from the nostril. Expansion into sinuses, contralateral nasal cavity, pharynx, or cranial vault may occur, but metastasis is rare. The neoplastic tissue is white, firm, and multinodular, or may contain brown-red areas of hemorrhage and necrosis.

The histologic appearance is of adenoma or low-grade adenocarcinoma. The cuboidal or pseudostratified nonciliated epithelial cells form orderly tubular, papillary, or acinar arrangements. Neoplastic cells have basal round nuclei and a variable mitotic rate. Mucus secretion is occasionally abundant, and the fibrovascular stroma is usually scant. Neoplastic tissue and adjacent nonneoplastic tissues often contain numerous lymphocytes, and glandular hyperplasia or polyps may be present.

The diagnosis is usually based on gross and histologic findings. Sporadic (nonviral) nasal tumors are apparently rare in small ruminants. Extracellular or budding retroviral particles may be demonstrated in neoplastic tissue by electron microscopy in 75–100% of cases. Other diagnostic methods include polymerase chain reaction and Western blot of neoplastic tissue.

Ovine pulmonary adenocarcinoma (jaagsiekte)

Ovine pulmonary adenocarcinoma (OPA), also known as jaagsiekte or ovine pulmonary adenomatosis, is a contagious retroviral bronchioloalveolar carcinoma of sheep, and may rarely affect goats. The disease is common in South America, South Africa, and Scotland, where 5–20% of necropsy cases contain pulmonary tumors. OPA occurs regularly in the rest of Europe, Africa, and Asia, but is rare in North America and not reported in Australia. Mortality rates tend to increase gradually for several years following introduction of infection, and subsequently decline gradually. Clinical disease is most common in 2–4-year-old sheep, but 3-month-old lambs have also been affected. Clinical signs include progressive dyspnea, tachypnea, exercise intolerance, nasal discharge, coughing, and weight loss; fever and anorexia are unusual unless secondary infections occur. Drainage of lung fluids from the nose following elevation of the hindlimbs is a characteristic clinical sign seen in some sheep.

Ovine pulmonary adenocarcinoma virus (OPAV; Jaagsiekte sheep retrovirus), the agent of OPA, is a 100 nm diameter, enveloped, betaretrovirus. The following arguments support the role of OPAV as the etiology: OPAV is consistently present in neoplastic cells but not in nonneoplastic epithelium or stroma, the disease can be reproduced with cell-free OPAV-containing filtrates of tumor tissue, and the incubation period is dependent on the amount of retroviral reverse transcriptase in the experimental inoculum. However, defining the exact role of OPAV in disease development is impeded by the inability to isolate OPAV in cell culture without the use of tumor-derived cells, by the presence of closely related endogenous retroviral proviral sequences that are common in neoplastic and nonneoplastic tissue of affected and normal sheep, and by the occasional, albeit inconsistent, isolation of other viruses from tumors.

Many aspects of the pathogenesis of OPA remain nebulous. The disease is presumably acquired by direct contact with infected nasal secretions. The typical incubation period has been estimated to be 2 years, but is age- and dose-dependent; tumors may develop in 10–20 days if high doses of virus are administered experimentally to neonatal lambs. Disease is more common in certain breeds of sheep, but the reasons for this familial predisposition are unknown. Oncogenes have not been identified in OPAV, but the envelope protein is sufficient to induce similar tumors in immunodeficient mice, and is the likely mechanism of tumor formation in sheep. Acquired resistance to disease has been identified in endemically infected flocks, and this disease resistance has been attributed to immunotolerance as a result of expression of related endogenous retroviruses.

Lungs of sheep with OPA contain multiple, firm, raised, gray or white, moist masses in the cranial and middle lung lobes, with less extensive involvement of caudal lobes (Fig. 5.77). Affected lungs are heavy, up to three times their normal weight, and airways are filled with foamy secretion from the neoplastic cells. The tumors are expansile, do not commonly form intrapulmonary metastases, and metastases to regional lymph nodes are present in fewer than 10% of cases. Maedi and/or bacterial pneumonia are often present in sheep with OPA, and the diffuse lymphocytic interstitial pneumonia or cranioventral suppurative bronchopneumonia induced by these diseases may complicate the gross and histologic appearance of the tumors.

The histologic appearance is of a well-differentiated bronchioloalveolar carcinoma. Within the neoplastic masses, the alveolar architecture remains, but alveoli are lined by cuboidal or columnar neoplastic epithelial cells (Fig. 5.78). Proliferation of neoplastic cells results in papillary or acinar structures filling alveoli and obscuring their outline. Alveoli adjacent to the tumors are atelectatic and contain many macrophages, and interstitial fibrosis may be present in advanced cases. Neoplastic cells exhibit ultrastructural features of type II pneumocytes, including cytoplasmic lamellar bodies and surface microvilli; less commonly, the presence of dense core granules suggests a Clara cell phenotype.

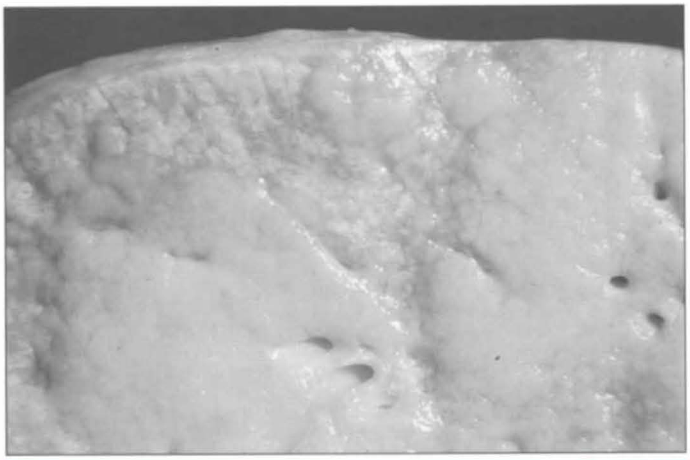

Figure 5.77 Ovine pulmonary adenocarcinoma (jaagsiekte) in a sheep. The lung contains irregularly sized, coalescing, bulging, white nodules.

The pulmonary lesions of OPA are characteristic, as spontaneous or noninfectious bronchioloalveolar carcinoma is rare in sheep. The disease may be confused with proliferative interstitial pneumonia, which may occasionally be multifocal rather than diffuse. Serologic tests are not sensitive, for antibody responses to the virus are minimal. A polymerase chain reaction assay appears promising as a method of confirming infection, and is able to differentiate OPAV from endogenous sheep retroviral sequences and *Enzootic nasal tumor virus*. Interpretation may be complicated by a high prevalence of infection in endemic areas. The assay would be of particular use in confirming the disease in geographic areas where jaagsiekte is rare, and in identification of infected sheep as a method of developing disease-free flocks.

Bacterial pneumonia

Bacterial pneumonia in sheep is caused by *Mannheimia haemolytica*, *Pasteurella multocida*, or *Histophilus somni (Haemophilus agni)*. *M. haemolytica* can also cause septicemia in the absence of pneumonia in lambs less than 2 months of age. The causative agents, predisposing factors, and pathogenesis are in many respects similar to those described in cattle. Sudden climatic changes, gathering and handling, and predisposing infection with *Mycoplasma* spp., *Ovine* or *Bovine respiratory syncytial virus, Bovine parainfluenza virus 3*, or adenovirus are the most commonly recognized predisposing causes. The lesions are of hemorrhagic or fibrinonecrotic, lobar or lobular bronchopneumonia and serofibrinous pleuritis in acute cases, and fibrinopurulent bronchopneumonia leading to abscessation and fibrous pleural adhesions in subacute to chronic cases.

M. haemolytica causes sporadic cases and small outbreaks of acute pneumonia and pleuritis in goat kids. The disease usually occurs as a peracute disease in late autumn and winter. At necropsy, a sheet of yellow fibrin adheres loosely to the pleural surfaces. The cranial lobes of the lungs are firm and dark red with a transition to less-firm tissue with mottled gray-pink discoloration in the caudal lobes. Acute diffuse bronchopneumonia is characterized microscopically by neutrophils, protein-rich exudate, and numerous bacteria filling bronchioles and alveoli. There is usually little evidence of necrosis. In the caudal lobes, neutrophils fill the bronchioles and extend into the alveoli.

Septicemic pasteurellosis

Septicemia caused by *Pasteurella trehalosi* (formerly *P. haemolytica*, biotype T) occurs mainly in weaned lambs during the fall months, but it can occur in other age groups and at other times of the year. Deaths, which seldom exceed 5% of the sheep at risk, usually follow within a few days of changes in pasture, feed, or other management practices.

Signs of illness are vague and the usual course is short, or lambs may be found dead with no opportunity to exhibit clinical signs. At necropsy, *petechial and ecchymotic hemorrhages* are usually present in subcutaneous tissues, particularly of the neck and thorax, in intermuscular fascia, and in the pleura, epicardium, and mesentery. Retropharyngeal and mesenteric lymph nodes are hemorrhagic and edematous. *Ulcerative lesions* covered by yellow plaques of fibrin and necrotic debris are common on the tongue, pharynx in the area of tonsillar crypts, larynx, and esophagus. The abomasal, intestinal and colonic mucosae occasionally have shallow ulcers (Fig. 5.79). The lungs are diffusely congested and edematous. *Multifocal hemorrhagic infarcts may be scattered throughout the lungs*, and the liver may contain pinpoint to 1 cm diameter yellow necrotic foci. There is occasionally inflammation of joints, pericardium, meninges, and choroid plexus, but these lesions are absent in peracute cases.

Microscopic examination of tissues reveals *widespread bacterial embolism*. Multifocal pulmonary lesions consist of masses of bacteria occluding capillaries, accompanied by hemorrhagic and fibrinous exudate into alveoli. A peripheral zone of necrotic leukocytes may be present. The pale hepatic foci consist of colonies of bacteria with a surrounding zone of ischemic necrosis. There may be thrombosis of the adjacent tributaries of the portal vein and small amounts of parenchymal necrosis, but the leukocyte response is generally slight. This is probably related to the short course of the disease and perhaps to the effects of bacterial toxin on leukocytes. Bacterial emboli are regularly found in the spleen and adrenals, occasionally in the kidney, but are rare in other organs. Masses of bacteria adhere to the surface of the pharyngeal ulcers and occlude underlying blood vessels and lymphatics, and probably represent the *principal site of bacterial proliferation and systemic invasion.*

Melioidosis

Melioidosis is a systemic infectious disease affecting a wide range of animal species in tropical climates. The disease is endemic in southeast Asia and northern Australia, is probably common in the Indian subcontinent and the Caribbean, and also occurs in southern Africa and the Middle East. The prevalence is highest in wet seasons, and causes acute outbreaks or chronic endemic disease. Clinical signs are variable and reflect the range of organs affected, and case fatality rates are high. Melioidosis is most common in goats, sheep, pigs, and rodents, and is an emerging tropical disease of humans. Horses, deer, camels, and laboratory animals are less commonly affected, while dogs, cats, cattle, water buffalo, and fowl are resistant to the disease unless they are immunosuppressed.

Melioidosis is caused by *Burkholderia (Pseudomonas) pseudomallei*, a facultatively anaerobic gram-negative bipolar-staining bacillus. Infection is acquired from contaminated soil or water, by inhalation, ingestion, or inoculation of cutaneous wounds. *Acute disease*, most common in young animals, may initially affect the lungs with later spread to other organs, or be primarily septicemic from the site of inoculation. *Chronic disease* is the more frequent manifestation, in which abscesses in multiple organs cause chronic nonspecific illness or are an incidental finding of public health importance at slaughter.

Virulence factors of *B. pseudomallei* include the iron-scavenging protein malleobactin, secreted proteases that degrade host tissues, capsular polysaccharide that confers resistance to killing by phagocytes, lipopolysaccharides, and an endotoxin-derived polysaccharide that allows serum resistance. The bacterium survives within

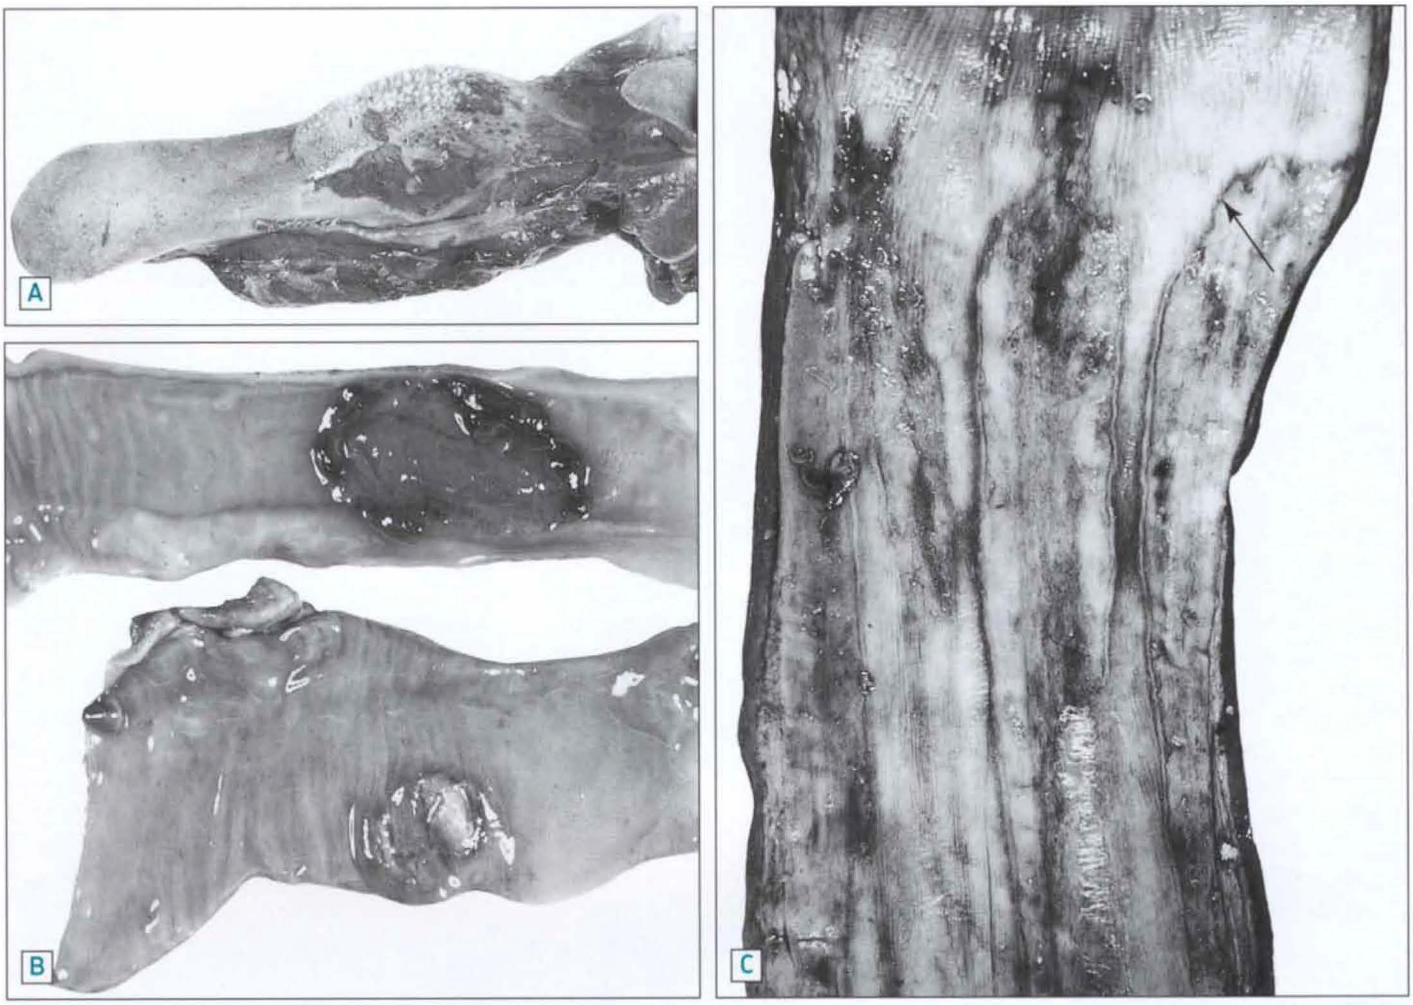

Figure 5.79 ***Pasteurella trehalosi* septicemia** in a lamb. **A.** Ulceration of tongue. **B.** Ulceration of intestine. **C.** Ulceration of esophagus. Only small areas of intact esophageal epithelium remain (arrow).

macrophage phagolysosomes and elicits a granulomatous and suppurative tissue reaction. The bacterial antigens that confer protective immunity are of current interest to human vaccine production; preliminary evidence suggests flagellar proteins and O-polysaccharides as promising targets of protective immune responses.

Melioidosis causes abscesses in multiple organs. The lungs are most consistently affected, with disseminated coalescing nodules, or locally extensive areas of consolidation. Abscesses also affect the spleen, liver, lymph nodes, kidney, or joints, and may occur in any visceral tissue (Fig. 5.80). Lesions are particularly widespread in goats, and may include mastitis or aortic aneurysm. Neurologic disease is most common in goats; gross lesions are rare, but multifocal aggregates of neutrophils and lymphocytic perivascular cuffs are present in the brainstem and spinal cord. Nodular lesions in the nasal mucosa may be mistaken for glanders. Endometritis and placentitis are important manifestations in cattle.

The abscesses of melioidosis are not distinctive in their appearance. *The chronic lesions are encapsulated nodular masses, up to 5 cm diameter, with creamy or caseous yellow centers.* Multifocal aggregates of neutrophils form within 12 hours of infection. Granulomas, present by 3 days, form nodular aggregates of epithelioid macrophages and lymphocytes, and these develop central areas of caseous necrosis and neutrophil infiltration.

The gross and histologic appearance of melioidosis is not pathognomonic. Caseous lymphadenitis, glanders, and abscesses caused by other bacteria may have a similar appearance, and the brain lesions may be mistaken for listeriosis. A tentative diagnosis may be based on identifying gram-negative bipolar-staining bacilli in sections or tissue smears, but *definitive diagnosis requires culture.*

Chlamydial diseases

Intratracheal challenge of lambs with *Chlamydophila psittaci* induces mild infiltration of neutrophils and macrophages into alveoli and alveolar septa, and mild proliferative alveolitis. Lesions were most prominent adjacent to terminal bronchioles. Moderately sized cuffs of lymphocytes are present around bronchioles and small blood vessels at the height of the lesion. The chlamydiae are mostly destroyed during the acute phase of inflammation, which then subsides. Resolution can

be complete within 3–4 weeks of experimental infection. Chlamydiae may contribute to some cases of enzootic pneumonia in lambs and calves, in combination with other agents, but are probably of *limited importance as primary pulmonary pathogens.*

Mycoplasmal diseases

Contagious caprine pleuropneumonia

Contagious caprine pleuropneumonia (CCPP) was first described in Africa in the late 1800s and remains an important disease in northern and western Africa, the Middle East, and the Indian subcontinent. The difficulty in isolating the causative agent in culture caused much confusion in the early literature, but CCPP is now defined as a specific disease of goats caused by *Mycoplasma capricolum* ssp. *capripneumoniae*. Although other mycoplasmas may cause similar lesions, these are not considered CCPP. Classical CCPP caused massive outbreaks with high morbidity and mortality in naive goats of all ages. *Currently, CCPP, an OIE list B disease, causes endemic sporadic disease in some countries and intermittent epizootics in others.* Affected goats are lethargic, dyspneic, and febrile, have bouts of coughing, but may continue to eat. Young goats may be lame due to polyarthritis.

Mycoplasma capricolum ssp. *capripneumoniae* (formerly *Mycoplasma* F38) is phylogenetically related to, but distinct from, *M. mycoides*. The virulence factors of this pathogen have not been well defined. Subclinical carriers are important sources of infection, and are the usual source of introduction of the disease into naive herds. Stress may trigger shedding of organisms from subclinically infected animals. Individual goats are infected by inhalation of droplets through close contact with coughing goats. The infection is restricted to the respiratory tract, and does not cause disease in species other than goats.

Pulmonary lesions are often unilateral but may be bilateral. The pleura is covered by a thick layer of fibrin, and serous fluid fills the pleural cavity. Lobular areas of consolidation and purple-gray discoloration are present in the lung, either diffusely or forming focal lesions, and these may contain extensive areas of necrosis or have a dry granular texture. Fibrinous pericarditis is common. Chronic cases develop focal nodules of necrosis and mineralization with a fibrous capsule, or lung abscesses if secondary bacterial infection develops. However, in contrast to contagious bovine pleuropneumonia, *sequestra and interlobular edema are not features of the caprine disease.* Histologically, the exudate in alveoli and interlobular septa varies from serofibrinous to fibrinopurulent. Thrombosis and vasculitis are often present. With time, the fibrinous exudates organize to form a mass of fibrous tissue.

Gross lesions are suggestive, but not diagnostic. Other mycoplasmas – particularly *M. mycoides* ssp. *mycoides* (large colony type), and *M. mycoides* ssp. *capri* – may cause epidemics with similar lung lesions. Features that suggest CCPP rather than other mycoplasmas include the absence of interlobular edema and inflammation, and the absence of mastitis, arthritis, or keratitis. Laboratory examination is required for definitive diagnosis.

M. capricolum ssp. *capripneumoniae* is an extremely difficult organism to propagate in culture, although it can often be recovered from the pleural fluid and consolidated lung of acutely ill animals. Improved isolation techniques are under development, and culture remains the gold standard for regulatory purposes. Detecting mycoplasmal nucleic acid using the polymerase chain reaction on samples of pleural fluid is a more rapid and sensitive method of diagnosis. A latex agglutination test is an effective method of serodiagnosis.

Other mycoplasmal pneumonias

Many mycoplasmas cause disease in sheep and goats throughout the world, including *M. mycoides* ssp. *mycoides* large colony type (LC), *M. mycoides* ssp. *capri*, *M. capricolum* ssp. *capricolum*, *M. putrefaciens*, *M. agalactiae*, and *M. ovipneumoniae*. *M. capricolum* ssp. *capripneumoniae*, the cause of contagious caprine pleuropneumonia (CCPP), is discussed above. *M. agalactiae* causes contagious agalactia of sheep and goats, but may also induce respiratory disease. Minimally pathogenic mycoplasmas in small ruminants include *M. arginini*, *M. auris*, *M. cottewi*, and *M. yeatsii*. Transmission requires close contact with infected animals. Young animals are often infected by ingestion or inhalation of contaminated milk.

These agents cause a diverse spectrum of clinical signs and lesions. *Mastitis and agalactia are common in adults, and may be accompanied by arthritis or keratitis. Kids and lambs more commonly develop pneumonia or pleuropneumonia, fibrinopurulent polyarthritis, or septicemia with fibrinous polyserositis and interstitial pneumonia.* The lung lesions may resemble those described above for CCPP, but thickening of interlobular septa by edema and fibrin exudation is not typically present in CCPP. *M. mycoides* ssp. *mycoides* LC is particularly capable of causing pleuropneumonia, polyarthritis, and septicemia in goat kids and to a lesser extent in lambs; the worldwide distribution of this pathogen is in contrast to those of contagious caprine and bovine pleuropneumonia. *M. capricolum* principally causes fibrinopurulent polyarthritis in kids, but may also cause septicemia in kids and mastitis in does.

Mycoplasma infections contribute to some cases of *enzootic pneumonia in lambs and kids*. Although the strains of mycoplasma isolated from these animals may not be highly pathogenic, the additional contributions of stress, poor air quality, adverse weather conditions, respiratory syncytial or parainfluenza viral infections, and secondary bacterial pneumonia combine to cause disease. Consolidation and rubbery texture of the cranioventral lung are typical gross features. Histologic lesions of catarrhal bronchitis and bronchiolitis with prominent lymphocyte infiltration in and around small airways should suggest the presence of mycoplasmas, but *diagnosis requires culture of lesional lung tissue*.

Parasitic diseases

Oestrus ovis

Oestrus ovis adult flies deposit first-stage larvae on the nares. The larvae molt twice as they *migrate through the nasal passages*. Larvae may become incarcerated in sinuses or recesses of turbinates as they grow, and eventually die there. Development in the nasal passages can take up to 10 months, although larvae deposited early in summer are able to mature in that season. The full-grown larvae are about 3 cm long, with black oral hooks, dorsal dark transverse bands, and ventral rows of small spines. Pupation occurs on the ground.

The larvae attach to the mucous membrane by their mouthparts. They produce mucosal defects at the points of attachment and, since the cuticle is spinous, cause irritation as they wander. An immune response against excreted or secreted larval antigens, and the ensuing eosinophil and mast cell response, may also contribute to nasal inflammation and irritation. Affected sheep develop catarrhal rhinitis and sinusitis. Apart from persistent annoyance and the debility that this may cause, *there are seldom untoward effects of the parasitism*. Rarely, larvae penetrate the cranial cavity, or secondary bacterial infections spread from the olfactory mucosa to the meninges. Mild infestations of *O. ovis* occur in goats and dogs, as well as conjunctival infections in humans.

Muellerius capillaris

Muellerius capillaris is the most common and ubiquitous lungworm of sheep and goats (Table 5.8). There is usually no clinical evidence of respiratory disease in sheep, although experimental infections may cause hyperpnea, impaired pulmonary gas exchange, and reduced weight gains. Heavy infestations are purported to predispose to bacterial and viral infections of the lung.

Muellerius capillaris, also known as the *small lungworm of sheep and goats*, is a nematode of the superfamily Metastrongyloidea, family Protostrongylidae. Adults, which are 12–24 mm long and thread-like, live in nodular lesions in the alveoli and rarely in bronchioles, but are usually not visible at necropsy. Eggs are laid and rapidly hatch, and first-stage larvae are coughed up, swallowed, and passed in the feces. In

Table 5.8 Major lungworms of sheep and goats

Lungworm	Gross features	Histologic features
Muellerius capillaris	Pale nodules Worms are microscopic	Adults and larvae mainly in alveoli Alveolar fibrosis ± granulomatous inflammation
Cystocaulus ocreatus	Dark nodules Hair-like worms	Adults and larvae in alveoli and ***small*** bronchioles
Dictyocaulus filaria	Focal atelectasis or consolidation ± emphysema Thread-like worms in bronchi	Bronchi and ***large*** bronchioles contain adult worms. Lymphoplasmacytic or eosinophilic inflammation, and smooth muscle and epithelial hyperplasia
Protostrongylus rufescens and *Neostrongylus linearis*	Angular nodules Adults grossly visible in parenchyma and smallest bronchi	Adults in ***terminal*** bronchioles Granulomatous and/or eosinophilic bronchiolitis, with prominent peribronchiolar lymphofollicular cuffs

some cases, each nodule in the lung may contain adult worms of only one sex. The infection in such cases is sterile, and larvae will not be detected in feces. The intermediate hosts are various slugs and snails. The infective stage is reached after two molts in the intermediate host, and the life cycle is completed when sheep and goats swallow the intermediate hosts. The larvae migrate to the lungs, presumably via the lymphatics, and break out into the alveoli. As a consequence of this type of life cycle, infections are gradually acquired, and large worm burdens are seldom observed in animals <6 months of age. On the other hand, heavy infections are not common in old sheep and goats, as repeatedly infected animals become resistant.

The characteristic finding is multiple, 1–20 mm diameter (usually 2–4 mm), subpleural nodules in the dorsal regions of the caudal lobes (Fig. 5.81). However, they may occur anywhere in the lung, and occasionally in the regional lymph nodes. The nodules are soft and hemorrhagic in the acute stages, corresponding to histologic lesions of hemorrhage and eosinophil infiltration. However, most necropsy cases represent chronic infestations with raised gray-pink or yellow nodules that may mineralize.

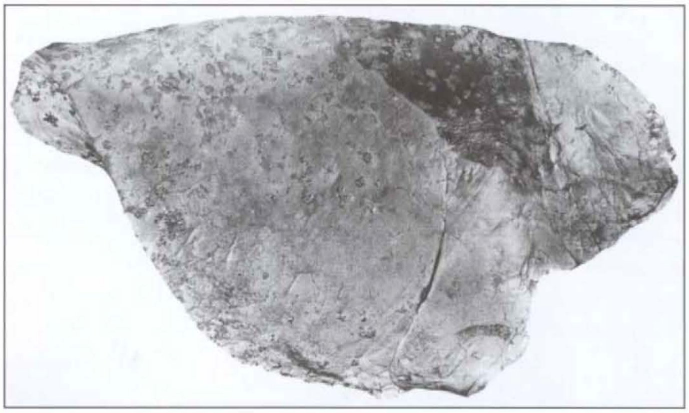

Figure 5.81 ***Muellerius capillaris* infection** in a sheep. Multifocal subpleural nodules of interstitial pneumonia, mainly in the dorsocaudal aspects of the lung.

The nodules are formed by masses of adult worms, embryonated eggs, and coiled larvae. The adults have polymyarian-coelomyarian musculature, the intestine is composed of few multinucleate cells with an indistinct brush border, and the uteri often contain embryonated eggs or larvae. The inflammatory response is often minimal, although alveolar septa may be thickened by fibrous tissue, lymphocytes, and smooth-muscle hyperplasia. In older animals or chronic infestations, presumably associated with developing resistance, the cellular reaction is more marked and targets the first-stage larvae and adults. Eosinophils aggregate around the larvae; the alveolar spaces contain macrophages, eosinophils, and giant cells. Larvae that escape into small bronchioles are enclosed in plugs of mucus and cellular debris. When larvae leave the nodules, the cellular reaction subsides, but thickening of the alveolar septa persists because of patchy or diffuse fibrosis. Adult worms incite a similar reaction of eosinophils, macrophages, and giant cells. *The cellular debris becomes mineralized, particularly when the worms die, and these mineralized nodules persist indefinitely as spherical masses of calcium salts surrounded by a fibrous capsule.*

The gross appearance of *Muellerius* infestation can closely resemble that of ***Cystocaulus***. However, the nodules of *Cystocaulus* are darker and may be larger than those of *Muellerius*, the adult worms may be grossly visible, and bronchial epithelial hyperplasia is more likely in *Cystocaulus* infestation. In ***Dictyocaulus*** and ***Protostrongylus*** infections, the adult worms are located in large bronchioles/bronchi and the terminal bronchioles, respectively.

Muellerius infestation in **goats** has been associated with severe diffuse interstitial pneumonia in the absence of nodular lesions. Histologic lesions included diffuse thickening of alveolar septa with mononuclear cells, and fibromuscular hyperplasia in alveolar septa; but the possibility that these lesions might have been caused by *Caprine arthritis encephalitis virus* or *Mycoplasma* infection cannot be ruled out.

Protostrongylus rufescens

Protostrongylus rufescens is a nematode of the superfamily Metastrongyloidea, family Protostrongylidae that infects sheep, goats, and deer. The adults are 16–35 mm in length, red, and mainly inhabit the terminal bronchioles. Eggs hatch to first-stage larvae in the lung, and are passed in the feces. They enter intermediate hosts, which are various genera of terrestrial snails, by boring through the foot. Two molts occur in the snail and the infective third-stage larvae develop in 46–49 days. Sheep and goats eating the snails are infected by the larvae, which pass by way of the mesenteric lymphatics to the lungs.

Lesions consist of 2–4 cm diameter, angular, firm, tan, nodules distributed throughout the lungs. The nodules are usually soft, in contrast to the firm texture of *Muellerius* nodules. Cross-sections may reveal fine white worms exuding from the parenchyma or occasionally leading to a small bronchus. Histologically, an eosinophil inflammatory reaction targets adult worms, larvae, and eggs in the terminal bronchioles. Prominent lymphofollicular aggregates surround these airways. Smooth-muscle hyperplasia is not a feature of *Protostrongylus* infestation.

Dictyocaulus filaria

Dictyocaulus filaria, the *large lungworm of sheep and goats*, is a slender, white, 3–10 cm long nematode that inhabits mainly the small bronchi. The life cycle and lesions are similar to those described for *D. viviparus*, which is described in detail with respiratory diseases of cattle. The lesions are localized, 3–4 cm diameter areas of atelectasis or consolidation that are most common in the dorsal aspects of the caudal lobes. Bronchi are prominently thickened by smooth muscle and cuffs of lymphocytes and granulocytes, and often contain adult thread-like worms. A granulomatous alveolar reaction to aspirated eggs may occur.

Bibliography

Miscellaneous parasites

Neostrongylus linearis, a comparable nematode to *Protostrongylus rufescens*, is common in western Europe, the Middle East, and probably elsewhere. The adults are 5–15 mm long, and terrestrial gastropods are the intermediate hosts. The worms are contained within 1–4 mm diameter, red-violet or gray-pink nodules that are most numerous in the caudal lobes.

Cystocaulus ocreatus (*C. nigrescens*) reside in 5–20 mm diameter, dark, firm nodules in the dorsocaudal lung. Cross-sections may reveal brown-black hair-like worms, which move when the lung section is immersed in saline. The life cycle resembles that of *Muellerius*.

Mammomonogamus (*Syngamus*) ***nasicola*** and *M. laryngeus* are nematodes of the nasal cavity and larynx. ***Schistosoma nasalis*** causes nasal granuloma in India. ***Habronema*** spp. is a rare cause of fibrotic nodules adjacent to bronchioles. In sheep, the lung is a common site of hydatid cysts caused by ***Echinococcus granulosus***.

Infectious respiratory diseases of horses

Viral diseases

Equine influenza

Equine influenza virus infection is widespread in most intensively managed horse populations, and causes outbreaks of disease when young naive horses are mingled at races and shows, particularly in the autumn and winter months. As well, epizootics of influenza occur when new antigenic variants of influenza viruses emerge. Serologic studies suggest that 19 and 24% of horses with upper respiratory disease seroconvert to **A/equi/1** and **A/equi/2** influenza viruses, respectively, in the 28 days after illness. As for influenza in swine and humans, *the disease in horses is usually characterized by high morbidity and low mortality, unless secondary bacterial pneumonia develops*. However, introduction of certain strains of A/equi/2 influenza virus into naive populations has caused outbreaks in which most horses became ill and up to 35% died. Most outbreaks spread rapidly through groups of horses, and are characterized by acute onset of fever of less than 4 days' duration, severe nonproductive cough, mucopurulent nasal discharge, lethargy, and anorexia. Dependent edema is an uncommon finding. Although most clinical signs resolve within 1–2 weeks, coughing may persist for weeks or months.

General features of orthomyxoviruses are described with swine influenza. H7N7 influenza virus, designated A/equi/1, was an important cause of equine respiratory disease in the 1950s, but has not been isolated since 1978. Nevertheless, the continued presence of antibody titers suggests that this virus continues to cause subclinical infections. **H3N8** subtypes, designated A/equi/2, were first isolated in 1963, and the propensity for antigen drift due to genomic mutation has resulted in periodic epizootics since that time.

Risk factors include close confinement, transportation, training, and mixing of animals. These factors probably increase the chance of contact between naive and subclinically infected animals, and reduce innate and acquired immunity. Infection is acquired by inhalation of infected aerosols. Viral replication is most extensive in epithelial cells of the upper respiratory tract and trachea, where infective viral particles bud from the plasma membrane within 2–4 days after infection. Influenza reduces mucociliary clearance both by impairing ciliary beating and by inducing necrosis of infected cells, and may also impair alveolar macrophage function; the ensuing bacterial pneumonia is responsible for many of the fatal cases. Influenza seems to favor the subsequent development of heaves, by increased reactivity of the airways to irritant stimuli and/or by increased antigen exposure in the lung as a consequence of reduced mucociliary clearance. Epithelial repair may take 3 weeks.

The surface hemagglutinin is the immunodominant antigen, and inactivated vaccines induce short-lived protection that correlates with induction of antibody to this antigen. Vaccinated horses may be infected and shed virus, but have a milder and shorter clinical course. There is no cross-protection between A/equi/1 and A/equi/2 subtypes, and incomplete cross-protection between strains of A/equi/2; consequently, it is essential to include currently circulating viral strains in vaccines. Horses that recover from natural infection have more prolonged resistance to disease, for at least 1 year, but in this case resistance is not closely correlated to antihemagglutinin antibody titers. The role of innate immunity and cellular immune responses in defense against equine influenza are uncertain.

Gross and histologic lesions of uncomplicated equine influenza have not been adequately described, as horses rarely die in the acute stages of disease. Occasional cases in foals have extensive pulmonary lesions, with necrosis of bronchiolar epithelium and infiltration of lymphocytes and neutrophils. Rarely, severe viral infection causes damage to brain, heart, gastrointestinal tract, kidney, and other parenchymal organs as well as severe ocular and pulmonary lesions.

In nonfatal cases of upper respiratory infection, **diagnosis** is based on demonstrating *seroconversion* and *virus isolation* from nasal swabs. Isolation of influenza virus is only reliable during the phase of pyrexia in the first day or two of illness. In the rare cases that are acutely fatal, virus may be demonstrated in lung by isolation or by immunohistochemistry.

Equid herpesvirus 4 and *Equine rhinitis A virus* (*Equine rhinovirus-1*) are the other major causes of upper respiratory infections in horses, in addition to *Equine arteritis virus*, *Equid herpesvirus 1*, adenovirus, and perhaps mycoplasmas. Serologic investigation and virus isolation are recommended methods of differentiating these pathogens. Bronchiolar necrosis is an uncommon lesion in horses; other causes include bronchointerstitial pneumonia of foals, and toxic injury to bronchiolar epithelium.

Equid herpesvirus

Equid alpha-herpesviruses (EHV) cause upper respiratory infections, abortion, systemic disease of neonates, and neurologic disease. The latter three manifestations are described in more detail elsewhere. Systemic disease of yearling horses or adults is rare, but notable for the high mortality rates that may occur. Herpesvirus infections of the upper respiratory tract are most common in foals less than a year of age. Affected animals are febrile with serous or mucopurulent nasal discharge, but coughing may not be present. Infection is rarely fatal, unless secondary bacterial pneumonia develops.

Upper respiratory infections may be caused by EHV-1 or 4, although the latter is more common in some surveys. Viral replication occurs in the nasopharynx and associated lymphoid tissue, and the development of viremia is dependent on the strain of the virus and prior exposure of the host. Virus is shed from nasal secretions starting 2–10 days after infection. Viral shedding commonly occurs only during the phase of pyrexia, but is occasionally prolonged up to 3 weeks after infection.

The low mortality rate in the absence of secondary bacterial infection is fortunate from a clinical standpoint, but has resulted in a paucity of descriptions of the naturally occurring lesions of the disease. Serous or catarrhal rhinitis and conjunctivitis are obvious clinically, and suppurative exudate may form as bacterial infection establishes. Intranuclear inclusions are apparently rare in postnatal respiratory infections. Definitive **diagnosis** of EHV-1 or 4 infection of the upper respiratory tract depends on *isolation of virus* from nasal swabs from febrile animals, or demonstrating *seroconversion* in paired serum samples.

EHV-1 may cause systemic disease in live-born neonates. Lesions are similar to those in aborted foals, described in Vol. 3, Female genital system. These lesions include bronchointerstitial pneumonia, multifocal necrosis in liver, spleen, adrenal, and other tissues, and prominent intranuclear inclusion bodies. EHV-1 occasionally causes systemic disease in yearling or adult horses. Lesions include pulmonary or systemic necrotizing vasculitis, pulmonary edema and hemorrhage, lymphoid necrosis, and encephalomyelitis with vasculitis.

Recently, a gamma-herpesvirus has been associated with lesions of necrotizing bronchiolitis, increased numbers of macrophages and neutrophils in alveoli, interstitial fibrosis, and syncytial cells in alveoli. Confirmation of a causal relationship between the gamma-herpesvirus infection and the lesions of bronchointerstitial pneumonia is pending.

Adenovirus

Equine adenovirus infection is widespread in horses. Adenoviral pneumonia is a well-described complication of inherited combined immunodeficiency in young Arabian foals, but the adenoviral disease has become rare as this genetic immunodeficiency becomes less common. At necropsy, there is a lobular or confluent pattern of atelectasis and/or consolidation of the cranioventral lung. In the early stage of severe infection, there is extensive necrosis and sloughing of bronchiolar epithelium. Later, bronchiolar epithelium is hyperplastic, and swollen superficial epithelial cells contain amphophilic intranuclear inclusion bodies. Occasionally, there are intranuclear inclusions in alveolar epithelial cells and increased numbers of macrophages and neutrophils. Secondary bacterial pneumonia or *Pneumocystis* pneumonia may also be present in these immunocompromised foals.

Hendra virus

Hendra virus (HeV) was first described in 1994 in Australia, as a cause of fatal pulmonary disease of horses. The virus also causes disease in humans, cats, and guinea pigs. Subclinical infections in fruit bats (flying foxes) are likely sources of infection for other mammals. HeV and the related *Nipah virus* are members of the genus *Henipavirus*, family Paramyxoviridae. *HeV has tropism for endothelial cells, and many of the lesions arise from vascular injury.* Viral particles are detectable in the cytoplasm of endothelial cells. Gross lesions in horses include prominent *pulmonary edema and congestion* with dilation of subpleural lymphatic vessels, petechial hemorrhages, and abundant tracheal froth. The most prominent histologic lesion is serofibrinous fluid and increased numbers of macrophages in alveoli. Closer inspection may reveal subtle vascular lesions in the lung, heart, glomeruli, and stomach, consisting of thrombi in capillaries and/or necrotic debris and hemorrhage in the walls of arterioles. The presence of syncytial cells in small vessels is a unique but inconsistent lesion. The *differential diagnosis* for massive pulmonary edema includes African horse sickness, heart failure, and anaphylaxis.

Bacterial diseases

Rhodococcus equi

Rhodococcus equi is an important cause of pneumonia and occasionally enteric disease in 2–4-month-old foals, and may affect animals up to 6 months of age. The prevalence of the disease is highly variable between farms, and probably reflects the level of contamination of the environment. Environmental factors favoring the disease include hot seasonal temperatures in temperate climates, neutral soil pH, and repetitive high-density stocking of dry paddocks. The clinical presentation may be either acute or insidiously progressive, although the infection and lesions are invariably chronic by the time clinical signs are noted. Affected foals usually develop disease in the summer, and are presented with pyrexia, tachypnea, dyspnea, cough, and mucopurulent nasal discharge. *Because of the chronic nature of the disease, case fatality rates are high in untreated foals.* Animals with the *colonic form* of disease may have diarrhea, weight loss, ascites due to hypoproteinemia, and occasionally colic.

Foals with bronchointerstitial pneumonia, described in detail elsewhere, frequently have concurrent *R. equi* infection, yet the relationship between these conditions remains obscure. Foals with *R. equi* pneumonia occasionally have histologic evidence of *Pneumocystis carinii* infection of the lung.

R. equi is a gram-positive facultative intracellular pathogen, distantly related to mycobacteria, which grows well in soil and in horse manure. *Pulmonary infection results from inhalation of soil-borne bacteria*, and inhalation of greater numbers of bacteria is facilitated by the presence of a dusty, contaminated environment. Enteric infections may result from ingestion of soil-contaminated feed, or swallowing expectorated material from the lungs. Experimental studies indicate that hematogenous spread from enteric lesions is not a common route of pulmonary infection.

The bacterium is engulfed by equine macrophages but survives this encounter by preventing phagosome–lysosome fusion. Nevertheless, macrophages are able to kill *R. equi* when the bacteria are opsonized or when the macrophages are activated by lymphocyte-derived cytokines. Infection elicits a pyogranulomatous inflammatory response, presumably due to cytokines secreted by infected macrophages or responding lymphocytes.

The *virulence* of *R. equi* varies between isolates, and correlates closely with the presence of an 85 or 90 kb virulence-associated plasmid. VapA is a 15–17 kDa protein encoded by the virulence-associated plasmid that is detectable in 88–98% of isolates from pneumonic lungs. Although experimental infection with plasmid-cured strains resulted in asymptomatic infection, recombinant expression of vapA by these strains did not cause reversion to virulence. Thus, although the virulence-associated plasmid seems necessary for the development of disease, plasmid-encoded proteins in addition to vapA, such as the recently described vapB and vapC, also contribute to virulence. Other virulence factors of *R. equi* include glycolipids containing long-chain mycolic acids, capsular polysaccharide, and the "equi factors" cholesterol oxidase and choline phosphohydrolase.

Immune responses to *R. equi* have been intensively investigated because of the interest in developing vaccines against this important disease of foals. The finding that passive immunization with hyperimmune plasma is effective in preventing disease indicates that humoral immunity is protective, probably because antibody-mediated opsonization augments phagocytosis and killing of *R. equi* by macrophages and neutrophils. The protective antigens of *R. equi* have not been clearly defined, but vapA is one likely candidate. In contrast to the role of humoral immunity in prevention of disease, T-helper-1 cellular immune responses are probably necessary for recovery from established infection. Both CD4+ and CD8+ T cells are important in clearing *R. equi* in mouse models of disease. CD4+ T cells produce interferon-γ, which activates macrophages to produce more bactericidal nitric oxide, oxygen radicals, and peroxynitrite, while CD8+ T cells induce lysis of infected macrophages.

The *pulmonary lesions* caused by *R. equi* are most constant in the cranioventral areas of lung, but most of the lung may be affected in severe cases. *The most consistent lesion is pyogranulomatous bronchopneumonia*, in which 1–10 cm, white-tan, firm, coalescing nodules occupy much of the lesional lung (Fig. 5.82). Intervening areas of lung are reddened and firmer than normal. With time, the centers of the pyogranulomas become friable and caseous or liquefying. These may be mistaken for abscesses, but they generally lack a fibrous capsule. Pleuritis is uncommon. Bronchial lymph nodes are enlarged and may contain focal caseous necrosis.

Intestinal lesions are present in half of the foals with lung lesions, and lesions are restricted to the intestine in about 5% of cases. The colon, cecum, and associated lymph nodes are most commonly affected, but small intestinal lesions may occur. Colonic lesions begin as focal mucosal ulcers that are centered on lymphoid follicles. The ulcer bed is reddened and covered with fibrin, and the borders of the ulcers are raised and pale due to pyogranulomatous infiltrates (Fig. 5.83). Pyogranulomas or foci of caseous necrosis may extend through the wall of the intestine. The colonic lymph nodes are often enlarged, pale, and contain necrotic foci. The colonic pyogranulomas enlarge over time, and may develop central areas of caseation or liquefaction. Large abdominal pyogranulomas with necrotic centers, which grossly resemble abscesses and cause intestinal adhesions, may be the sole lesion in some cases.

The earliest histologic lesion following *R. equi* infection is suppurative bronchopneumonia. By 4 days after infection, alveoli and bronchioles are filled with macrophages, neutrophils, and fewer lymphocytes and plasma cells. *Macrophages are numerous in the well-developed lesions, but neutrophils may also be plentiful. Gram-positive bacteria are present in the cytoplasm of plump uni- or multi-nucleate macrophages amid this exudate*, and are particularly numerous within degenerating macrophages that have cytoplasmic eosinophilia and nuclear pyknosis (Fig. 5.84). Areas of caseous necrosis, when present, usually contain cellular debris, many neutrophils and macrophages, fibrin, and edema.

In the intestine, the dome epithelium overlying lymphoid follicles is the primary route of infection. Macrophages underlying the dome epithelium contain intracytoplasmic bacilli, and neutrophils infiltrate the epithelium and exude into the lumen. With time the lymphoid follicles are invaded by macrophages and neutrophils, and central areas of caseous necrosis eventually extend to the mucosal surface. In the developed lesions of ulcerative colitis, ulcers are filled with fibrinonecrotic debris and encompassed by neutrophils and macrophages, many of which contain bacteria.

About one-third of affected foals have *polyarthritis*. This may cause severe lameness, suppurative synovitis, and positive joint cultures, due to hematogenous spread of infection. In contrast, other foals have milder, probably *immune-mediated polyarthritis*. These are characterized

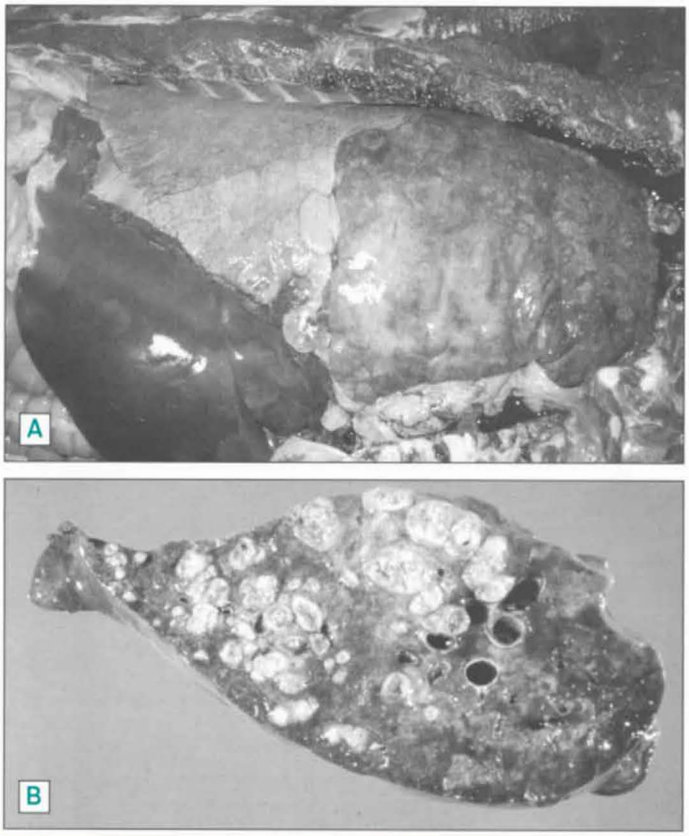

Figure 5.82 ***Rhodococcus equi* pneumonia** in a foal. **A.** The cranioventral lung is consolidated. **B.** The cut surface reveals multiple liquefying foci of pyogranulomatous inflammation.

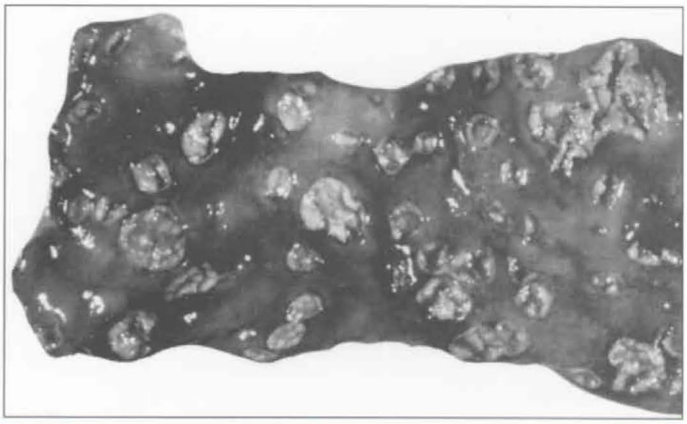

Figure 5.83 Multiple discrete ulcers in the colon of a foal with ***Rhodococcus equi* pneumonia**. (Courtesy of JA Johnson, et al., and Vet Pathol 1983:20:450–459.)

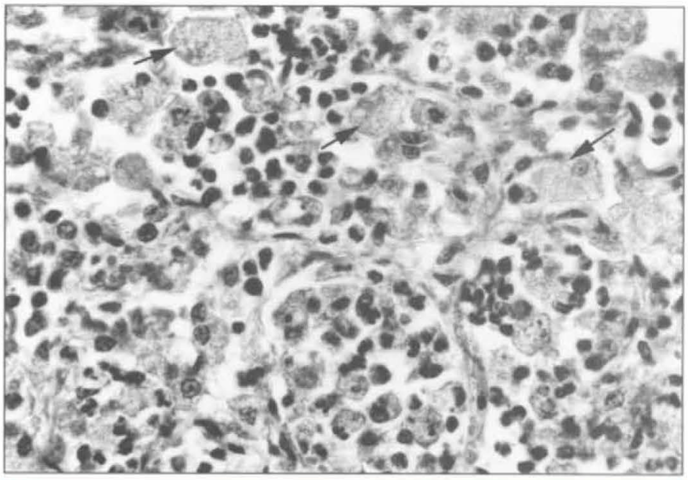

Figure 5.84 ***Rhodococcus equi* pneumonia** in a foal. Alveoli filled by macrophages, which contain large numbers of bacteria (arrows).

by sterile joints, lymphoplasmacytic synovitis, mononuclear cells in joint fluid, and immunoglobulin deposits in synovium.

More widespread dissemination of infection in foals can occasionally give rise to dermal abscesses, hepatic or splenic abscesses, osteomyelitis affecting the vertebrae or metaphyses of long bones, and hypopyon. *R. equi* may also cause ulcerative lymphangitis, and has been associated with metritis and abortion in mares, metritis in cows, pneumonia in calves, and tubercle-like lesions in lymph nodes of pigs and cattle.

Lesions of cranioventral pyogranulomatous pneumonia or multifocal ulcerative colitis in foals are highly suggestive of *R. equi* infection. In most cases, the *diagnosis is easily confirmed by culture*, or by identifying intracytoplasmic gram-positive bacilli in macrophages on impression smears or tissue sections. Idiopathic bronchointerstitial pneumonia or *Pneumocystis carinii* infection may be present in foals with *R. equi* pneumonia.

Opportunistic bacterial pathogens in foals

Pneumonia caused by opportunistic bacterial pathogens is common in 1–8-month-old foals, and appears to be of similar pathogenesis as in other species. *Streptococcus zooepidemicus* is the most prevalent cause, with occasional cases resulting from infection with α-hemolytic streptococci, *Bordetella bronchiseptica*, *Staphylococcus epidermidis*, *Klebsiella pneumoniae*, *Actinobacillus equuli*, and others. Pneumonia in neonates is commonly caused by bacteria that cause septicemia, and the two processes may be concurrent; *Escherichia coli*, *Streptococcus* spp., *A. equuli*, and *K. pneumoniae* are the most common isolates.

Equine bacterial pneumonia and pleuropneumonia

Pleuropneumonia is common in 2–4-year-olds, and older horses may also be affected. Presenting signs include fever, depression, respiratory distress, and colic. Evidence of thoracic pain may be apparent at rest, with grunting respiration or abduction of the elbows, or be elicited by thoracic percussion. Horses with bacterial pneumonia develop fever, tachypnea, and coughing. Risk factors for the development of both pneumonia and pleuropneumonia include recent transportation, general anesthesia (probably leading to aspiration pneumonia), other stressful events, and viral infection.

Numerous opportunistic bacterial pathogens have been isolated from lesions of pleuropneumonia in horses, and *mixed infections are present in most cases*. Attempts to isolate bacteria may fail in cases that have been heavily treated with antibiotics. *Streptococcus equi* ssp. *zooepidemicus* is the most common isolate; others include *S. equi* ssp. *equi*, *Actinobacillus suis*-like bacteria, other streptococci, *Pasteurella* spp., *Bordetella bronchiseptica*, and *Escherichia coli*, *Bacteroides*, and *Fusobacterium*. *Mycoplasma felis* is an agent to be considered in the differential diagnosis of cases of pleuritis without pneumonia.

Identification of a unilateral distribution of lesions and a mixed infection with aerobic and anaerobic bacteria imply that *many cases result from aspiration pneumonia*. The equine trachea at the thoracic inlet often contains a pool of secretions contaminated by bacteria – the so-called "*tracheal puddle*." One frequent pathogenesis seems to involve transport of horses with the head held in an elevated position, thus predisposing to aspiration of these contaminated secretions into the lung.

The morbid anatomy of well-developed cases of pleuropneumonia is spectacular, and the lesions are often more chronic than suggested by the clinical history. Massive amounts of fibrin and malodorous serofibrinous exudate fill the pleural space, and may form cavitating masses encased in maturing fibrous tissue (see Fig. 5.42). Most cases of pleuritis in horses arise from underlying pulmonary lesions, although the lesions of pneumonia are overshadowed by the pleural exudate. Although often described as lung abscesses, the lung lesions are more usually localized areas of consolidation. Occasionally, pleuritis extends from bilateral lesions of bronchopneumonia, which are reddened, firm, and may contain crumbly necrotic debris. Localized areas of hemorrhagic infarction are frequently present in the consolidated lung, and careful inspection of the arteries may reveal the thrombi that caused the infarcts. Lesions in the lung are often unilateral; pleural exudate in these cases is also usually unilateral.

Strangles and *Streptococcus equi*

Strangles is a common acute contagious disease of horses characterized by inflammation of the upper respiratory tract and abscessation in the regional lymph nodes. The disease commonly occurs in young horses following exposure to carriers or diseased horses. Clinical signs may include purulent nasal discharge, inappetence, fever, depression, unilateral or bilateral swelling of the throat region, stertor, and dysphagia.

Strangles is caused by *Streptococcus equi* ssp. *equi*, a Lancefield group C streptococcus that is an obligate parasite of the upper respiratory tract of equids. A range of virulence factors has been described for *S. equi*. The hyaluronic acid capsule is necessary for virulence, mediates binding of the bacterium to host cells, and confers resistance to phagocytosis. The M protein and a second cell wall protein bind fibrinogen and prevent deposition of complement factor C3b, thereby blocking recognition and phagocytosis by macrophages. Peptidoglycan activates complement by the alternative pathway, inciting recruitment of neutrophils to sites of infection. The fact that many of the recruited neutrophils rapidly undergo necrosis may be an effect of streptolysin-S and another cytotoxin.

S. equi in exudates can survive for many months in the external environment, and may be transmitted by fomites. The initial source of infection, however, is usually a carrier animal or one with active but not necessarily obvious clinical disease. The incubation period of strangles is 3–4 days, although it may be as short as 2 or as long as 15 days. The pathogenesis of the infection involves rapid transport of bacteria from the tonsil to local lymph nodes, and adhesion to nasopharyngeal epithelial cells. There is intense chemotaxis of neutrophils to the mucosa and regional lymph nodes, yet the organisms resist phagocytosis and neutrophil-mediated killing. Recovery from strangles confers immunity in about 75% of horses, associated with immunoglobulin A (IgA) and IgG antibody produced locally in the nasopharynx. Although antibodies to M protein confer partial immunity, other protective antigens are not yet fully defined.

The submandibular and retropharyngeal nodes are the first and usually the most severely affected. The swollen lymph nodes are initially firm, but this swelling becomes fluctuant as the suppurative exudate liquefies. The typical and favorable outcome of the lymphadenitis is for the abscesses to rupture on to the skin 1–3 weeks after onset of infection, releasing creamy yellow-white pus containing numerous infective bacteria. The nasal lesions are those of a purulent rhinitis but are otherwise nonspecific.

Most cases of strangles recover quickly unless the enlarging lymph nodes obstruct the upper respiratory tract. Twenty percent of clinically affected animals develop complications. These may involve extension of infection to adjacent structures, resulting in purulent sinusitis, guttural pouch empyema, periorbital abscessation, facial cellulitis, or local damage to cranial nerves, resulting in laryngeal paralysis (roaring), facial nerve paralysis, or Horner's syndrome. Horses with guttural pouch empyema may remain infected, intermittently shed bacteria, and be an important source of infection for at least 8 months after resolution of the acute disease.

More serious complications of pneumonia or pleuropneumonia, myocarditis, mesenteric lymph node abscesses, and purpura hemorrhagica are often fatal. Retropharyngeal abscesses may discharge into the pharynx, allowing pus to be aspirated into the lungs where localized areas of necrotizing pneumonia develop. Metastatic abscesses ("*bastard strangles*") occasionally form in the liver, kidneys, synovium, and brain, but are most common in mediastinal and mesenteric lymph nodes. Abscesses in these lymph nodes tend to be very large and, although rupture is unusual, the suppurative process can permeate to adjacent serous membranes and cause purulent pleuritis or peritonitis. Purpura haemorrhagica is a systemic leukocytoclastic vasculitis, and follows deposition of immune complexes of IgA or IgG with bacterial M protein in small blood vessels and glomeruli. Purpura hemorrhagica develops in 1–2% of cases, 2–4 weeks after the acute infection. There is edema of the head and limbs, petechial hemorrhages on mucosal and serosal surfaces and in muscles, and occasionally glomerulonephritis.

Because similar, but usually more mild, lesions may be caused by *S. zooepidemicus* or other bacteria, *definitive diagnosis relies on isolation of S. equi from purulent exudate.* A polymerase chain reaction (PCR) assay is described and is apparently more sensitive in detecting chronically infected horses.

Glanders

Glanders is a disease of historic importance, and flourished especially among cavalry horses. It has disappeared from many countries, but still exists in Eastern Europe, Asia, and South America. It is caused by *Burkholderia (Pseudomonas) mallei* and typically affects horses. Disease may occur in carnivores, sheep, and goats, but not in cattle or pigs. Humans are susceptible, and glanders is of current interest as a potential bioterrorist threat. *B. mallei* is sensitive to the external environment, and infection is acquired directly or indirectly from excretions and discharges of affected animals. In the absence of definitive information, it is assumed that the organisms traverse the pharyngeal mucosa, and perhaps the intestinal mucosa, and are conveyed to the lungs, where lesions almost always occur. From there, hematogenous spread is believed to result in nasal, cutaneous, and lymph node lesions.

Glanders is characterized by nodular lesions in the lungs, and ulcerative and nodular lesions of the skin and respiratory mucosa. Lung lesions are present in all cases. There is a generalized distribution of pinpoint to 2 cm diameter *pyogranulomatous nodules throughout the lung*, often with central areas of liquefactive necrosis. Histologically, the nodules

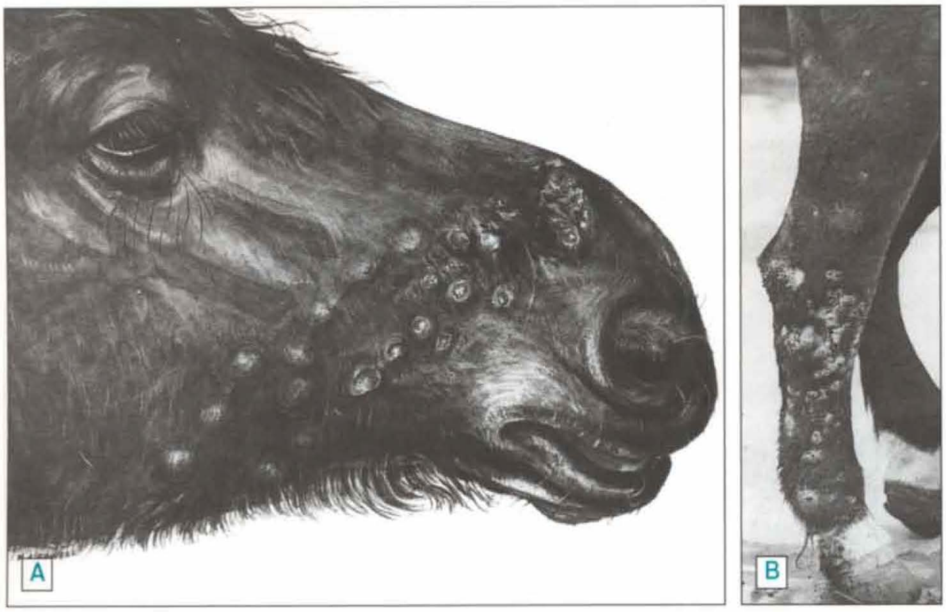

Figure 5.85 Glanders in a horse. **A.** Ulcers and farcy buds along facial lymphatics. **B.** Cutaneous glanders with nonulcerated buds. (Reproduced from Hunting W. Glanders. London: W Brown, 1908.)

are composed of a central core of neutrophils, often with necrosis of neutrophils and liquefaction of the tissue, and a peripheral rim of epithelioid macrophages and fibrosis. The relative proportions of neutrophils, macrophages, fibrosis, and mineralization are variable.

Nasal lesions are often unilateral, with copious, purulent, green-yellow exudate. Multiple small nodules in the submucosa each consist of an inner core of neutrophils and a periphery of macrophages. The core liquefies and the overlying mucosa may slough, leaving a crateriform ulcer that heals to form a white stellate scar. Similar pyogranulomatous ulcerative lesions line the pharynx, larynx, and trachea. Hematogenous metastases are common in the spleen and less common in other tissues. Enteric lesions are rare. *The cutaneous lesions of glanders are termed "farcy."* These consist of chains of nodules or ulcers that follow lymphatic vessels, and represent purulent lymphangitis with extensive leukocyte necrosis (Fig. 5.85).

Mycoplasmal diseases

Although several mycoplasmas have been isolated from the respiratory tract of horses, particularly *Mycoplasma equirhinis* and *M. felis*, there have been no studies to determine whether they are capable of causing bronchiolitis or bronchointerstitial pneumonia. *M. felis* is an uncommon cause of fibrinous pleuritis without pneumonia, and lesions were reproduced by intrapleural inoculation of *M. felis*. *M. felis* has also been associated with outbreaks of lower respiratory tract disease in horses, based on seroconversion and isolation of the organism.

Fungal diseases

Coccidioidomycosis, cryptococcosis, and pneumocystosis are described elsewhere in this chapter. **Pulmonary aspergillosis** is an uncommon disease of horses, and usually represents hematogenous spread of fungal hyphae resulting from colitis, as a consequence of both neutropenia and disruption of the mucosal barrier. Lesions are multifocal embolic pneumonia, often centered on pulmonary vessels, and include neutrophil and fibrin exudate in alveoli, hemorrhage, necrosis, and leukocytoclastic vasculitis. Septate branching hyphae are most common at the periphery of foci of necrosis.

Phycomycosis is a chronic nasal or cutaneous disease of horses and rarely of cattle. It is caused by *Conidiobolus coronatus* and *Basidiobolus haptosporus*, which are saprophytic fungi of the class *Zygomycetes*, and is limited to tropical and subtropical climates. The nasal lesions are most common in the nostril, and consist of ulcerating and cavitating granulomas containing coral-shaped granules. Histologic evaluation reveals eosinophils, neutrophils, macrophages, and giant cells. Fungal hyphae are numerous only in the granules and may be encased in brightly eosinophilic amorphous material (Splendore–Hoeppli phenomenon) that is grossly visible as granules in the necrotic areas of the mass. The hyphae of *C. coronatus* are nonpigmented, commonly septate, irregular in contour, 5–13 μm, and irregularly branched. Hyphae of *B. haptosporus* appear similar but are 5–20 μm diameter. *Pythium insidiosum* (an aquatic fungus-like oomycete pathogen) induces a similar lesion, and the hyphae are 2–7 μm diameter, thick-walled, and infrequently septate. The diagnosis is based on clinical and histologic findings; definitive diagnosis requires culture. The differential diagnoses for eosinophilic cutaneous or nasal masses in horses include habronemiasis and mast cell tumor.

Parasitic diseases

Dictyocaulus arnfieldi is mainly a lungworm of donkeys, in which it survives for long periods with few clinical signs. *D. arnfieldi* is an occasional cause of chronic coughing in horses. Infection of adult horses often results in failure of the worm to develop to sexual maturity, and larvae cannot be detected in the feces of these animals. The worms can mature if horses or ponies are infected as young foals. The gross lesions are scattered, wedge-shaped foci of overinflation, mostly in caudal lobes. In the center of the lesions are *small bronchi packed with coiled adult worms*. Histologically, the worms are associated with goblet-cell hyperplasia and lymphocytic infiltrates. Adult worms cause relatively little luminal response, whereas first-stage larvae stimulate an intense mucopurulent reaction, or chronic catarrhal and eosinophilic bronchiolitis.

Parascaris equorum larval migration may cause *nodular lesions in the lung*. The acute lesions are distinctive by virtue of the mass of eosinophils present and the occasional presence of ascarid larvae in bronchioles or alveoli. However, the chronic nodules consist of aggregates of lymphoid tissue with fibrosis and mineralization, and need to be differentiated from residual lesions of small abscesses or granulomas.

Miscellaneous parasitisms include *Schistosoma nasalis*, a cause of nasal granuloma in India; hydatid cysts; and *Habronema* spp., a rare cause of fibrotic nodules adjacent to bronchioles.

Infectious respiratory diseases of dogs

Viral diseases

Canine distemper

Canine distemper is now uncommon in many vaccinated dog populations but remains as a cause of periodic outbreaks, even in regions where vaccination is practiced, when naive groups of dogs are exposed to the virus. Canine distemper continues to be a frequent and serious disease in many parts of the world. *Canine distemper virus (CDV) infects a wide range of terrestrial carnivores*, including Canidae (wild and dometic dogs), Mustelidae (ferrets, mink), and Procyonidae (raccoons). Ferrets are particularly susceptible. Some species of seals are vulnerable to CDV infection, but distinct phocid morbilliviruses are also important causes of distemper-like disease. Neurologic disease is reported in javelinas, or collared peccaries. Large felids develop a fatal neurologic disease caused by a variant of CDV. A role for CDV has been proposed for hypertrophic osteodystrophy of dogs and Paget's disease of humans, but other investigations refute these hypotheses.

Clinical disease is most common at 12–16 weeks of age, as puppies with waning passive immunity are exposed to subclinically infected dogs. *The infection is systemic, and clinical signs are often referable to the respiratory, gastrointestinal, and nervous systems*. Ocular disease, pustular and/or hyperkeratotic cutaneous lesions, dental defects, and abortion are other manifestations. In some cases, clinical signs are primarily due to secondary infections that are a consequence of *virus-induced immunosuppression*, probably an effect of viral infection of lymphocytes and macrophages. Secondary diseases include *Bordetella*, adenovirus, and *Pneumocystis* infections of the lung; toxoplasmosis, Tyzzer's disease, sarcocystosis and encephalitozoonosis; and enteric infections with *Cryptosporidium* or attaching-and-effacing *Escherichia coli*.

The systemic form of the disease often begins as fever and conjunctivitis, with rapid progression to coughing, depression, anorexia, vomiting, and diarrhea. Affected dogs may die at this stage, fully recover, or develop neurologic disease 1–4 weeks later. Neurologic disease may also be the primary clinical manifestation, particularly in animals with partial immunity. Neurologic manifestations are quite variable depending on the anatomic location of the lesions, and include seizures, cerebellar or vestibular ataxia, paraparesis or paraplegia, and myoclonus.

CDV is in the genus *Morbillivirus,* family Paramyxoviridae. As for *Measles virus* and *Rinderpest virus*, which are closely related morbilliviruses, CDV is a large, 150–250 nm diameter, irregularly shaped virus composed of an outer lipoprotein envelope, an inner matrix, and a nucleocapsid containing single-strand negative-sense RNA. The envelope is studded with hemagglutinin glycoproteins, which mediate viral attachment to host cells; and fusion glycoproteins, which allow penetration of host cells and fusion of infected with uninfected cells.

Virus is shed in secretions of the respiratory tract, and to a lesser extent in other secretions. Infection is usually acquired by inhaling aerosols or by close contact with infected dogs. The virus infects macrophages of the upper respiratory tract or lungs, which convey it to local lymph nodes and tonsils during the first 24 hours. The virus replicates further in local lymphoid tissues, and by 2–5 days after exposure is present in lymphoid tissues throughout the body, including bone marrow, thymus, spleen, and intestinal lymphoid tissue.

Clinical signs of fever, depression, and anorexia develop about 5 days after infection. At this stage of viremia, virus particles are free in the plasma as well as within blood mononuclear cells. *Further development of the disease is highly dependent on the immune status of the host, the titer of antibodies to envelope glycoproteins, the age of the host, and the strain of virus.* Dogs with adequate humoral and cellular immunity are able to neutralize the virus and clear the infection by 14 days after infection, and may not shed virus from mucosal surfaces. In dogs with intermediate levels of cellular and humoral immunity, viremia may result in infection of mucosal epithelium and brain. Virus is shed in secretions but clinical signs attributable to epithelial infection may be minor or absent, although neurologic disease may develop in these partially immune dogs. Dogs that fail to mount an adequate immune response develop systemic infection of epithelial tissues that evokes clinical signs of respiratory and enteric disease, infection of the central nervous system, and shedding of virus in respiratory secretions, feces, and urine.

The **histologic lesions** of canine distemper are fairly specific when the disease is well developed, particularly if inclusion bodies are apparent. However, *lesions in mild cases are nonspecific*, particularly in dogs with clinical signs limited to the upper respiratory tract. *Inclusion bodies are most numerous at 10–14 days after infection*, but their numbers diminish rapidly by 5–6 weeks. *Inclusions are most obvious in brain and epithelial tissues*, and less easily identified in lymphoid tissues. Inclusion bodies can be found in the central nervous system before changes of encephalomyelitis are present, and they often persist in the neural tissue when they have disappeared from other sites. The inclusion bodies are eosinophilic and often intranuclear in nervous tissue but usually intracytoplasmic in other tissues.

Lymphopenia and lesions in lymphoid organs are regularly present. *Lymphoid lesions* may be inapparent on gross examination, or there may be either atrophy or edematous swelling. Thymic atrophy is particularly common. In the earliest lesions following experimental infection, there is depletion of lymphocytes in the cortical zone of the lymph nodes within 6 days of infection. By day 9, the lymph nodes and spleen contain lymphocytic necrosis and depletion, and infiltration of neutrophils. Syncytial cells may form in the nodes and these often contain inclusion bodies. Approximately 2 weeks after exposure, hyperplasia of histiocytic cells develops, but repopulation of the node by lymphocytes may be delayed for weeks or months. Thymic atrophy is due both to loss of cortical thymocytes as well as to great reduction in the medulla.

Respiratory tract lesions are common. Serous, catarrhal, or mucopurulent exudate covers the congested nasopharynx. The lungs are edematous, and secondary bronchopneumonia is often present, particularly in subacute or chronic cases. *The specific lesion of canine distemper is bronchointerstitial pneumonia*, which usually appears as patchy, generalized, red-tan, rubbery lesions beneath the pleura and at the margins of the lung. Generalized diffuse reddening with firm texture is a less common manifestation. Histologically, bronchioles contain scant suppurative exudate, there is patchy necrosis and attenuation of bronchiolar epithelium, and lymphocytes are present around bronchioles. *Inclusion bodies are often most obvious in the cytoplasm of bronchial and bronchiolar epithelial cells*. Alveoli contain protein-rich edema fluid, scant fibrin, mononuclear cells, and necrotic epithelial cells. Alveolar septa are thickened by mononuclear cells. Proliferation of type II pneumocytes, which occasionally contain cytoplasmic inclusions, may result in a complete cuboidal lining to scattered groups of alveoli (Fig. 5.86). Inclusion bodies are common in type II pneumocytes and alveolar macrophages, and *alveolar epithelial syncytial cells are a characteristic feature when present* (Fig. 5.87). Chronic lesions in subpleural and peribronchiolar alveoli include macrophage accumulation, type II pneumocyte proliferation, and alveolar septal fibrosis. Inclusion bodies tend to persist in the bronchiolar and alveolar epithelium longer than in other nonneural tissues.

Intracytoplasmic and rarely intranuclear inclusion bodies are regularly found within swollen transitional epithelial cells of the *urinary bladder and renal pelvis* in the acute systemic disease. Inclusion bodies, mild degenerative changes, and mononuclear cell infiltrates may be present in a variety of other epithelia, including the gastric surface epithelium, chief and parietal cells of the stomach, cholangiolar epithelium in the liver, pancreatic ductular epithelium, epididymis, and testis.

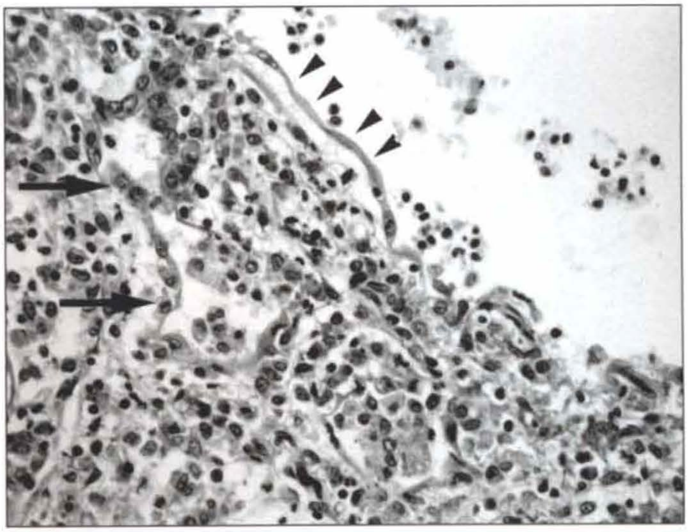

Figure 5.86 Canine distemper. Bronchointerstitial pneumonia, with a bronchiole (upper right) lined by attenuated epithelium (arrowheads), and alveoli lined by cuboidal type II pneumocytes (arrows).

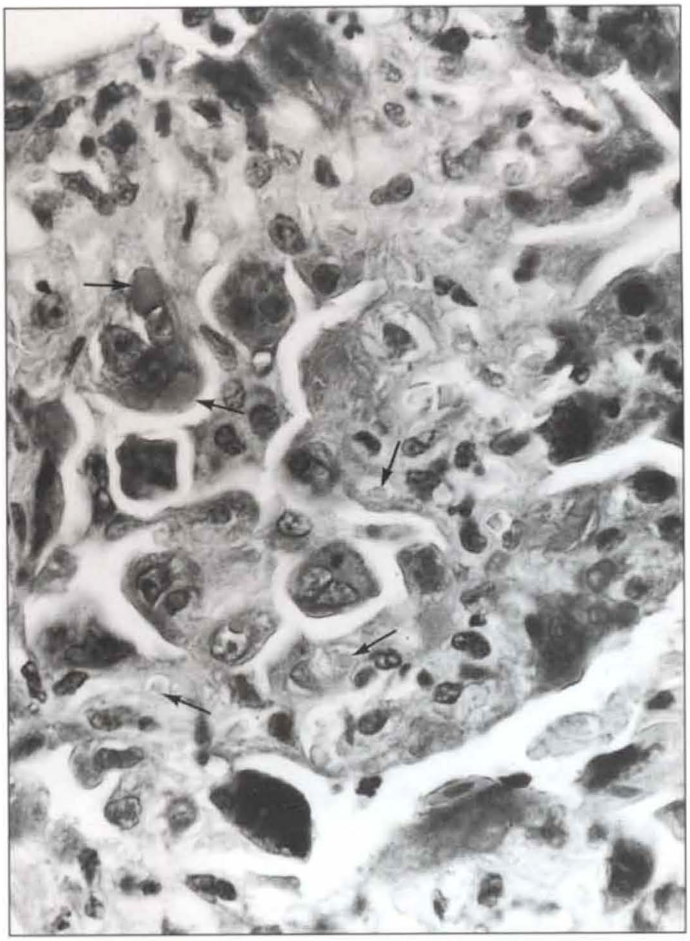

Figure 5.87 Canine distemper in a dog. Syncytia in alveoli with cytoplasmic inclusion bodies (arrows).

In the *central nervous system*, the virus appears first in perivascular astrocytes and macrophages, but infection of the choroid plexus epithelium occurs early, and the cerebrospinal fluid contains large amounts of virus. Lesions in the white matter and gray matter

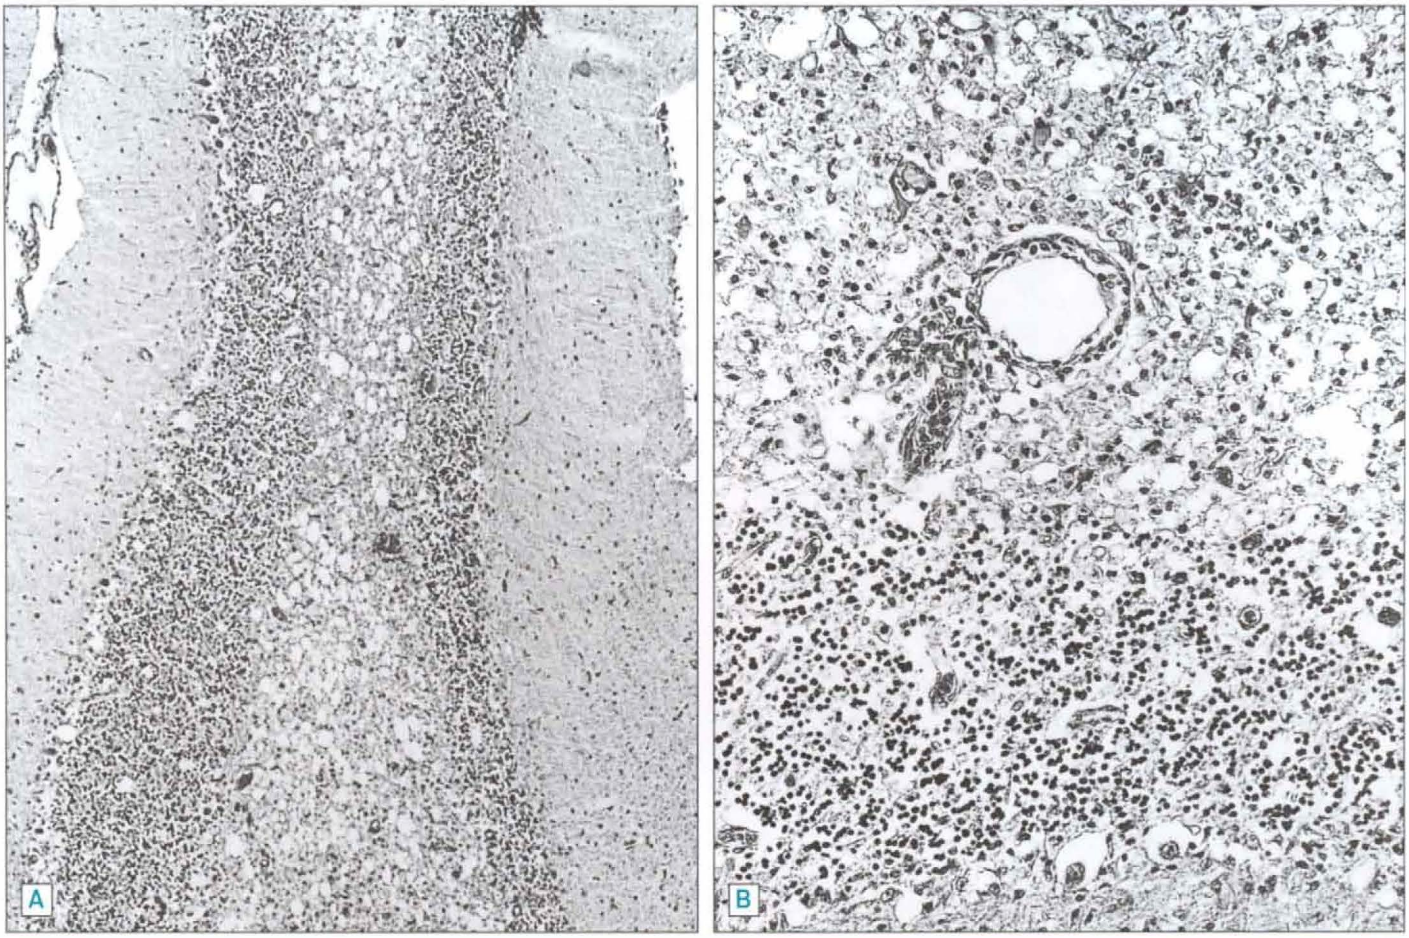

Figure 5.88 Canine distemper in a dog. **A. Demyelination** in cerebellar white matter. **B.** Perivascular cuffing and demyelination in cerebellar white matter.

differ histologically; these may occur concurrently or one may predominate. *Demyelination in white-matter tracts* is most severe in the cerebellum, rostral medullary velum, optic tracts, spinal cord, and surrounding the fourth ventricle, and probably arises from distribution of virus through the cerebrospinal fluid. The lesions are multifocal or patchy in distribution, with vacuolation of the neuropil, loss of myelin (particularly notable with Luxol fast blue stain), and, in the early stages, preservation of axons (Fig. 5.88). Astrocytes usually contain nuclear and less frequently cytoplasmic inclusions, and astrocyte-derived syncytia are present in a minority of cases. As the lesion progresses, gliosis and axonal degeneration may occur and mononuclear cells infiltrate the lesion in low numbers; however, the early lesion is noninflammatory. Animals that survive may be left with sclerotic astrocytic foci and myelin loss.

Gray-matter lesions, which are less frequent than lesions of white matter, often target the cortex of the cerebellum and cerebrum, brainstem, and spinal cord. In early stages, inclusion bodies are usually present in the nucleus or occasionally in the cytoplasm of neurons; these neurons undergo necrosis and mononuclear cells congregate around the dying neurons. With time, a nonsuppurative inflammatory response develops, and mononuclear cells aggregate around blood vessels and infiltrate the neuropil. Nonsuppurative meningitis is usually mild.

Old-dog encephalitis is a rare variant, possibly caused by infection with replication-defective virus. This syndrome is characterized by chronic progressive neurologic disease, widely distributed perivascular infiltrates of lymphocytes and plasma cells, and intranuclear inclusions in astrocytes and neurons. Viral antigen may be demonstrated by immunohistochemistry, but virus cannot be isolated from the brain. Canine distemper may occasionally result from administration of modified live CDV vaccines. Neurologic disease is the usual manifestation in these cases, and lesions in the gray matter include neuronal necrosis, intranuclear inclusions, and lymphocytic encephalitis.

Dental lesions follow infection of young animals with CDV. Necrosis and cystic degeneration of ameloblastic epithelium of the developing tooth, associated with syncytia and cytoplasmic inclusions, give rise to the *defective enamel* seen in animals that have recovered from infection. The defects vary from focal depressions to large, sharply demarcated areas of enamel hypoplasia.

Ocular lesions include conjunctivitis, keratitis, retinitis, and optic neuritis. Conjunctivitis is very common in the early stages of disease, and occasionally extends to the cornea to cause ulcerative keratitis. Retinal lesions, which are common following systemic infection, include intranuclear inclusions in ganglion cells and glia, degeneration of ganglion cells, photoreceptor loss, retinal edema, and perivascular cuffs of mononuclear cells. These lesions progress to neuronal loss, retinal scarring, and proliferation of retinal pigment epithelium in the chronic stages. Lesions in the optic nerve are inconstant, but papilledema may be observed in acute cases, and gliosis or demyelinating neuritis in chronic ones.

Cutaneous lesions of hyperkeratosis and parakeratosis affect the footpad and nose, and rarely the haired skin. The epidermis may contain syncytial cells, and nuclear and cytoplasmic inclusion bodies. Pustular dermatitis due to secondary pyoderma may be present. Experimentally infected dogs commonly develop *bone lesions*, with necrosis of osteoclasts and consequent persistence of the primary spongiosa. Pale streaks in the heart caused by multifocal *myocardial necrosis and mineralization* are described in association with canine distemper.

The histologic findings are characteristic if a spectrum of lesions is present and inclusion bodies are discovered. Rabies and poxviruses are the other causes of intracytoplasmic inclusions in dogs, but the clinical and pathologic findings in these diseases are usually distinct from canine distemper. Other viruses causing inclusion bodies in bronchiolar or airway epithelial cells include *Canine adenovirus 2*, *Canid herpesvirus 1*, and *Canine minute virus* (*Canine parvovirus 1*). Confirmation of the diagnosis benefits from a diversity of diagnostic options, including virus isolation, immunohistochemistry, indirect immunofluorescence, in situ hybridization, and the polymerase chain reaction.

Infectious tracheobronchitis – kennel cough

Infectious tracheobronchitis, or kennel cough, is a common clinical entity that is usually encountered following mixing of dogs at kennels, pet stores, and dog shows. Affected dogs develop persistent, harsh, nonproductive or productive coughing, but are often not febrile or anorexic. Most cases recover spontaneously, although signs can persist for 3 weeks or longer. Bacterial pneumonia is a well-recognized but uncommon complication of kennel cough in dogs.

Tracheobronchitis in dogs may be caused by a variety of infectious agents, and more than one agent can often be isolated from individual cases. *There is emerging consensus that* ***Bordetella bronchiseptica*** *should be viewed as the primary agent of kennel cough*, but that *Canine parainfluenza virus 2* and *Canine adenovirus 2*, and to a lesser extent *Canine distemper virus* and *Mycoplasma* spp., have predisposing roles. However, *Bordetella* cannot be isolated in some outbreaks of kennel cough, suggesting that *primary viral tracheitis may occasionally be of primary clinical significance.*

B. bronchiseptica is a gram-negative coccobacillus that is commonly carried in the upper respiratory tract, but not the lungs, of healthy dogs and many other domestic animals. It is an opportunist that is associated with infectious tracheobronchitis in dogs, atrophic rhinitis in pigs, and suppurative bronchopneumonia in many species. There is considerable genetic diversity among strains of *B. bronchiseptica*, but the relation of genetic variation and virulence remains an area for exploration. The expression of virulence factors of *Bordetella* is dependent on environmental conditions, regulated by the *Bordetella virulence gene (bvg) operon*, such that virulence genes are repressed at 25°C or in the presence of sulfate or nicotinic acid, and activated at 37°C. After entering the host, a first wave of *bvg*-regulated genes is expressed, encoding the adhesive proteins filamentous hemagglutinin (FHA), pertactin, and fimbriae that allow *B. bronchiseptica* to attach to ciliated epithelial cells. Following attachment of bacteria to the mucosal surface, a second wave of *bvg*-regulated genes is expressed that mediate motility, iron scavenging, and urease and phosphatase activity.

Secreted toxins are important contributors to bordetellosis. The adenylate cyclase toxin (hemolysin) is an RTX (repeats in toxin) toxin, like *Mannheimia haemolytica* leukotoxin and the Apx toxins of *Actinobacillus pleuropneumoniae*. The RTX domain of the toxin forms pores in target cell membranes that permit transfer of the adenylate cyclase component. Entry of this toxin into leukocytes causes increased cyclic adenosine monophosphate production that impairs phagocytosis and oxidative burst. Other virulence factors that are not regulated by the *bvg* operon include a lipooligosaccharide with endotoxin activity and a soluble peptidoglycan-derived tracheal cytotoxin. The latter is not directly toxic to tracheal epithelium, but stimulates host cells to produce nitric oxide that in turn induces ciliostasis and apoptosis of ciliated epithelial cells.

B. bronchiseptica adheres to macrophages and neutrophils, probably by binding FHA to complement receptors on macrophages. Following adhesion, the bacteria are internalized and survive within macrophages without inciting an oxidative burst, and may induce apoptosis of these cells through secretion of the adenylate cyclase toxin. In addition, *Bordetella* is able to enter and survive within nonphagocytic cells, presumably affording protection from host defenses and a ready supply of nutrients.

Although mucosal antibody responses are detectable within 4 days of infection and the duration of clinical illness is usually only 2–3 weeks, *Bordetella* infections often persist for 2–3 months and infected dogs may remain a source of infection for others in the kennel. Immune responses to *B. bronchiseptica* confer partial protection against subsequent challenge. FHA and pertactin are immunodominant antigens, and mucosal antibody responses to these antigens are partially protective.

Canine parainfluenza virus 2 (CPIV-2), also known as parainfluenza type 2 or SV-5, is commonly isolated from dogs with kennel cough. Clinical signs develop in experimentally infected dogs 3–10 days after infection. Virus is shed in nasal secretions for about 8 days after infection. Lesions are those of mild tracheobronchitis and bronchiolitis, with epithelial necrosis, mixed cellular inflammatory infiltrates, and submucosal edema. The virus does not replicate in macrophages and does not induce significant bronchointerstitial pneumonia in immunocompetent dogs. However, some strains may cause clinically detectable tracheobronchitis without concurrent *Bordetella* infection. In addition, CPIV-2 predisposes to bacterial pneumonia by impairing mucociliary clearance, and increases the bronchoconstrictive response to agonists such as histamine. Infection has been shown to impair olfaction in the absence of nasal lesions, but the clinical significance of this intriguing phenomenon is unknown.

Gross lesions may be absent in dogs with kennel cough, or mucopurulent exudate may be noted in bronchi. Enlargement of tonsils and tracheobronchial lymph nodes is inconsistent. *Histologic lesions* are by definition restricted to the trachea and bronchi; involvement of terminal bronchioles and alveoli would prompt a diagnosis of bronchopneumonia. Neutrophils infiltrate the tracheobronchial mucosa within 24 hours of infection with *B. bronchiseptica*, and increase in intensity as the disease worsens. Bacteria may be faintly visible as clumps of amphophilic material amid the cilia at the epithelial surface. Necrosis of ciliated epithelium is uncommon, but may result from underlying viral infection, neutrophil-mediated epithelial injury in areas with extensive purulent exudate, and effects of secreted bacterial toxins. As the disease progresses, there is lymphoid hyperplasia around bronchi and in draining lymph nodes. Infection is restricted to the respiratory tract and associated lymph nodes. Sequelae to tracheobronchitis include bronchiectasis and suppurative bronchopneumonia, which probably develop when the secreted toxins of *Bordetella* cause impairment of mucociliary clearance and leukocyte function.

Canine adenovirus 2

Canine adenovirus 2 (CAV-2) is serologically related to, but genetically distinct from, CAV-1, the cause of infectious canine hepatitis. The contribution of CAV-2 to infectious tracheobronchitis or kennel cough is discussed above. Naturally occurring adenoviral pneumonia is rare in dogs, and is usually a consequence of immunosuppression. Gross lesions may be cranioventral or disseminated, lobular or confluent, and consist of atelectasis, reddening, edema, and mild firmness. *Amphophilic intranuclear inclusions* are present in alveolar macrophages, with fewer in type II pneumocytes and airway epithelium. Bronchioles contain necrotic epithelial cells and suppurative exudate, and macrophages, neutrophils, and fibrin are present in alveoli. Peribronchiolar and interstitial infiltrates of lymphocytes occur but are not prominent.

Canine herpesvirus

Although most commonly diagnosed as a systemic disease in neonatal puppies, *Canid herpesvirus 1* may occasionally be isolated from older dogs with *acute respiratory disease*. Aerosol challenge of 12-week-old dogs caused necrotizing rhinitis, bronchointerstitial pneumonia, and multifocal alveolar necrosis with infrequent eosinophilic intranuclear inclusion bodies. Intraperitoneal inoculation of neonatal puppies with the same viral strain caused necrosis and hemorrhages in many organs, supporting the contention that the manifestation of disease is dependent on the route of exposure and the age of the host. Herpesviruses are infrequently isolated from dogs with acute tracheobronchitis (kennel cough), either alone or with other infectious agents. The respiratory lesions are those to be expected from herpesviruses, namely necrotizing rhinotracheitis and possibly bronchopneumonia. Eosinophilic intranuclear inclusions can sometimes be found in epithelial cells in early lesions, particularly in nasal mucosa.

Bacterial diseases

Pneumonia caused by opportunistic bacterial pathogens is moderately common in dogs. Because most of the pathogens involved are commonly isolated from healthy dogs, a diagnosis of bacterial pneumonia should prompt a search for predisposing causes. *Aspiration pneumonia* may result from megaesophagus, anesthesia, coma, or other causes of regurgitation or vomiting. Alternatively, bacterial pneumonia may arise as a consequence of *impaired respiratory defenses*. These include respiratory viral infections, particularly canine distemper, parainfluenza, or adenovirus-2; immunosuppressive therapy that induces immunosuppression or neutropenia; concurrent disease conditions that impair immune responses or neutrophil function, including uremia, hyperadrenocorticism, diabetes mellitus, parvoviral enteritis, systemic mycoses, or primary immunodeficiencies; ciliary dyskinesia; and environmental and social stresses.

Multiple bacterial pathogens are isolated from the lung of many dogs with bacterial pneumonia, as would be expected if the primary problem in these dogs is failure of lung defenses. *Pasteurella multocida, Bordetella bronchiseptica, Escherichia coli, Streptococcus* spp., *Moraxella* spp., *Staphylococcus intermedius, Klebsiella pneumoniae*, and *Acinetobacter* spp. are the most common isolates from transtracheal aspirates of dogs with pneumonia. *Bordetella* is discussed more fully under the heading of Infectious tracheobronchitis – kennel cough, above. Pneumonia caused by β-hemolytic group C and group G streptococci may develop into septicemia, or bacteremia leading to polyarthritis, meningitis, endocarditis, or hematogenous infection of other viscera. Some outbreaks of streptococcal pneumonia have no identifiable predisposing causes, suggesting that some highly virulent strains may be primary pathogens in dogs. *E. coli* seems to be most frequently associated with aspiration pneumonia; complications include bacteremia or disseminated intravascular coagulation.

The morphology of bacterial pneumonia in dogs does not usually suggest a specific infectious agent. Lesions may affect entire lobes or follow a lobular distribution. In contrast to the characteristic cranioventral distribution of bronchopneumonia in ruminants and swine, *bronchopneumonia in dogs may affect primarily the cranial or middle lobes, or present a patchy or diffuse distribution throughout the lung.* Acutely affected areas of lung are plum red, swollen, firm, and edematous. Fibrinous pleuritis is usually minimal. As the lesion ages, they become white or gray-brown, mottled, and granular. In cases of aspiration pneumonia, the lesions are often localized, foul-smelling, and necrotic. Histologically, neutrophils fill alveoli and bronchioles, but leukocyte necrosis and thrombosis are not typical features of canine pneumonia.

Handt LK, et al. Clinical and microbiologic characterization of hemorrhagic pneumonia due to extraintestinal pathogenic *Escherichia coli* in four young dogs. Comp Med 2003;53:663–670.

Mycoplasmal diseases

Mycoplasmas that infect the respiratory tract of dogs include *Mycoplasma canis, M. cynos, M. bovigenitalium, M. spumans, M. edwardii, M. gatae, M. feliminutum*, and several unclassified species of *Mycoplasma, Ureaplasma*, and *Acholeplasma*. Mycoplasmas are present in the nasopharynx of most normal dogs, and can be isolated from tracheobronchial washes from about 30% of normal adult dogs and a similar percentage of those with pneumonia. Mycoplasmas are more likely to be isolated from young dogs with septic inflammation and colonization of airways by aerobic bacteria. However, it remains possible that mycoplasmas secondarily colonize airways that are injured by other pathogens, for many dogs with suppurative pneumonia are concurrently infected with mycoplasmas and other bacterial pathogens. Experimental infection with *M. cynos* did not result in clinical signs of disease, but did induce peribronchial infiltration of lymphocytes and plasma cells, exfoliation and hyperplasia of bronchiolar epithelium, and neutrophil exudation into bronchioles and alveoli. Experimental infection with *M. bovigenitalium* resulted in mild suppurative and lymphocytic bronchiolitis. Pathologic changes were not apparent in dogs challenged with *M. spumans, M. canis*, or *M. gatae*. Clinical signs were not apparent in any of the *Mycoplasma*-challenged dogs. Unclassified mycoplasmas have been associated with similar lesions and with chronic bronchitis and bronchiectasis in dogs. Thus, although *M. cynos* may induce mild pulmonary lesions, and although *Mycoplasma* sp. colonizes the lungs of many dogs with pneumonia, *the importance and prevalence of Mycoplasma sp. as a primary cause of lung disease in dogs are uncertain.*

Fungal diseases

Mycotic rhinitis

Mycotic rhinitis is common in dogs and occasionally diagnosed in other species. Cases may be presented with variable combinations of chronic sneezing, stertor, unilateral or bilateral mucopurulent nasal discharge, nasal hemorrhage, and nasal pain. Distortion of nasal bones may occur, and extension of infection to adjacent structures may rarely induce exophthalmos or neurologic disease.

Aspergillus fumigatus is the usual cause of mycotic rhinitis in dogs, although other species of *Aspergillus* or *Penicillium* are occasional causes of otherwise similar disease. These fungi are common in the environment and reach the nasal cavity of most normal animals by inhalation. It is not known whether disease results from exposure to higher numbers of inhaled fungi or from suppression of the normal nasal defenses, but immunosuppression or other predisposing causes has only rarely been identified in dogs with nasal aspergillosis.

Lesions are often focal within the nasal cavity or paranasal sinuses, and consist of yellow, green, or black plaque-like mats or masses of fungal growth. The surrounding mucosa is hyperemic and edematous, and there is often purulent exudate, caseous debris, or hemorrhage throughout the nasal cavity. Destruction of turbinate bones is common, and remodeling of the nasal septum or nasal bones may occur. *Histologic diagnosis requires biopsy of the fungal plaques*, which may be very localized despite the presence of widespread exudate. If these plaques can be harvested by an aggressive rhinoscopist, the diagnosis is not usually challenging – they consist entirely of numerous fungal hyphae, which occasionally contain conidia. *Aspergillus* spp. hyphae are 5–7 μm diameter and have parallel sides, frequent septa, and branch dichotomously at 45°. Other histologic lesions may include ulcerative suppurative rhinitis and necrotizing vasculitis.

Rhinosporidiosis

Rhinosporidiosis is a disease of humans and dogs, and rarely of other domestic mammals and fowl. The disease is endemic in wet environments of the Indian subcontinent, uncommon in North America and Africa, and rare in Europe. Molecular analyses suggest that the causative agent, ***Rhinosporidium seeberi***, is not a fungus, but is a member of the Mesomycetozoa or so-called "DRIP" clade of aquatic protistan parasites. The agent can only be cultured with specialized techniques. The pathogenesis is uncertain, but infection may result from exposure of nasal mucosa to contaminated water.

The typical lesion is a *single unilateral nasal polyp*, which is soft, pink, up to 3 cm diameter, and bleeds easily. Histologic investigation reveals loose fibrous tissue, granulomatous inflammation, and sporangia of *R. seeberi*. Juvenile sporangia are 15–75 μm diameter, unilamellar, and contain a single nucleus. Mature sporangia, which may be visible grossly as pinpoint white foci, are 100–400 μm diameter and contain numerous 5–10 μm diameter endospores. The large size of the sporangia and the presence of endospores might only be mistaken for *Coccidioides*, and finding such structures in a nasal polyp is considered diagnostic.

Blastomycosis

Blastomycosis is an infectious noncontagious disease of dogs and humans, with occasional cases in cats, horses, and other species. The disease occurs primarily in North America, with occasional cases in Africa, Europe, Asia, and Central America. Endemically infected areas in North America include the Mississippi, Ohio, and St. Lawrence river basins, northern Ontario, and the mid-Atlantic States.

Blastomycosis is most common in young male sporting dogs that reside near water. The highly variable clinical presentation reflects the diversity of organs affected. Many dogs have insidious onset of weight loss, fever, coughing, and dyspnea due to pulmonary involvement. Ocular pain and blindness, nodular ulcerating skin lesions, and lameness are other common presenting signs.

Blastomyces dermatitidis is a dimorphic fungus. At environmental temperatures, it grows as a mycelial form and produces spores that are infectious to animals. The ecological source of the mycelial form is uncertain, but is associated with acidic sandy soils. *Recently disturbed soil* is a recognized factor in some outbreaks, and geographic clustering of cases is well documented. *At body temperatures, the fungus grows as a yeast form that is not contagious.* Although the potential exists for mycelial forms to grow in cooled tissue specimens, reports of infection acquired at necropsy are rare and have been caused by accidental penetrating wounds rather than inhalation.

Virulence factors of *B. dermatitidis* are poorly described. BAD-1 is a surface protein that mediates adhesion to host cells, may modulate the inflammatory response, and is an immunodominant antigen. Antibody responses to BAD-1 reduce disease severity, but are not completely protective. The cell wall polysaccharide α-glucan is associated with virulence and may protect against killing by macrophages.

Infection is usually acquired by inhalation of mycelial forms into terminal bronchioles, where they rapidly convert to the yeast form. Local inoculation may be the cause of the rare lesions that are restricted to the skin. Experimentally infected dogs develop a much higher prevalence of lesions than for other systemic mycoses, although in most the disease is mild and resolves without treatment. Subclinically infected dogs are apparently rare. Yeast forms proliferate in the lungs and disseminate via the blood and lymphatic vessels. Naturally infected animals may have suppression of humoral and cellular immune responses but, as for other systemic mycoses, this probably represents an effect rather than a cause of the disease. The mechanisms of this immunosuppression are not known. Whether immunosuppression is a prerequisite for disseminated disease is uncertain. T-helper-1 immune responses have been associated with protection in mouse models, and immune responses target cell wall components, including BAD-1.

The lung is the most consistently affected site. There is generalized multifocal distribution of coalescing gray-white nodules, which often range from 3 to 20 mm diameter (Fig. 5.89). Most pulmonary nodules are firm throughout, but some become abscesses or undergo central caseation and then may fistulate into a bronchus or on to the pleura. Mineralization is minimal or absent. Microscopically, the granulomas are formed by a mass of epithelioid macrophages usually accompanied by histiocytic giant cells and variable numbers of neutrophils, an outer layer of lymphocytes and less reactive macrophages, and often a peripheral rim of fibrous tissue. In some cases, there is extensive caseous necrosis in the centers of the granulomas, with merely a thin rim of macrophages. *Yeast bodies are quite variable in number and may be missed if only hematoxylin and eosin-stained sections are examined*; in cases treated with antifungal drugs or with partial immunity, a diligent search of sections stained by the periodic acid–Schiff reaction or with methenamine silver may be required to reveal the fungi. The yeast forms are 5–15 μm (or occasionally up to 30 μm) diameter, round, nonencapsulated, with a distinct wall about 1 μm thick, and granular protoplasm completely or partly filling the center (Fig. 5.90). The double contour of the wall that is well described in cytologic preparations or culture imprints is often inapparent histologically. Occasional yeast display *broad-based budding* of single daughter cells. Filamentous or pseudohyphal forms and conidia are infrequently found in tissues, and are usually accompanied by yeast forms.

Disseminated lesions are common in lymph nodes, eyes, skin and subcutaneous tissues, bones, and joints. Testes, prostate, brain, heart, liver, spleen, kidneys, intestines, and other organs are less commonly affected. The lesions are either granulomas with numerous epithelioid and giant cells, or pyogranulomatous foci with central accumulation and necrosis of neutrophils and macrophages.

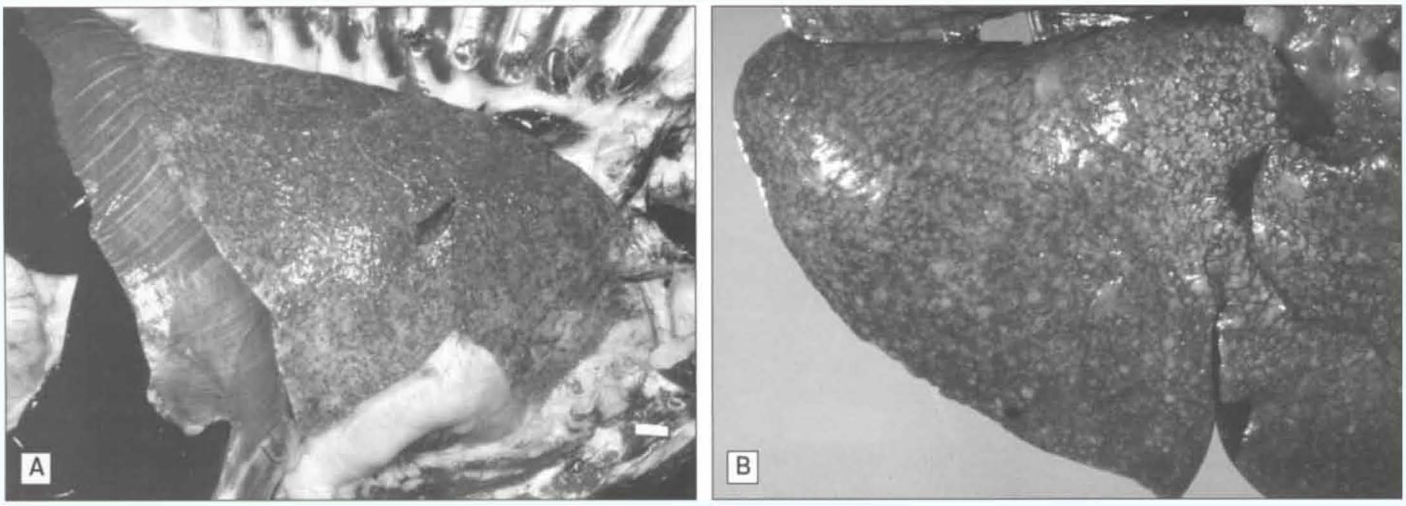

Figure 5.89 Blastomycosis in a dog. The lung contains a generalized pattern of coalescing white raised nodules.

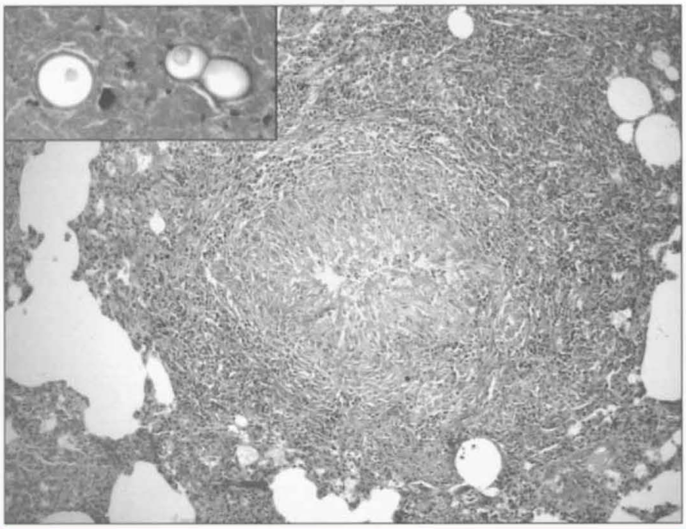

Figure 5.90 Blastomycosis in a dog. Granuloma in the lung with yeast in the center. Inset: Yeast with thick wall and broad-based budding.

Demonstration of the yeast bodies in tissue section or in cytologic preparations is the usual method of diagnosis. Blastomyces is readily differentiated from other fungi in culture, but safety precautions must be in place because infection of laboratory personnel by the cultured mycelia is well documented. Serologic tests are available, but false negatives are common.

The *differential diagnosis* for multinodular lesions in lung and other organs includes other systemic mycoses and metastatic neoplasia. Neoplastic nodules are often larger and more variable in size than the lesions of blastomycosis; examination of impression smears or histologic sections readily differentiates the two. Morphologic features are usually adequate to differentiate *Blastomyces* from other fungi: *Cryptococcus neoformans* usually has a thick capsule and only a mild inflammatory response, *Histoplasma capsulatum* at 2–4 μm is much smaller and resides in the cytoplasm of macrophages, and *Coccidioides immitis* at 20–200 μm is much larger and often contains endospores. Mutants of *Cryptococcus* that lack the characteristic thick capsule may closely resemble *Blastomyces* and incite a similar granulomatous response, but the presence of narrow-based budding differentiates them from *Blastomyces*, which divides by broad-based budding. *Blastomyces*, *Cryptococcus*, and *Histoplasma* are reliably differentiated in culture by the presence and morphology of mycelia, conidia, and yeast.

Cryptococcosis

Cryptococcosis, also referred to as European blastomycosis, is a mycotic disease of worldwide distribution. *Cryptococcosis is the most common systemic mycotic disease of cats*, and also affects dogs, horses, cattle, humans, and many other species. Disease is sporadic and, as is usually true for the systemic mycoses, the infection is apparently *neither contagious nor zoonotic. Most cases have chronic nasal disease*, with sneezing and serous or mucopurulent discharge. Other common manifestations include ulcerating cutaneous nodules, neurologic disease, chorioretinitis or panophthalmitis, and pneumonia.

Cryptococcus neoformans is a basidiomycete yeast-like fungus. Unlike the dimorphic fungi *Blastomyces* and *Coccidioides*, the sexual mycelial phase of *Cryptococcus* does not occur under normal laboratory conditions. *C. neoformans* ssp. *neoformans*, the usual cause in temperate climates, is a saprophyte found in soil, pigeon or other avian guano, and decaying organic matter. *C. neoformans* ssp. *gatti* is found mainly in association with eucalyptus trees in tropical climates. Four serotypes are defined by antigenic variation of the capsule; serotypes A and D comprise *C. neoformans* ssp. *neoformans*, and serotypes B and C comprise *C. neoformans* ssp. *gatti*.

Most infected animals do not develop clinical disease. It is commonly assumed that, as in humans, clinical disease only develops if immune responses are impaired by malnutrition, corticosteroid therapy, or immunosuppressive lentiviral infection. However, predisposing causes of immunosuppression are not often discovered in naturally occurring cases in cats. Infection is mainly acquired by inhalation of basidiospores (yeast cells) from contaminated dust. Most cases develop nasal disease, and infection may progress by local spread to the brain, aspiration to the lung, or hematogenous spread to brain, eyes, lymph nodes, skin, and other organs. Occasional cases of cutaneous cryptococcosis are probably the result of local inoculation, and *cryptococcal mastitis* in cows is an ascending rather than hematogenous infection.

The major virulence factors of Cryptococcus are the capsule and the production of melanin. The thick capsule, composed of glucuronoxylomannan and other mannose-rich polysaccharides, impairs phagocytosis, activates complement, and may suppress T-cell responses. The role of the capsule in concealing the yeast from the immune response is highlighted by uncommon strains of *Cryptococcus* that lack a capsule; these are readily phagocytosed, incite a strong granulomatous response, and are generally minimally pathogenic. Most strains consistently produce a capsule in tissues, but its thickness is variable in cultures.

The ability to synthesize melanin when grown on specific substrates is associated with virulence, and attributed in part to the enzyme phenoloxidase (laccase). Melanin and/or phenoloxidase may scavenge oxygen radicals produced by activated macrophages, and modulate the host immunoinflammatory response. Other potential virulence factors include secretion of eicosanoids and mannose protein that modulate immune and inflammatory responses, and production of superoxide dismutase and laccase that augment resistance to oxidative killing.

Immunity to *Cryptococcus* is dependent on delayed-type hypersensitivity reactions, in which interferon-γ and other cytokines elicit and activate macrophages and perhaps neutrophils to kill the yeast using reactive nitrogen and oxygen intermediates. In addition, cytotoxic T-cell responses may directly limit viability or proliferation of this pathogen.

The lesions take the form of gelatinous masses, granulomas, or ulcerating nodules. Facial swelling is a common feature of cryptococcal rhinitis of cats. Infection may spread locally from the nasal cavity to involve the skin, oral mucosa, eyes, or brain, and occasionally there is wider dissemination to local lymph nodes, lung, and other viscera. Skin lesions are often nodular and ulcerative. Visceral lesions consist of multifocal discrete white gelatinous lesions. Gross lesions in the brain are often subtle, but may include gelatinous material in meninges.

The prominent histologic lesion is a mass of yeast, and the abundant non-staining capsular material lends a "soap bubble" appearance to the lesion (Fig. 5.91). In contrast to other mycotic infections, the granulomatous reaction is often quite minimal, presumably because the capsule masks the yeast from recognition by phagocytes. *C. neoformans* yeast bodies are 4–8 μm diameter, plus a capsule which varies from 1 to 30 μm thick (Fig. 5.92). Occasional yeast have single buds that are

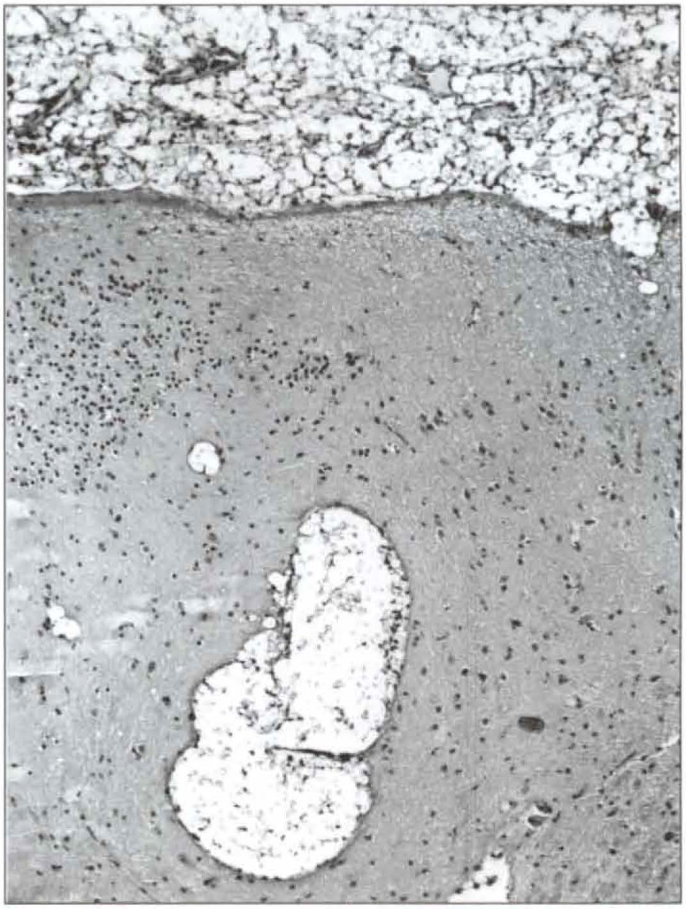

Figure 5.91 Cryptococcosis in a cat. Granulomatous meningitis with extension along Virchow-Robin space. Note the characteristic soap-bubble appearance.

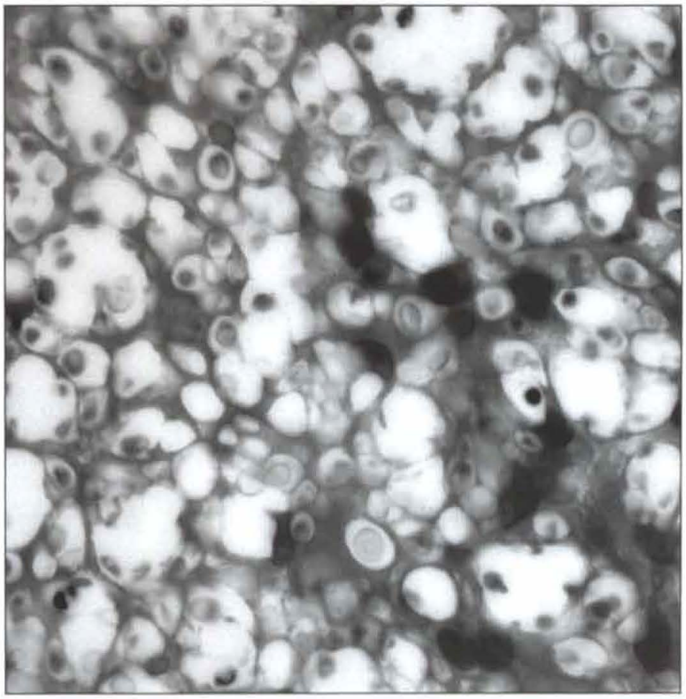

Figure 5.92 Cryptococcosis in a cat. The material in the lung is mainly formed by yeast with a thick capsule, and relatively few macrophages.

attached by a thin stalk; *this narrow-based budding differentiates Cryptococcus from Blastomyces.*

The *diagnosis* is usually based on identifying the yeast in histologic sections or cytologic smears. *The thick capsule is characteristic – C. neoformans* is the only pathogenic fungus with a capsule – and it can be easily identified with mucicarmine. In wet mounts, the capsule can be identified by negative staining with India ink. The yeast bodies stain with periodic acid–Schiff (PAS) or methenamine silver, and melanin production may be demonstrated with Masson–Fontana stain. Culture, which is required for definitive diagnosis, is easily performed on Sabouraud's agar. Detection of antibodies to capsular antigen in serum or cerebrospinal fluid is a useful method of clinical diagnosis.

Coccidioidomycosis

Coccidioidomycosis is endemic in the semiarid Lower Sonoran life zone of the southwestern USA, northern Mexico, and parts of Central and South America. The disease affects humans and dogs, is less common in horses and cats, and may cause incidental pulmonary lesions in cattle and swine. Clinical manifestations in dogs include fever; chronic respiratory disease with coughing, weight loss, and eventual respiratory distress; visceral disease causing anorexia, weight loss, and malaise; draining cutaneous nodules; lameness resulting from osteomyelitis; ocular disease; and heart failure due to myocardial or pericardial lesions. Nodular skin disease is the most common presenting sign in cats. Clinical findings in horses include chronic weight loss, pulmonary disease, and lameness due to osteomyelitis.

Coccidioides immitis is a geophilic dimorphic fungus. The mycelial form survives well in dry hot conditions, grows after periods of intense rainfall in soil containing fecal or other organic matter, and releases arthroconidia that are widely disseminated in wind-blown dust after the soil desiccates. *Inhalation of airborne arthroconidia is the usual route of infection*; local inoculation occasionally causes a cutaneous lesion that does not usually progress to systemic infection. *Although most animals in endemic areas probably become infected during their life, relatively few develop disease.* Following deposition in the lung, the arthroconidia transform into the yeast form. Immature *spherules* are 10–20 μm diameter (Fig. 5.93); as they mature, the spherules (or

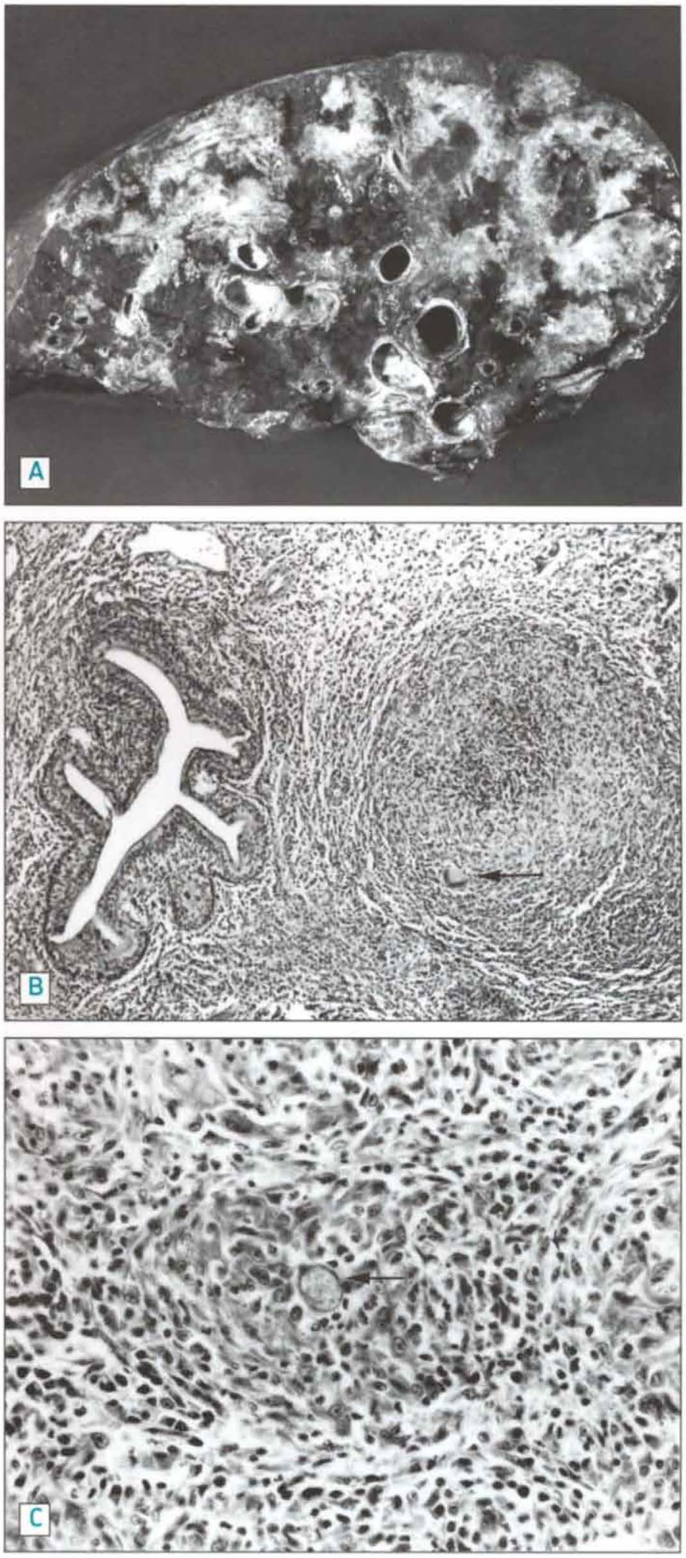

Figure 5.93 Pulmonary coccidioidomycosis in a horse. **A.** Chronic granulomatous interstitial pneumonia, with multiple coalescing foci of consolidation. **B.** Granuloma adjacent to a bronchiole, with a giant cell (arrow). **C.** Spherule (arrow) in the center of a small granuloma. (Courtesy of TE Dorr.)

sporangia) enlarge up to 200 μm diameter and develop numerous 2–5 μm *endospores*. Mature spherules rupture, and the released endospores form either new spherules in tissue or mycelia if released to the environment. Infection of necropsy personnel has been attributed to inhalation of aerosolized tissue endospores, although the paucity of such cases suggests the risk is limited.

Lesions may be limited to the *lungs*, where they vary from nodular to miliary. The *pyogranulomas or granulomas* are gray-white nodules that often contain a caseous or liquefying center (Fig. 5.93). Large nodules may be formed by a collection of small discrete granulomas separated by fibrous tissue. The initial reaction to the infectious forms – inhaled arthroconidia and endospores released from mature spherules – is primarily suppurative. The lesion forms a pyogranuloma or granuloma as it matures, with epithelioid macrophages, a few giant cells, lymphocytes, and neutrophils. Spherules may be numerous, but chronic cases with little neutrophil reaction may have only a few organisms engulfed by giant cells. In cattle, spherules are often enmeshed in eosinophilic material similar to the Splendore–Hoeppli phenomenon; this may reflect the higher level of resistance of this species.

Systemic lesions are present in a minority of infected animals, and result from hematogenous spread from the lung. Cases with systemic lesions that lack pulmonary involvement probably reflect resolution of the lung disease rather than an extrapulmonary route of infection. Tracheobronchial lymph nodes are often enlarged and reactive, but generalized lymphadenopathy is uncommon. Nodular lesions in the skin develop into draining nodules or fluctuating abscesses. Osteomyelitis often occurs late in the disease, with osteolytic granulomatous or cavitating masses surrounded by proliferating new bone tissue. Granulomatous lesions may be present in the pericardium or the heart and cause right-sided heart failure. Granulomas in the central nervous system are most common in cerebrum and midbrain. Ocular lesions include chorioretinitis, retinal detachment, anterior uveitis, and keratitis. Other organs affected include liver, spleen, kidney, and testes. Abortion and mastitis are described in horses.

The **diagnosis** is usually established by identifying the spherules in tissue sections. Spherules are most numerous in lesions with prominent suppuration. *The large size and endosporulation of the mature spherules are characteristic*, and can only be confused with *Rhinosporidium seeberi*. Culture is a useful method of definitive identification; safety precautions are essential because arthroconidia are easily detached from the mycelial form and are highly infectious for laboratory personnel. Serum antibodies to *C. immitis* can be detected in most cases, particularly in the acute stages of disease, and high titers suggest active disease.

Adiaspiromycosis – *Emmonsia* spp.

Adiaspiromycosis is primarily a disease of wild rodents, but rarely affects domestic animals and humans. The causative agents, ***Emmonsia parva*** and ***E. crescens*** (formerly *Chrysosporium* spp.), are dimorphic fungi that are closely related to *Blastomyces*. Lesions are most common in the *lung* but occasionally involve local lymph nodes, and consist of *nodules of granulomatous inflammation*. The diagnosis is based on finding adiaspores – large, spherical, uninucleate conidia – in the nodules. The adiaspores of *E. parva* are often 10–20 μm diameter, while those of *E. crescens* may be up to 300 μm diameter. Both have a thick PAS-positive wall. Their large size and thick wall might be mistaken for *Coccidioides*, but endosporulation is not a feature of *Emmonsia*.

Parasitic diseases

Pneumonyssoides caninum

Pneumonyssoides (Pneumonyssus) caninum is a parasitic mite of the nasal cavity and paranasal sinuses of dogs. The prevalence is ~20% in Scandinavian dogs, but it appears to be less common in other areas. The female adult mite is motile, oval, light yellow, and 1–1.5 mm long. The mites are presumably transmitted by direct contact. They are usually an incidental finding, but clinical signs include sneezing, head-shaking, and impaired olfaction. The mites induce catarrhal rhinitis and sinusitis with goblet-cell hyperplasia, hyperemia, and infiltration of neutrophils, eosinophils, and lymphocytes. *Pneumonyssoides* is, in addition to allergic rhinitis, a consideration in cases of eosinophil-rich inflammation in the nasal mucosa.

Linguatula serrata – pentastomiasis

Linguatula serrata, a member of the phylum *Pentastomida*, is of wide geographic distribution. Adult pentastomes are large, long-lived, specialized hematophagous parasites of the respiratory tracts of reptiles, amphibians, and carnivorous mammals. They are related to, but distinct from, the arthropods. The adults of *L. serrata* are transversely striated and tongue-shaped (hence the name). Males are ~2 cm in length and females 1.0–1.2 cm. The definitive hosts are carnivores, but in aberrant parasitisms herbivores and humans may be host to the final stage. Herbivorous animals are the intermediate hosts. Carnivores are infected by eating the infected viscera of herbivores, and the nymphs migrate to the nasal passages, where they mature. The parasites may be found anywhere in the nasal cavity, and occasionally they find their way into the paranasal sinuses or pass via the eustachian tube to the inner ear. They lie on the surface of the nasal mucosa and induce nasal irritation and a catarrhal to lightly blood-stained exudate. The gravid females discharge a large number of eggs that are removed by sneezing. The larvae develop in the alimentary tract of the intermediate host and migrate to the mesenteric lymph nodes and other organs, where they encyst and develop into infective nymphs. The small cysts are common in mesenteric nodes of cattle and sheep in some countries, and contain brown fluid; older lesions may mineralize and resemble tubercles.

Eucoleus aerophilus

Eucoleus aerophilus (Capillaria aerophila) is a trichurid nematode (order Enoplida, superfamily Trichuroidea, family Trichuridae) *that parasitizes the trachea and bronchi of wild canids, domestic dogs, and occasionally cats.* The worms are slender, 2–3 cm long, and embedded in the airway mucosa. Histologic examination reveals characteristic features: bacillary bands, which are segmental thickenings of the hypodermis; a stichosome, which is a deeply basophilic gland encircling the esophagus; and the possible presence of embryonated eggs. The eggs are laid in the airways, move with mucus to the pharynx, are swallowed and passed in the feces. The eggs are oval with bipolar plugs, and closely resemble those of *Trichuris vulpis* of the intestine or *Pearsonema* (*Capillaria*) plica of the urinary bladder. The larvae undergo initial development in the egg, and then progress to the infective stage within earthworms, which are a required intermediate host. Eggs also hatch in about 40 days under suitable environmental conditions, but the resulting larvae are apparently not infective. After ingestion of the earthworm, the larvae reach the lungs in ~1 week and are mature in the trachea in about 25 days. Most infestations of *E. aerophilus* are inapparent and provoke only mild catarrhal inflammation. Heavy infestations cause more severe irritation that may result in obstruction of the lumen of the airways. Chronic coughing and intermittent dyspnea may then be observed, and secondary bacterial bronchopneumonia may occur.

A related trichurid, *E. (Capillaria) bohmi*, is occasionally reported in the nasal cavity and sinuses of wild canids and rarely in domestic dogs.

Oslerus osleri

Oslerus (*Filaroides*) *osleri* is of wide geographic distribution and is common in wild canids. The tracheal nodules are uncommonly encountered during bronchoscopy or necropsy of domestic dogs, and they rarely cause clinical signs of chronic coughing or dyspnea. Most infestations occur in dogs less than a year of age, and are acquired from the dam through grooming or regurgitative feeding.

O. osleri is a 5–15 mm long nematode of the superfamily Metastrongyloidea, family Filaroididae. The thin-walled embryonated eggs are coughed up and swallowed and many hatch before being passed as infective larvae in the feces. Unlike other metastrongyles, the Filaroididae do not require an intermediate host. The first-stage larvae of *O. osleri* are immediately infective, and pups are infected by ingestion of larvae in the saliva, tracheobronchial secretions, or feces of their dams. Larvae migrate from the gut through the blood to the lung. They develop into fifth-stage larvae by 5 weeks after infection, and the tracheal nodules are detectable at 10 weeks and well developed by 18 weeks. The caudal end of the gravid female protrudes through the epithelium, and the eggs are laid on to the tracheal surface.

The typical lesions are single or multiple, 1–10 mm diameter, firm, gray-pink, sessile or polypoid, submucosal nodules in the trachea and bronchi, often in the region of the tracheal bifurcation (Fig. 5.94). The larger masses are oval with the long axis parallel to that of the trachea. On careful inspection, coiled worms are visible through the intact overlying mucosa.

The nodules are formed by coiled adult or fifth-stage larval nematodes lying in tissue spaces in the lamina propria, and the nodules are often encircled by fibrous tissue (Fig. 5.94). The adults have coelomyarian musculature, a gut formed by few multinucleate cells with indistinct microvilli, and larvae or embryonated eggs within the uterus. The live worms provoke little reaction apart from a few lymphocytes and plasma cells. Dead worms incite a foreign-body reaction with neutrophils and giant cells. Immature worms, probably still migrating towards the trachea, may be found in the pulmonary lymphatics and occasionally in the alveoli without significant tissue reaction. The *diagnosis* is based on identifying the adults in histologic or crush preparations of the tracheal nodules, or discovering larvae in smears of tracheal mucus or Baermann preparations of feces.

Crenosoma vulpis

Crenosoma vulpis is a common lungworm of foxes, but also occurs in other canids, including domestic dogs, perhaps in mustelids, but not in cats. It is a nematode of the superfamily Metastrongyloidea, family Crenosomatidae, and snails and slugs are intermediate hosts. *Adult worms reside in bronchioles and small bronchi.* After a prepatent period of 18–21 days, adults produce larvae that are passed in the feces for about 8 months. The usual gross lesions in dogs are gray consolidation of the dorsocaudal lung. Histologically, the lesions caused by adult worms are catarrhal, eosinophilic bronchitis and bronchiolitis. Aspirated larvae may induce a granulomatous reaction in alveoli.

Filaroides hirthi

Infection is mostly reported in colonies of laboratory Beagles, but cases are described in pet dogs. Adult *Filaroides hirthi* are 6–10 mm in length and contain larvae or embryonated eggs in the uterus. *The adults live in alveoli and respiratory bronchioles.* Like other members of the Filaroididae, *F. hirthi* has a direct life cycle, and infective first-stage larvae are passed in the feces. Many infections are probably acquired from the dam.

In most cases the lesions are incidental at necropsy, with gray-tan or black-green, 1–5 mm diameter nodules scattered widely in subpleural regions of the lung. Nodules may have clear cystic centers, or be white and firm. The lesions in fatal cases, which may occur in immunosuppressed dogs, are of severe generalized diffuse or miliary *granulomatous pneumonia.* Histologically, there is little response to living adult worms, but a severe granulomatous response with many eosinophils occurs around dead or degenerating worms. Killing the worms with an anthelmintic may incite the severe response. Larvae stimulate an acute neutrophilic reaction. Foci of granulomatous interstitial pneumonia can often be found in which worm remnants may no longer be identified. The **diagnosis** is based on discovery of larvae in smears of bronchial exudate, or identifying the adults in histologic sections of lung. Definitive diagnosis requires extraction of intact adults from the lungs, as the histologic appearance is similar to *Andersonstrongylus milksi.*

Torgerson PR, et al. *Filaroides hirthi* verminous pneumonia in a West Highland white terrier bred in Ireland. J Small Anim Pract 1997;38:217–219.

Andersonstrongylus milksi

Andersonstrongylus milksi (*Angiostrongylus milksi*, *Filaroides milksi*) is a metastrongylid nematode in the superfamily Metastrongyloidea, family Angiostrongylidae. The literature related to this parasite is confusing, because the diagnosis in many reports is exclusively based on histologic lesions. However, examination of intact worms, which are difficult to tease from the lung, is required to differentiate *A. milksi* and *Filaroides hirthi* definitively. A molluscan intermediate host has been proposed, but the life cycle is unknown. *Adults inhabit the bronchioles and the alveoli*, and the gross and histologic lesions are similar to those caused by *F. hirthi*. Larvae may also be found in the brain, abdominal viscera, and other organs.

Angiostrongylus vasorum

Angiostrongylus vasorum, or French heartworm, occurs in endemic foci in parts of western Europe, and is also reported in Uganda, South America, Eastern Asia, and Canada (Newfoundland). Most cases develop *chronic heart failure*, but *acute interstitial pneumonia* occurs in heavily infected dogs. Uncommon manifestations include disseminated intravascular coagulation, uveitis in response to aberrant migration to the anterior chamber of the eye, and larval emboli in kidneys, brain, or other tissues.

A. vasorum is a nematode of the superfamily Metastrongyloidea, family Angiostrongylidae. *Adults inhabit the pulmonary arteries and right ventricle of dogs and foxes.* Eggs pass via the blood to the lungs, where the larvae hatch, penetrate into alveoli, are coughed up, and are passed in the feces. The prepatent period is 38–57 days. Snails and slugs serve as intermediate hosts. *Angiostrongylus* can be differentiated from *Dirofilaria* by examination of intact adults, or by histologic examination. *Angiostrongylus* has thin coelomyarian musculature, a large, strongyloid intestine composed of few multinucleate cells, and eggs in the uterus. The larvae in the lungs are wider and more developed than the microfilariae of *Dirofilaria*. In contrast, *Dirofilaria* has well-developed coelomyarian musculature, a smaller intestine, and a uterus containing microfilariae.

Lesions during the prepatent period are mild. *Adult, 14–21 mm long worms are present in the pulmonary arteries*, and the lungs contain a few 1–2 mm red nodules, consisting of aggregates of eosinophils and mononuclear cells. The females have a "barber-pole" appearance due to the helically arranged red gut and white ovaries. More severe lesions develop at the time of patency, including proliferative endoarteritis in response to the adult worms in the pulmonary arteries, and eosinophilic and granulomatous pneumonia as a consequence of embolized eggs and larvae. Arterial lesions include thrombosis, thickening of the tunica intima by fibromuscular tissue and numerous eosinophils, medial hypertrophy, and lymphoplasmacytic aggregates in the adventitia. Pulmonary lesions consist of red or golden-brown, nodular or confluent areas of hemorrhage, edema, and firmness at the periphery of the lung. Histologically, *coalescing granulomas* formed by macrophages, eosinophils, and giant cells are centered on parasite eggs and larvae in the lung. There is mild proliferation of type II pneumocytes, alveolar hemorrhage, hemosiderin-laden macrophages, and arteriolar thrombosis. Fibrosis and recanalization of arterial thrombi develop as the lesion ages. Similar granulomas are reported in brain, kidney, and other tissues.

Infectious respiratory diseases of cats

Viral diseases

Feline viral rhinotracheitis and *Felid herpesvirus 1* infection

Felid herpesvirus 1 (FeHV-1) infection is widespread in most cat populations, is an important contributor to upper respiratory tract disease in cats, and is a common cause of conjunctivitis and keratitis. Clinical signs are most common in kittens but occur regularly in adult cats, perhaps due to recrudescence of latent infections. Morbidity may be high in naive populations of kittens, but mortality is generally low and most cats recover in 10–14 days. Clinical signs include fever, oculonasal discharge, sneezing, coughing, and anorexia. *Chronic rhinitis and sinusitis* may develop due to intermittent reactivation of latent infections, loss of respiratory defenses due to epithelial or turbinate damage, or failure of drainage of sites of secondary bacterial infection in the sinuses.

General features of this family are described in the section on Infectious bovine rhinotracheitis, above. FeHV-1, like other α-herpesviruses, *causes cytolytic infections of mucosal epithelial cells and establishment of latency in the trigeminal ganglion, optic nerve, olfactory bulb, and cornea.* Reactivation of latent infection is often of unknown cause, but may be triggered by corticosteroid therapy, stresses associated with environmental changes, or parturition. The virus replicates optimally at temperatures less than 37°C; thus, most infections are limited to the upper respiratory tract and conjunctiva.

FeHV-1 is transmitted by contact with infected nasal or ocular secretions, or by aerosol for a distance of about 1 meter. Transmission by fomites may occur, but the virus survives for less than 18 hours under most environmental conditions. The host range is limited to felids; occasional cases are reported in cheetahs. The incubation period is typically 2–4 days. In most cases, infection is restricted to the nasal mucosa, nasopharynx, sinuses, and tonsils, with lesser viral replication in the conjunctiva and upper trachea. Viremia may occur in neonates, but is not common in older kittens. It is likely that most cats that recover from the disease remain latently infected, and perhaps 20–40% of these cats intermittently shed infective virus during periods of stress, corticosteroid therapy, change in housing, or lactation.

The distribution of **gross lesions** corresponds to the predilection sites for viral replication – the epithelium of nasal passages, pharynx, soft palate, conjunctivae, tonsils, and, to a lesser extent, trachea. The initial serous inflammation becomes mucopurulent or fibrinous within a few days, and crusting is often present around the eyes and nares. Multifocal erosions of the nasal mucosa are covered by mucoid or mucopurulent exudate. The trachea may contain hemorrhage or fibrinous exudate. Tonsils are enlarged and contain petechiae or rare foci of necrosis. The regional lymph nodes are usually enlarged, reddened, and edematous. Ulceration of the tongue is rare and only in severely affected cats. This contrasts with the frequent finding of vesicular to ulcerative lesions on tongue, hard palate, or nostrils with *Feline calicivirus* infection. Ocular involvement is usually limited to purulent conjunctivitis, but it can progress to ulcerative keratitis.

Microscopically, *large eosinophilic intranuclear inclusion bodies* are present in many virus-infected cells during the period of active viral replication from 2 to 7 days after infection. They may be found in lesions from cats dying of the disease, but are rarely detected beyond 7 days after infection and cannot be relied upon for diagnosis. Infected cells undergo hydropic change with cytoplasmic swelling and pallor. There is loss of epithelial organization and the disrupted epithelium is soon eroded or ulcerated. An acute inflammatory reaction develops with exudation of fibrin and many neutrophils. Focal necrosis accompanied by acute inflammation may be found in tonsils and local lymph nodes. Necrosis and resorption of turbinate bones have been described in experimental infections, and may impair nasal clearance of opportunistic bacterial pathogens. Repair may be delayed for up to 17 days after infection, and the epithelial tissue may undergo squamous metaplasia as it repairs.

Pulmonary involvement is uncommon except in fatal cases. In fulminating cases of viral infection, there is widespread multifocal necrotizing bronchitis, bronchiolitis, and interstitial pneumonia, with extensive serofibrinous flooding of airspaces. Secondary bacterial bronchopneumonia is a more common complication of FeHV-1 infection than is primary viral pneumonia.

Systemic disease is uncommon in FeHV-1 infection, in contrast to the analogous infections of young calves and dogs. Ocular lesions are described elsewhere. Experimental infection of pregnant queens produces abortion and generalized neonatal disease, but this has been difficult to identify in natural outbreaks. Multifocal hepatic, pancreatic, and adrenocortical necrosis are the expected features of systemic disease. A syndrome of nasofacial ulcerative dermatitis and stomatitis with histologic lesions of eosinophilic inflammation and infrequent epithelial intranuclear inclusion bodies may be associated with corticosteroid therapy or crowding. Necrosis accompanied by inclusion bodies has also been found in sites of osteogenesis in a wide variety of bones of kittens after intravenous inoculation. Degeneration of olfactory nerve fibers and focal lymphocytic infiltration of the olfactory bulbs have occurred in experimentally infected, germ-free cats, but the extent of lesions in the brain has not been properly documented.

The major *differential diagnosis* for upper respiratory disease in cats is *Feline calicivirus* infection. Minor or uncommon contributors include *Chlamydophila felis*, *Bordetella bronchiseptica*, and *Mycoplasma* spp.

The finding of eosinophilic intranuclear inclusion bodies amid necrotizing lesions of respiratory epithelium is usually sufficient for **diagnosis**. If necessary, this diagnosis can be confirmed by *virus isolation*. Several other techniques are applicable to necropsy tissues, including immunohistochemistry, polymerase chain reaction (PCR), in situ hybridization, and indirect immunofluorescence assays. PCR assays may be more sensitive than virus isolation for detection of infection in vaccinated cats, presumably due to the presence of serum neutralizing antibodies.

Feline calicivirus

Feline calicivirus (FCV) is a common cause of upper respiratory tract disease, and also causes oral ulcers, chronic stomatitis, pneumonia, and lameness. Infection with FCV is widespread, and 15–25% of cats are subclinical carriers. Morbidity is often high, particularly in kittens, but most cats recover from clinical disease. Clinical signs are variable and include serous or mucopurulent nasal and ocular discharge, *oral ulcers*, conjunctivitis, sneezing and coughing, anorexia, and fever. Outbreaks of rapidly progressive fatal disease have been described.

FCV is a nonenveloped, 35–40 nm diameter, positive-sense, single-stranded RNA virus in the genus *Vesivirus*, family Caliciviridae. Open reading frames 1, 2, and 3 encode a helicase, a protease, and polymerase; the single capsid protein; and an RNA-associated structural protein, respectively. The capsid protein is the target of protective immune responses, but hypervariable regions in this gene confer antigenic variability that allows viral persistence in the face of a developing immune response.

Transmission is by direct contact with infected oronasal secretions, and fomites are a potential source of infection. The clinical manifestation of the disease probably depends on the strain of the virus, the immune status of the host, and the route of infection. The incubation period varies from 2 to 14 days, and many cats recover in 7–14 days after onset of illness. However, *viral infection persists despite resolution of clinical signs*, and 25% of infected cats continue to shed virus for months or years. These cats are important sources of infective virus for naive cats or cats with immunity to other strains of calicivirus. Occasionally, these chronically infected cats develop chronic lymphoplasmacytic and/or ulcerative stomatitis that is refractory to therapy.

Although FCV may cause upper respiratory infections, *ulcerative stomatitis and interstitial pneumonia are the predominant manifestations.* The oral ulcers, which begin as vesicles that rapidly rupture, are most often present on the dorsal surface or lateral margins of the tongue and on the hard palate. Cutaneous ulcers may occur on the nares and the muzzle.

Caliciviral pneumonia is an uncommon but not rare occurrence. Pneumonia is more likely following aerosol rather than oronasal exposure, and specific strains or quasispecies of FCV may have tropism for the lungs. Gross lesions are irregularly distributed but often include the margins of the cranioventral lung. The virus causes lytic infection of type I pneumocytes, resulting in acute to subacute interstitial pneumonia. Hyaline membranes may be present, and the alveoli often contain serofibrinous exudate and neutrophils. As the lesion heals, type II pneumocytes proliferate and form a cuboidal lining of the alveoli, and alveolar septa are thickened by lymphocytes, plasma cells, and fibrous tissue in the later stages.

An epizootic of highly contagious, rapidly fatal, systemic FCV infection affecting both kittens and adult cats has been described. Affected cats had oral ulcers as well as alopecia and cutaneous ulcers on the limbs, footpads, and inguinal region. Subcutaneous tissues were edematous with foci of fat necrosis, and there was pancreatitis with peripancreatic fat necrosis, disseminated intravascular coagulation, intestinal crypt necrosis, single-cell necrosis of hepatocytes, and interstitial pneumonia.

It is often impossible to distinguish FCV infection from other causes of upper respiratory tract infection in cats, particularly *Felid herpesvirus 1 (FeHV-1)* and *Chlamydophila*. *The finding of oral ulcers is suggestive of calicivirus infection.* In contrast to the bronchointerstitial pneumonia caused by FeHV-1, airway lesions are usually not present in FCV infection. Toxoplasmosis, sepsis, and aspiration of gastric acid are additional causes of interstitial pneumonia in cats. The lesions are, in most cases, not etiologically specific and *definitive diagnosis requires laboratory support.* FCV can be isolated from early lesions. Immunohistochemistry and polymerase chain reaction are alternative methods of diagnosis.

Bacterial diseases

Bacterial pneumonia is uncommon in cats. The most common isolates are *Pasteurella multocida* and *Bordetella bronchiseptica*. These agents are carried in the nasopharynx of most healthy cats, and development of pulmonary infection requires that the normal lung defenses be impaired or overwhelmed. In addition to infection with *Felid herpesvirus 1* or *Feline calicivirus*, the predisposing causes are analogous to those described for canine bacterial bronchopneumonia.

Welsh RD. *Bordetella bronchiseptica* infections in cats. J Am Anim Hosp Assoc 1996;32:153–158.

Chlamydial diseases

Chlamydophila felis (formerly *Chlamydia psittaci*) is of most importance as a *cause of persistent conjunctivitis in cats.* It is a minor contributor to upper respiratory disease in cats and, despite the disease name "feline pneumonitis," does not apparently cause pulmonary infection or disease.

Bibliography

Masubuchi K, et al. Experimental infection of cats with *Chlamydophila felis*. J Vet Med Sci 2002;64:1165–1168.

Mycoplasmal diseases

Mycoplasma felis, M. gatae, M. arginini, and *Acholeplasma laidlawii* often colonize the upper respiratory passages of cats. Limited evidence suggests that mycoplasmas are probably not important primary causes of respiratory disease in cats. Mycoplasmas can be isolated from tracheobronchial washes of 20% of cats with pulmonary disease, but from few normal cats. As in dogs, the significance of this finding is complicated by the potential for mycoplasmas secondarily to colonize lungs that are diseased for other reasons. Kittens could be experimentally infected with *M. felis, M. gatae, and M. arginini*, but did not develop clinical signs of respiratory disease. Unclassified *Mycoplasma* spp. have been isolated from pulmonary abscesses and lesions of suppurative pleuritis in cats.

Parasitic diseases

Toxoplasmosis

Toxoplasmosis is described more fully in Vol. 2, Alimentary system. Lung lesions are most commonly identified in kittens, and consist of *pinpoint white foci or diffuse interstitial pneumonia* (Fig. 5.95), either alone or as a component of multisystemic disease. Histologically,

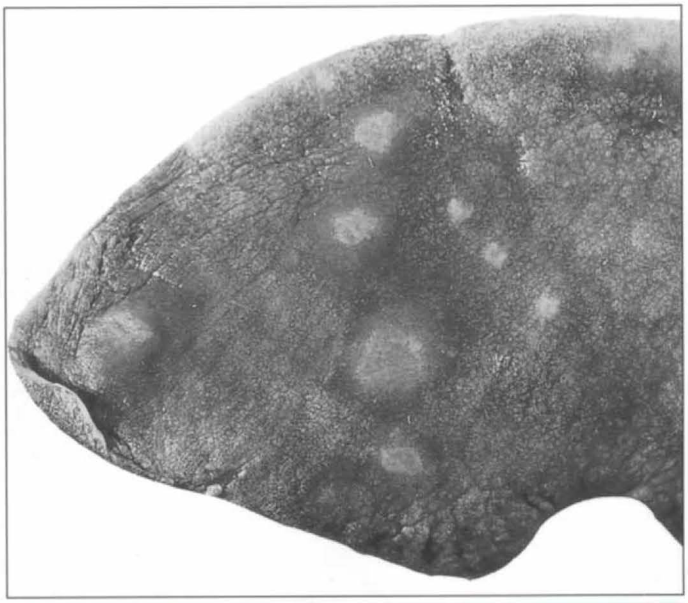

Figure 5.95 Toxoplasmosis in a cat. Multifocal necrotizing interstitial pneumonia.

there are multifocal to diffuse alveolar lesions, consisting of fibrin exudate or hyaline membranes, fibrinonecrotic debris in alveoli, proliferation of type II pneumocytes, and infiltration of neutrophils, mononuclear cells, and variable numbers of eosinophils. *Diagnosis* requires identification of cysts in the interstitium or in alveolar lining cells (Fig. 5.96).

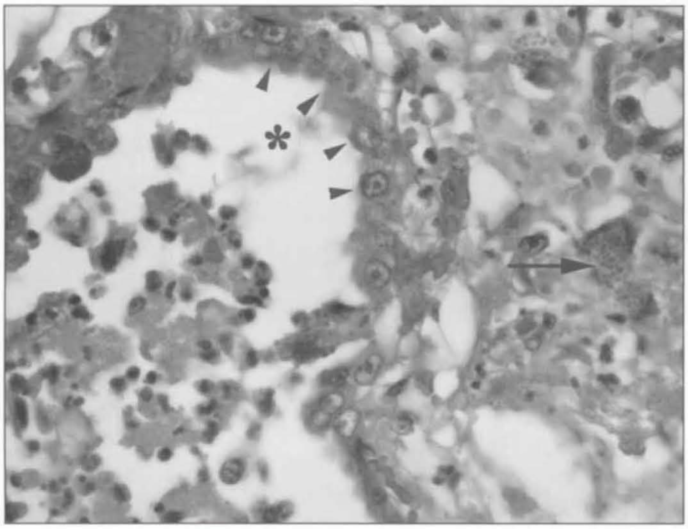

Figure 5.96 Toxoplasmosis in a cat. The alveolus (asterisk) is lined by cuboidal epithelium (arrowheads). A protozoal cyst is present in the interstitium (arrow).

Aelurostrongylus abstrusus

Aelurostrongylus abstrusus is a moderately common lungworm of cats. Many cats with nodular lung lesions display no clinical signs, but heavy infections cause chronic coughing or increased respiratory rate.

A. abstrusus is a nematode of the superfamily Metastrongyloidea, family Angiostrongylidae. The adults, which are slender and up to 1 cm long, live in the terminal and respiratory bronchioles. The eggs form nodular deposits in alveoli, where they embryonate and hatch to give first-stage larvae. The larvae reach the airways, are coughed up and swallowed, and are passed in the feces. Snails and slugs are intermediate hosts, while birds, rodents, frogs, and lizards are paratenic (transport) hosts. The life cycle can be completed if a cat eats either an intermediate host or a paratenic host. Infective larvae migrate to the lungs and reach maturity ~4–6 weeks after ingestion of the third-stage larvae.

Heavy infections in the prepatent period result in randomly distributed hemorrhages or white foci, which represent an eosinophilic and granulomatous reaction to the migrating larvae. *In the patent period, there are 1–10 mm diameter, firm, yellow, protruding nodules scattered throughout the lungs.* In severe infections, nodules may coalesce to form confluent areas of consolidation.

Microscopically, *the nodules are formed by masses of eggs and larvae in the alveoli and terminal bronchioles, with fewer adult worms* (Fig. 5.97). Eosinophils and neutrophils infiltrate the early lesions, but most cases are dominated by mononuclear cells and giant cells in the alveoli and around degenerating eggs and larvae. Alveoli are dilated and alveolar septa may be disrupted. Necrosis and mineralization seldom occur. Lymphocytic nodules form around vessels and airways, and there is hypertrophy and hyperplasia of the smooth muscle in the walls of the bronchioles and alveolar ducts. The presence of adult worms, eggs, or larvae in the bronchioles is associated with chronic catarrhal and eosinophilic bronchiolitis. In older lesions from which eggs and larvae have disappeared, alveoli remain epithelialized and septa are persistently thickened by fibrous tissue and smooth muscle.

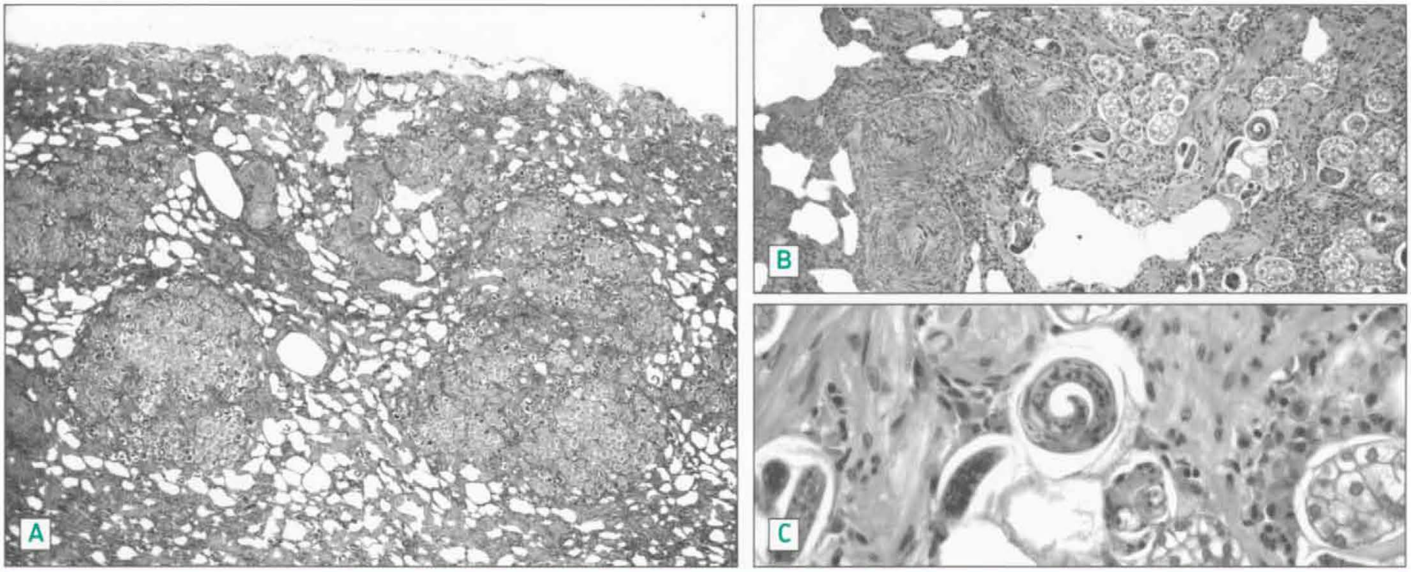

Figure 5.97 ***Aelurostrongylus abstrusus* infection** in a cat. **A.** The lung contains multiple subpleural nodules. **B.** Medial hypertrophy of pulmonary arteries and hyperplasia of smooth muscle in terminal bronchioles and alveolar septa. **C.** Nodules are filled with nematode adults, coiled larvae, and eggs.

Bronchial submucosal glands and smooth muscle in the media of small pulmonary arteries and arterioles may be quite prominent in cats infected with *Aelurostrongylus*, but these changes are also common in clinically healthy cats that have no evidence of parasitism.

Paragonimus kellicotti

Of the *trematodes*, the only genus that has its final habitat in the lungs is *Paragonimus*. *Paragonimus kellicotti* occurs in the USA, and *P. westermanii* in the Far East. Mink and other fish-eating carnivores are the usual hosts of *P. kellicotti*, but it infects many other species. Among domestic animals, it is *most commonly found in cats* and occasionally in dogs. Clinical signs are usually absent in animals with paragonimiasis.

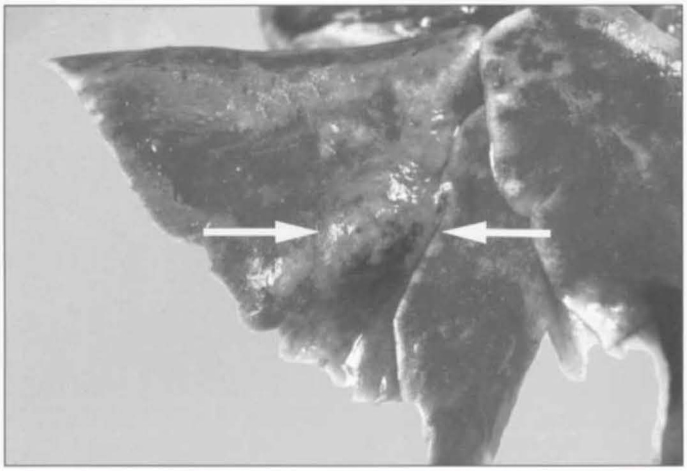

Figure 5.98 ***Paragonimus kellicotti*** infection in a cat. The caudal lung lobe contains a raised 1-cm-diameter nodule (arrows) containing an adult trematode.

The life cycle of the parasite is typical of the trematodes. The first intermediate hosts are small aquatic snails. The second intermediate host is a freshwater crab or crayfish. When the crayfish is eaten by the definitive host, the metacercariae are liberated in the intestine and migrate across the peritoneal and pleural cavities to the lungs. Their passage through the pleura is marked by multiple small hemorrhages and foci of eosinophilic and fibrinous pleuritis that heal as small umbilicated scars. Adult flukes are ovoid, red-brown, and up to 17 mm in length. They are often found in pairs in inflammatory cavitations in the pulmonary parenchyma and occasionally in the bronchi. The cavitations frequently communicate with bronchioles, permitting liberation of eggs into the airways, expulsion to the nasopharynx, and passage in the feces.

The cavitations, which are more common in the caudal lobes, are spherical, 1–3 cm diameter, soft, and dark red-brown (Fig. 5.98). The cavitations contain intense eosinophilic and granulomatous inflammation, hemorrhage with numerous hemosiderin-laden macrophages, a fibrous capsule, and adult flukes. The adults exhibit characteristic features of trematodes: the body is filled with loose parenchyma and there is no body cavity, paired ceca contain dark pigment, oral suckers are present in some sections, the tegument has surface spines, and vitellaria beneath the tegument contain eosinophilic globular yolk material. In patent infections, there are numerous 80–100 μm long, yellow-brown, operculate eggs, which persist as fractured shells in chronic lesions (Fig. 5.99). As cavitations mature and establish connections with bronchioles, they become partially lined by cuboidal epithelium to form *true cysts*. At this stage, bronchioles contain eggs and eosinophilic exudate, with hyperplasia of peribronchiolar glands and smooth muscle. Other lesions include chronic catarrhal eosinophilic bronchiolitis, granulomatous pleuritis, and pleural lymphangitis associated with the presence of eggs. Rupture of the cysts may rarely cause pneumothorax.

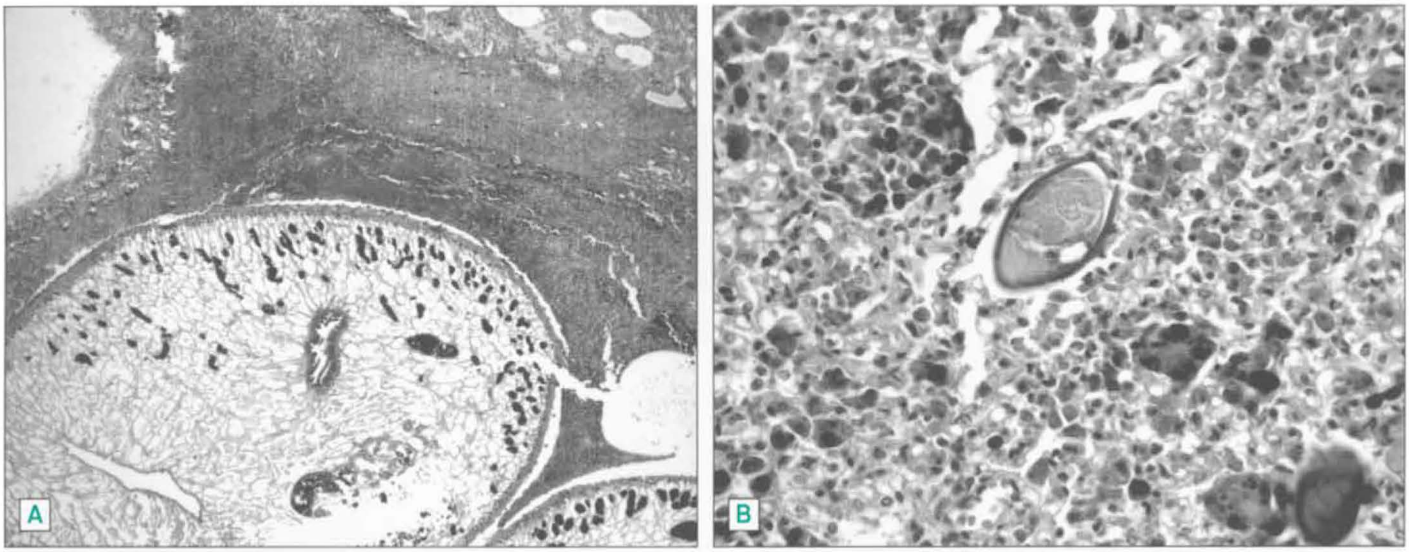

Figure 5.99 ***Paragonimus kellicotti*** **infection** in a cat. **A.** Adult trematode with adjacent atelectatic lung tissue. **B.** Operculate pigmented egg, with granulomatous inflammatory response.

Miscellaneous parasites

Mammomonogamus (*Syngamus*) *ierei* is a common nematode causing lymphocytic laryngitis of cats in the Caribbean. *Eucoleus aerophilus (Capillaria aerophila)* is described in the section on Infectious respiratory diseases of dogs, above. *Oslerus (Anafilaroides) rostratus* is a viviparous parasite of cats that causes sinuous thickenings of the walls of large bronchi, formed by adult worms within cystic spaces. When the adults die, they provoke intense infiltration of neutrophils, with eventual mineralization and fibrosis.

Troglostrongylus spp., bronchial nematodes related to *Crenosoma*, are found near the Dead Sea. *Vogeloides felis* and *Metathelazia spp.* are spirurid nematodes that inhabit the bronchial wall and lung parenchyma, respectively. Ascarid larval migration is common in the lung of kittens and puppies, and may cause mild coughing.

Diseases of the heart

The pathologic and functional changes observed in an organ or organ system are intimately related to the biology of the organ affected. We therefore first consider the normal form and function of the heart, and then its reaction to injury, under the anatomic units of the pericardium, endocardium, and myocardium.

NORMAL CARDIAC STRUCTURE AND FUNCTION

Gross anatomy

The heart is a **muscular pump** that sends oxygenated, nutrient-rich arterial blood throughout the body via the systemic circulation, and pumps de-oxygenated blood into the pulmonary circulation. Located within the mediastinum, the heart is enclosed in the fibroserous **pericardial sac**, which is lined by a serosal membrane and contains several milliliters of clear serous fluid that acts as a lubricant. **Heart weight** varies with species, age, sex, nutritional status, and fitness level of the animal, and averages about 1% of body weight in newborns, and decreases to 0.3–0.8% in juveniles and adults.

The heart consists of a right and left side; each side consists of an atrium and a ventricle. The ventricles function as two pumps in series. Venous blood from the body enters the **right atrium**, passes into the **right ventricle**, and is pumped through the pulmonary artery into the lungs to be oxygenated and to give up its carbon dioxide. Oxygenated blood returns via the pulmonary veins to the **left atrium**, enters the **left ventricle**, and is then pumped to the body via the aorta. Ventricular thickness varies greatly. Left ventricular free wall and interventricular septum are normally 2–4 times thicker than the right ventricular free wall. *An increase in myocardial mass is termed* **hypertrophy**; *an increase in chamber volume is termed* **dilation**. *An overall increase in cardiac size is termed* **cardiomegaly**.

The four cardiac valves are structured to allow unimpeded unidirectional blood flow, to prevent backflow, and to withstand high pressure. The **atrioventricular (AV) valves**, supported by tendinous cords (chordae tendineae) and papillary muscles of the ventricles, allow flow from the atria into the ventricles and prevent backflow into the atria. The right AV (RAV, tricuspid) valve has 3 valve cusps; the separation into 3 cusps may be difficult to discern. The left AV (LAV, bicuspid) valve consists of 2 cusps. The **pulmonic and aortic semilunar** (crescent moon-shaped) **valves** each have 3 cusps, and they allow flow into the pulmonary artery and aorta respectively and prevent backflow into the ventricles. The nodules (*nodules of Arantius*) in the center of the free edges of the semilunar valve cusps are normal structures. Valve cusps are normally thin and translucent. The free edges of the valve cusps (*cooptation region*) normally overlap during closure, and therefore fenestrations of the valve edges are usually insignificant. Normal valvular function depends on coordinated actions of the respective annulus and leaflets, and in the case of AV valves, the tendinous cords, papillary muscles, and ventricular walls.

The cardiac muscle and valves are supported at the base of the heart by the **cardiac skeleton**, *which consists of four fibrous rings, the fibrous triangle, and the fibrous or membranous part of the ventricular septum*. The fibrous triangle fills the space between the atrioventricular openings and the base of the aorta – it consists of dense fibrous connective tissue in pigs and cats, fibrocartilage in dogs, hyaline cartilage in horses, and bone (*os cordis*) in large ruminants.

The **blood supply to the heart** is primarily via two major coronary arteries. The *left and right coronary arteries* arise, respectively, behind the left and right cusps of the aortic valve at the base of the aorta. The left coronary artery gives rise to the left descending and the left circumflex coronary arteries. The epicardial coronary arteries give rise to the intramural arteries that penetrate the myocardium. Most coronary arterial blood flow occurs during ventricular diastole, when the coronary microcirculation is not compressed by myocardial contraction.

The **conduction system of the heart** consists of specialized conduction fibers that initiate and conduct an electrical impulse. The **sinus node** (sinoatrial node, SA node) is located subepicardially at the junction of the cranial vena cava and the right auricle. The impulse from this pacemaker causes atrial depolarization and contraction, and travels through internodal bundles to the **atrioventricular (AV) node** located in the interatrial septum just cranial to the coronary sinus. The impulse is delayed in the AV node before traveling via the **AV bundle** (bundle of His) to the **left and right bundle branches**, or crura, before terminating in **Purkinje fibers**. These modified myocardial cells ramify within the myocardium and transmit the depolarizing impulse to ventricular myocytes.

The components of the conduction system have different rates of diastolic depolarization, with the sinus node the most frequent and dominant. The frequency of depolarization of the sinus node is in turn modified by the autonomic nervous system. Atrial and ventricular myocytes do not normally exhibit the property of automaticity. When injured, however, the myocytes may repeatedly depolarize independent of a stimulus from the conduction system and may become dominant pacemakers. There are diseases that specifically affect the conduction system, but in domestic animals dysrhythmias are usually the result of disease involving the atrial and ventricular myocytes.

Histology

The cardiac wall has three layers:

1. the **epicardium**, the outermost layer;
2. the **myocardium**, the thick muscular middle layer; and
3. the **endocardium**, the innermost layer, which is continuous with the tunica intima of the great vessels entering and leaving the heart.

The **epicardium**, or visceral pericardium, consists of a thin layer of mesothelium resting on elastic fiber-rich connective tissue that merges with that of the myocardium. The epicardium is continuous with the **parietal pericardium**, which consists of an inner mesothelial layer and a thick layer of collagen and elastic fibers. The cavity between the visceral and parietal pericardium contains serous fluid that lubricates the surfaces and provides frictionless cardiac motion. Although the **pericardial sac** is not a vital organ, its proper function includes prevention of sudden cardiac dilation; assurance of equal end-diastolic transmural pressures throughout the ventricles; limitation of right ventricular stroke work; hydrostatic compensation for gravitational or inertial forces; reduction of friction; and maintenance of cardiac alignment and streamlined cardiac flow.

The **myocardium** consists of unique striated muscle cells – **cardiac myocytes** – embedded in a well-vascularized connective tissue framework. Individual myocytes are intimately joined at intercalated discs in order to function as a unit, and account for about 2/3 of the myocardial volume. Each myocyte consists of a single, central nucleus; mitochondria; contractile myofibrils composed of actin and myosin; sarcoplasmic reticulum that stores calcium needed for contraction; and the cell membrane (sarcolemma) and T tubules needed for impulse conduction. Myocytes may be binucleate in some species, e.g., dogs, and are commonly multinucleate in pigs (4–16 nuclei per cell). The actin and myosin filaments comprise contractile units called **sarcomeres**, which are demarcated by Z lines. Mitochondria occupy about 20–30% of the volume of cardiac myocytes versus 2% in skeletal muscle, reflective of the great dependence of cardiac muscle on aerobic metabolism. Sarcomere length varies from 1.6 to 2.2 μm; *ventricular dilation increases sarcomere length, which enhances contractility (Frank–Starling relationship)*. Atrial cardiac myocytes are typically smaller than ventricular cardiac myocytes; specific granules in atrial myocytes contain the hormone **atrial natriuretic factor** (ANF).

The cardiac **interstitium** contains blood vessels and fibroblasts in a diverse extracellular matrix that consists of collagens, proteoglycans, noncollagenous glycoproteins, growth factors and cytokines, and extracellular proteases. The collagen network of the heart is arranged into 3 interconnected regions: the collagenous weave of the *endomysium* around individual fibers, the *perimysium* around groups of fibers, and the *epimysium* around the whole muscle. This fibrillar collagenous network of the myocardium prevents over-stretching of myofibers, transmits myofiber-generated force to the chamber, and provides tensile strength and stiffness to the chamber. The collagenous struts that connect adjacent myofibers provide proper alignment during contraction. Struts that connect myocytes to capillaries help to maintain capillary patency during high intraventricular pressure.

As do all tissues, the myocardium has a limited set of *reactions to injury*, but the pattern and distribution of lesions may aid in arriving at a morphologic and etiologic diagnosis. The stage of irreversible damage to a myocyte, at least in ischemia, is determined by structural and functional changes in the mitochondria. Irreversible damage occurs after only 30 min of ischemia, whether or not flow is restored.

Only in neonatal hearts are cardiac myocytes able to *regenerate*. Once the neonatal period passes and a particular myocyte or group of myocytes is lost, there is no replacement. There is progressive scavenging of the necrotic remnants of the myocytes and replacement by fibrosis. Remaining myocytes do have the capacity for *compensatory hypertrophy*.

Myocardial injury may be functionally manifest as either irregularities in the rate or rhythm of impulse formation and conduction (dysrhythmias), or as depression in the force of myocardial contraction. **Dysrhythmias** are usually associated with acute, often focal myocardial injury. **Contractility disturbances** occur when there are either insufficient numbers of ventricular myocytes for effective contraction, or when there is ineffectual contraction of normal numbers of myocytes. Generalized, ineffective myocardial contraction is most commonly seen as a feature of dilated cardiomyopathies.

The **endocardium** lines the heart and consists of a monolayer of *endothelium* on a continuous basement membrane, covering the *inner subendothelial layer* of dense collagen, and the *outer subendothelial layer* composed of collagen, elastin, and blood and lymph vessels. The **atrioventricular (AV) valves** are endocardial infoldings with a central layer (*fibrosa*) of dense irregular connective tissue covered by layers of elastic fibers and, on the ventricular side, loose connective tissue (*spongiosa*). The central collagen of the AV valves is continuous with the dense collagen of the *chordae tendineae*, which are attached to the ventricular papillary muscles. The **aortic and pulmonic semilunar valves** consist of a *ventricularis* layer of collagen and radially aligned elastin on the ventricular side, a central *spongiosa* layer of water and glycosaminoglycans, and a *fibrosa* layer of collagen and elastin arranged in a circumferential direction on the great vessel side of the valves to resist back pressure of blood. Valve cusps are predominantly avascular.

Valvular abnormality from any cause can lead to disturbances of blood flow through the heart either by altering the normal unidirectional pattern of flow, or by impeding the chamber inflow or outflow. Alterations in hemodynamics reflect changes in systolic workloads characterized by changed pressure loading during contraction (*afterload*), or changed volume loading during diastole (*preload*). Most disorders have only a single preload or afterload change imposed. This encompasses all of the valvular disorders that cause either **insufficiency** (*failure to close*) or **stenosis** (*narrowing, failure to open*). Some of the congenital heart abnormalities, such as tetralogy of Fallot, have multiple preload and afterload effects. The general rules are:

1. valvular insufficiency increases the preload on the ventricle;
2. semilunar valvular stenosis, outflow tract stenosis, and hypertension increase the afterload on the ventricle
3. AV valvular stenoses and pericardial disorders decrease the preload on the ventricles.

The **coronary arteries** feed a dense capillary network that supplies the myocardium, endocardium, epicardium, cardiac skeleton, and bases of the cardiac valves. Blood collected by venules and veins is drained into the right atrium via the *coronary sinus*. Lymphatic capillaries draining the cardiac connective tissue, and are continuous with larger lymph vessels in the endocardium and epicardium. Sympathetic and parasympathetic innervation is extensive in the atria, and particularly around the SA and AV nodes.

HEART FAILURE

Heart failure *is the end-point of a number of causes, rather than a specific disease*, and denotes a situation in which all compensatory mechanisms have been exhausted, and the heart is unable to meet the demands of the animal. The syndrome is characterized by *diminished cardiac output ("forward failure")*, or *damming back of blood in the venous system ("backward failure")*, or both. The heart can fail because of **impaired pump function** or because of **increased cardiac work demands** – both mechanisms may be operative in some cases. The heart can fail as a pump because of

1. decreased myocardial contractility, or loss or replacement of myofibers, or
2. decreased distensibility (*compliance*), or
3. dysrhythmia (abnormal heart rate and/or rhythm).

Increased cardiac work demands on one or both ventricles result from disturbed hemodynamics, in the form of sustained *pressure overload* (e.g., obstructed flow in aortic valvular stenosis) or *volume overload* (e.g., regurgitant flow in mitral valvular regurgitation).

Congestive heart failure *is characterized by vascular congestion and edema fluid within the interstitium and body cavities.* Not all cases of heart failure are of the congestive type. While in congestive heart failure the clinical manifestations are more or less constant, in **acute heart failure** there may be intermittent weakness and syncope caused by a substantial change in heart rate or rhythm resulting in a precipitous drop in cardiac output. The effect of acute heart failure is often sudden unexpected death, often with minimal lesions. **Circulatory failure, or shock**, *denotes a state of inadequate peripheral vascular perfusion* and is used to describe a state that may or may not be the result of heart failure. It is characterized by a drop in effective circulating blood volume. Common causes are acute internal or external hemorrhage, dehydration, or endotoxic shock. Shock can of course lead to acute heart failure.

Based on clinical manifestations, heart failure may be predominantly either left-sided failure or right-sided failure. **Left-sided failure** *results in left atrial dilation, pulmonary congestion and edema*, and clinical signs of dyspnea and cough. A prominent feature of chronic left-sided heart failure is the presence of hemosiderin-laden macrophages ("*heart failure cells*") in pulmonary alveoli, the result of diapedesis of red cells into the alveoli. **Right-sided failure** *results in excessive right atrial pressure and systemic venous congestion*, expressed as jugular distension, hepatic and splenic enlargement, ascites, and peripheral edema. **Cor pulmonale** *is defined as right heart failure secondary to pulmonary disease*, such as chronic obstructive pulmonary disease, dirofilariasis, or pulmonary thromboembolism. Because the cardiovascular system is closed, failure of one ventricle will ultimately lead to failure of the other, culminating in global or **biventricular failure**.

While there are many causes that lead to intermittent or permanent lowering of effective cardiac output, there is a limited set of responses to this by the animal. The major compensatory mechanisms include the **intrinsic cardiac responses** *of dilation and hypertrophy*, and the **systemic responses**, *which include increased heart rate and peripheral resistance, redistribution of blood flow, venular constriction, and increased blood volume.* In each case, the compensatory responses are at least temporarily beneficial and are directed toward increasing cardiac output to meet the metabolic needs of the animal. The range within which the compensatory mechanisms result in an increase in cardiac output is wide. Indeed, the increase may be up to five times the basal rate. As cardiac output falls below the requirements of the animal, signs of congestive heart failure appear.

These may be intermittent or prolonged, depending on the nature of the defect.

An untoward side effect of the systemic responses is increased capillary hydrostatic pressure that leads to the accumulation of **edema fluid.** This can involve the systemic or pulmonary veins. *Right-sided lesions*, such as right atrioventricular valvular insufficiency, pulmonic stenosis, or pulmonary hypertension, result in peripheral dependent edema [e.g., submandibular edema ("bottle-jaw"), brisket edema], ascites, hydrothorax, and hydropericardium. *Left-sided defects*, such as left atrioventricular or aortic valvular insufficiency cause pulmonary edema as the predominant finding.

Intrinsic cardiac responses in heart failure

Cardiac dilation

Dilation is a response to an increased workload in both physiologic and pathologic states. Increasing the end-diastolic volume, and hence stretching the myofibers, can increase the contractile force of the heart and increase the stroke volume and cardiac output. This is known as the **Frank–Starling relationship**, or heterometric autoregulation. Transient cardiac dilation is an acute response to increased demands, e.g., increased exercise. Continued stretch increases contractile force to a limit, after which increased stretch will result in a decrease in tension developed. The limit of stretch in most species appears to be a sarcomere length of 2.2–2.4 μm. Chronic dilation of a ventricle can occur through addition of sarcomeres and hence lengthening of myocytes.

Various disease conditions can cause an increased diastolic workload (preload) and hence dilation of the heart, such as arteriovenous shunts, and atrioventricular and semilunar valvular insufficiencies. *Acute volume overload of a chamber is expected to lead to physiologic dilation*, whereas chronic volume overload is one stimulus to the development of cardiac hypertrophy.

Cardiac hypertrophy

Cardiac hypertrophy is a reversible increase in the mass, but not the number, of myocardial cells. In general, **chronic pressure overload** *leads to myocardial hypertrophy*, whereas **chronic volume overload** *leads to combined ventricular dilation and hypertrophy*. Hyperplasia, or increase in the number of cells, is not an option as a myocardial response to workload given that the capacity of the myocyte to divide decreases rapidly prior to birth, and little mitotic activity is observed after the first few weeks of life. Cardiac hypertrophy is a compensatory response to an increase in mechanical work or to trophic signals, e.g., stimulation of β-adrenergic receptors in hyperthyroidism. The following discussion will be concerned only with the process of hypertrophy following a defined change in workload or stimulation. The presence of hypertrophy in the absence of an observable increase in workload will be considered to be primary and is discussed under the cardiomyopathies.

For hypertrophy to occur, there are requirements of **time, a healthy myocardium, and adequacy of nutrition of the myocardium.** The mass and size of the heart are increased through the actions of mechanical stimuli (stretch) and trophic stimuli (polypeptide growth factors; vasoactive agents such as angiotensin II and α-adrenergic agonists) that increase the rate of protein synthesis, the amount of protein in each cell, the size of myocytes, and the number of sarcomeres and mitochondria. The hypertrophic response is accompanied by selective up-regulation of several immediate early-response genes and embryonic forms of contractile and other proteins. The phenotype of the hypertrophic myocyte may be changed by this expression of embryonic genes, e.g., induction of atrial natriuretic factor occurs in ventricular myocytes, and late response genes such as β-myosin heavy chain and skeletal α-actin may be expressed (a switch from adult to fetal/neonatal forms). Other genes are also activated and selectively regulated in hypertrophy, including immediate early genes or proto-oncogenes that encode early regulatory factors (*c-jun*, *c-fos*, *egr-1*); growth factors (transforming factor-β, insulin-like growth factor, fibroblast growth factor), vasoactive agents (α-adrenergic agonists, endothelin-1, angiotensin II), and components involved in receptor-mediated signaling pathways, such as protein kinase C.

Physiologic hypertrophy of the myocardium in response to strenuous exercise is an extension of the normal growth process, and is usually without deleterious effect. However, *in pathologic states, hypertrophy is an adaptive response of limited benefit.* Hypertrophic myocytes have impaired intrinsic contractility and relaxation; impaired ventricular relaxation and compliance cause increased end-diastolic pressure and limited exercise performance. Once further muscle mass cannot meet the demands posed by increased workload, heart failure ensues. Degenerative changes occur in myofibers, including loss of myocardial contractile elements. Limitations to continued hypertrophy and the reasons for eventual myocardial failure include inadequacy of the vascular supply to the enlarged fibers, diminished oxidative capacity of mitochondria, altered protein synthesis and degradation, and cytoskeletal alterations. The capillary density in hypertrophic myocardium typically does not keep pace with myofiber size, intercapillary distances increase, and fibrous tissue is deposited in the interstitium ("*reactive interstitial fibrosis*"). Also, the altered isoforms of proteins produced by expression of fetal genes may be less functional than adult forms. Myocyte hypertrophy occurs only if increased protein synthesis exceeds the rate of degradation. Similarly, hypertrophy of the ventricle occurs only if growth of individual myocytes exceeds the apoptotic loss of myocytes; excessive apoptosis can contribute to failure of a hypertrophic heart. This postulate is supported by experimental work with receptor-mediated Gαq signaling of cultured rat cardiac myocytes (Gαq is the α subunit of the Gq family of G proteins, guanine nucleotide-binding proteins, which transduce signals) – moderate levels of Gq signaling stimulate cardiac hypertrophy, whereas high-level Gq activation results in cardiac myocyte apoptosis.

There are distinctive anatomic patterns of hypertrophy that accompany the increase in workload. **Concentric cardiac hypertrophy**, *that is, an increase in mass of the ventricle without accompanying increase in end-diastolic volume*, characterizes increased systolic loads (*increased afterloads*), such as aortic stenosis, pulmonic stenosis, and pulmonary hypertension in patent ductus arteriosus. There is often a decrease in the volume of the ventricular lumen. An increase in diastolic load (*increased preload*), typically produced by atrioventricular or semilunar valvular insufficiencies or by arteriovenous shunts, results in **eccentric cardiac hypertrophy**, *which is an increase in myocardial mass accompanied by increased end-diastolic volume (dilated chamber).* Because of dilation, the thickness of the involved ventricular wall is usually no more than normal and may be less.

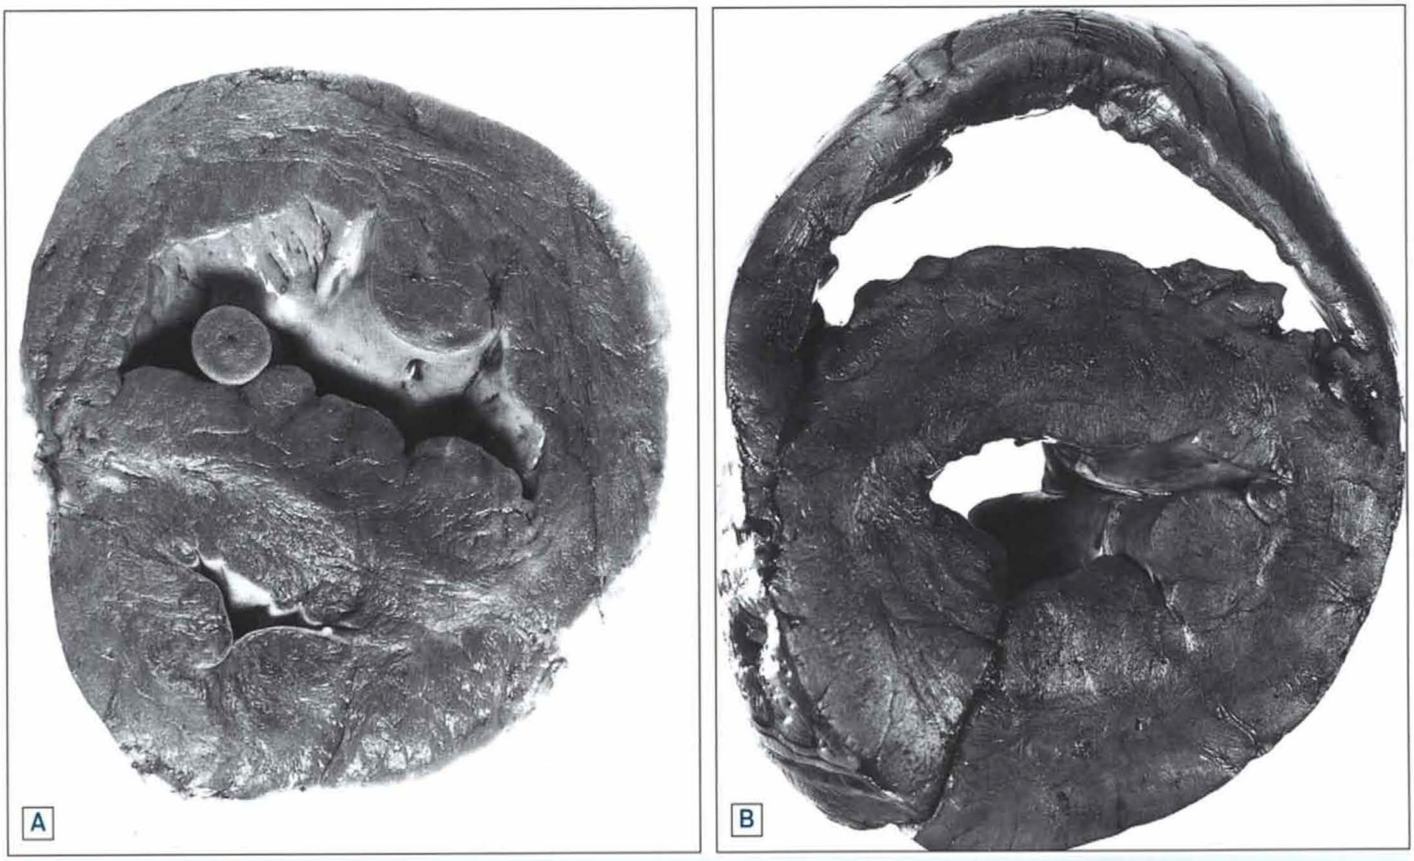

Figure 1.1 Myocardial hypertrophy. **A.** Cross-section of heart of a cow with chronic interstitial pneumonia. The **right ventricle** is greatly hypertrophied. Note marked increase in size of trabecula septomarginalis (moderator band). **B.** Cross section of heart of a dog with chronic glomerulonephritis. The **left ventricle** is hypertrophic and encroaching on the diastolic capacity of the right ventricle.

The gross appearance of the hypertrophic heart depends on the chamber affected and the nature of the insult. In general, hypertrophy of the right side of the heart makes the heart broader at its base; hypertrophy of the left side increases the organ length; bilateral hypertrophy produces a more rounded shape than normal.

In *concentric hypertrophy*, there is increased thickness of the wall of the affected chamber, and a marked increase in the size of the papillary muscles and the trabeculae carneae. Although the hypertrophy may emphasize one or other chamber, the whole heart is involved. When the right ventricle is involved, the moderator band (trabecula septomarginalis) may be much thickened (Fig. 1.1A). Extreme hypertrophy of one chamber may encroach on the diastolic capacity of its opposite number (Fig. 1.1B). Microscopically, the myocytes are enlarged, but the increase in the size of fibers is not uniform and is not always easy to discern on routine microscopy.

In *eccentric hypertrophy and dilation*, the heart tends to be globose, and even though the mass is increased, the wall is usually thin. The papillary muscles may also be attenuated.

In both types of hypertrophy and dilation, the endocardium may be diffusely opaque as a result of subendocardial fibrosis, and this alteration may be the best indication of dilation in the atria, in which dilation and hypertrophy can be difficult to assess.

An example of concentric cardiac hypertrophy occurs in cats with **hyperthyroidism** (thyrotoxicosis), a condition usually due to the presence of thyroid hyperplasia or adenoma. The thyroid glands in these cases are unilaterally or bilaterally enlarged, nodular, pink to dark-brown, and may contain cysts. Microscopically, the thyroids usually exhibit a mixture of hyperplastic areas, adenomatous nodules, and normal follicles (see also disorders of the thyroid gland in Vol. 3, Endocrine glands). The pathogenesis of ventricular hypertrophy in this disease is not clear, but may involve the direct action of thyroid hormones on myocardium, enhanced myocardial adrenergic receptor number or affinity, peripheral vasodilation, and work hypertrophy in response to increased peripheral tissue demands for oxygen and dissipation of heat. The hearts in most cases are symmetrically hypertrophied; however, some exhibit asymmetric hypertrophy. The left ventricular lumen is usually reduced in size. Affected myofibers are enlarged, but are not in disarray in the great majority of cases. The hypertrophy is reversible on return to euthyroidism.

Systemic responses in heart failure

The *extracardiac features of heart failure* stem from two basic pathophysiologic changes: **fluid accumulation** and **tissue or organ ischemia**. Depending on the cause of the heart failure, both effects may be present, but it is more usual for one to predominate.

Fluid accumulation results from the retention of sodium and water, which primarily involves the kidneys, and also involves atrial natriuretic factor released from the heart. The influence of the failing heart on the kidneys stems from its inability to supply them with an adequate flow of blood. Blood flow through different parts of the kidneys depends on the vasomotor tone of blood vessels within the parenchyma. It is considered that many, if not all, of the intrarenal blood flow changes in heart failure follow increased activity of the sympathetic nervous system.

The kidneys receive approximately 20% of the output of the left ventricle, almost all of which flows through the renal cortices. One of the earliest changes following a drop in cardiac output is redistribution of blood flow within the kidney. There is reduced flow through the outer renal cortex and increased flow within the outer renal medulla. This results in readjustment of the *filtration fraction*, which is the ratio of glomerular filtration rate (GFR) to renal blood flow. Contrary to expectations, there is a *less* than proportionate drop in GFR compared with renal blood flow resulting in an *increased* filtration fraction. As a consequence, proportionally more sodium moves through the glomerular filter, leading to proportionally more sodium being delivered into the proximal convoluted tubule. Because the rate of sodium resorption remains constant, a greater number of sodium ions are resorbed. Also, because of the increased filtration fraction, local plasma osmotic pressure in the efferent arteriole increases, causing greater resorption of sodium and water.

The alteration in renal blood flow in heart failure also increases the activity of the **renin–angiotensin–aldosterone** system, producing more sodium resorption from the distal convoluted tubule. There is also increased water-retaining activity by **antidiuretic hormone**.

A mechanism within the heart also regulates blood volume complementing the activity of aldosterone and the renin–angiotensin system. **Atrial natriuretic factor** (ANF), with natriuretic and diuretic properties, is present in granules in some of the atrial myocytes. If the atrial pressure is elevated or the atria are distended, ANF is released and causes natriuresis, vasodilation, suppression of the renin–angiotensin–aldosterone axis, and decreased arterial blood pressure. *In terms of homeostasis, ANF has effects opposite to those of aldosterone, thus providing a balance to fluid regulation.* Although plasma ANF is significantly increased in dogs with chronic left AV valvular insufficiency, it is not clear whether the metabolic effects of aldosterone or ANF predominate, but it would appear that the effects of aldosterone override those of ANF.

It should be noted that none of the hormones mentioned produce the edema of congestive heart failure if administered alone. In addition, once a new steady state has been reached, the hormonal state returns to relatively normal limits. Lastly, *the mechanisms that are brought into play are not exclusive to the syndrome of heart failure.* Any situation that leads to a drop in effective circulating blood volume will activate the sodium- and water-retaining mechanism. The fundamental difference between these states and congestive heart failure is that the total blood volume in heart failure is already more than adequate, but the *effective blood volume* is much diminished because of the poor cardiac output. The volume changes in heart failure should be viewed as an integrated response by the body to compensate for the inability of the heart to respond to the normal hemodynamic needs of the body.

The expansion of blood volume has both a beneficial and a detrimental effect. By increasing blood volume, venous return is enhanced and, in turn, cardiac output and tissue perfusion are improved. However, this is to the detriment of the balance between capillary hydrostatic pressure and plasma osmotic pressure. This leads to an increase in the amount of fluid in the interstitial spaces and body cavities.

Syndromes of circulatory failure

Circulatory failure, the term implying severe systemic consequences, falls into three general categories: cardiac syncope, peripheral circulatory failure, and congestive heart failure.

Cardiac syncope

Cardiac syncope is characterized clinically by profound changes in blood pressure and heart rate with bradycardia or tachycardia, either of which may result in inadequate output of blood. Both may occur in the presence or absence of organic heart disease.

In one form of cardiac syncope, hypersensitive or hyperactive reflexes, for which the vagus nerve is the efferent limb, may result in reflex inhibition of the heart, manifest as extreme bradycardia or as asystole. The sudden deaths that result from acute pleural irritation or the tracheal irritation of aspirated vomitus fall into this group, and obviously there may be no organic heart lesion.

In a second form of cardiac syncope, the heart rate is extremely rapid, and the cardiac output severely reduced. Such may occur in paroxysmal tachycardia, atrial flutter or fibrillation, and ventricular fibrillation.

Third, in organic heart disease with complete obstruction of impulse conduction from the atrium to the ventricle (complete heart block), syncope may occur if there is sufficient delay before the ventricle assumes an independent rhythm.

Finally, cardiac syncope may terminate a syndrome of congestive cardiac failure when the cardiac reserve is depleted and the heart cannot increase its output sufficiently to meet sudden increases in peripheral needs.

Peripheral circulatory failure

Peripheral circulatory failure is characterized by reduction in the effective circulating blood volume with insufficient venous return and reduced cardiac output. Acute hemorrhage and shock are examples of this form of circulatory failure.

Congestive heart failure

The combination of compensatory mechanisms, brought into play to maintain cardiac output, is in general successful. However, there is also the planting of the seeds of destruction. Both the local increase in venous hydrostatic pressure and the increased sodium and water retention by the kidneys tend to promote the development of interstitial edema. Depending on the inciting abnormality, it is usual for one side of the heart to fail before the other, but it must be remembered that the cardiovascular system is a closed circuit and that failure of one side will eventually embarrass the other.

Left-sided heart failure is ushered in by progressive dilation of the left ventricle and atrium, although this progression may be marked by exacerbations and remissions if hypertrophy is given time to develop. The major extracardiac manifestations of left-sided failure arise from the damming back of blood in the lungs and the diminution in cardiac output. The *pulmonary venous congestion* is transmitted back to the capillaries of the alveolar wall, and edema fluid accumulates in the interstitial tissue and the alveolar spaces. The consequent reduction in pulmonary vital capacity and impaired gaseous exchange of cardiogenic pulmonary edema result in hypoxic stimulation of the carotid sinus and medullary respiratory centers so that *reflex dyspnea* occurs. A *wheezing bronchial cough* is common and is presumed to be due to irritation of the respiratory mucosae by the edema fluid. Cyanosis may be present but is more often the rule in right ventricular failure.

At necropsy the **lungs** are usually of normal color, but may be light brown, and are heavy and wet. Stable, white froth is present in the airways, and fluid exudes from the cut surface. There is little evidence of the abundant fluid on microscopic examination, because of its low protein content. The alveoli contain erythrocytes and a scattering of macrophages, some of which contain hemosiderin. It may be necessary to use a differential stain for iron to confirm the presence of these so-called "*heart-failure cells*" or siderophages. They are more numerous in chronic disease, and hemosiderin within their cytoplasm may be sufficient to produce tawny discoloration of the lungs.

In **right-sided heart failure**, the major extracardiac manifestations depend on increased hydrostatic pressure in the systemic and portal venous systems, and the reduction of flow from the lungs to the left ventricle. Renal complications occur more frequently in right-sided than in left-sided heart failure, leading to increased blood volume, peripheral edema, and more marked azotemia.

There is some species difference in the **distribution of edema** in congestive heart failure. In ruminants and horses, *dependent subcutaneous edema* is expected; in the other species, excess subcutaneous fluid is scant or absent. In dogs, the predominant accumulation of fluid is in the *peritoneal cavity*. In cats, it is in the *thorax*.

Grossly the **liver** is enlarged and congested and has a "nutmeg" appearance on section due to *chronic passive congestion*. Microscopically the sinusoids are dilated, with atrophy of the parenchyma about the central veins. In more severe or acute cases, the parenchyma in this location may undergo degeneration or necrosis. It is exceptional for an animal with congestive failure to live long enough for severe fibrosis and nodularity to occur. Impaired hepatic function is not usually a significant part of the clinical course, although jaundice may be observed.

Congestion of the **stomach and intestines** is evident and this may impair their function, which is manifest usually as diarrhea. In horses, the subserosal lymphatics, particularly of the large bowel, are often readily discernible, dilated, and filled with edema fluid. The systemic and portal veins are distended and the **spleen** is enlarged and congested. However, this latter finding is masked if the animal in question has been euthanized using barbiturates.

Figure 1.2 A. Gross examination of the heart (see text for details). (1) Transect apex of heart and examine ventricular walls. (2) Open right atrium from caudal vena cava to the tip of the right atrial appendage. (3) Follow blood flow through right ventricle. (4) Cut right ventricular free wall adjacent to septum and out pulmonic valve. (5) Right ventricle and pulmonary trunk opened: moderator band transected. (6) Open left atrium. (7) Open left ventricle towards the apex. (8) Left ventricle opened and left atrioventricular valve exposed: aorta may be opened as indicated by arrow.

EXAMINATION OF THE HEART

In a **gross postmortem examination** of the heart, it is important to examine four major areas: pericardium, myocardium, mural and valvular endocardium, and the great vessels. A useful system is to follow the route of blood flow through the heart, that is, an inflow–outflow method of dissection (Fig. 1.2A). This technique may require modification in the case of cardiac anomalies. Examination of the heart in the planes used for echocardiographic examination could be beneficial.

- The initial examination of the heart and great vessels is best made with the organs in situ to assess abnormalities of size and position.
- Incise the pericardial sac and examine the pericardial fluid before the thoracic viscera are removed; note the volume and color of the fluid, the presence of fibrin, etc.
- Remove the thoracic viscera and examine the external surfaces of pericardium, epicardium, and great vessels.
- Open the abdominal aorta in situ to the iliac bifurcation and examine for thrombi and verminous arteritis; remove the aorta with the abdominal viscera in a horse to better examine the cranial mesenteric artery and its branches.

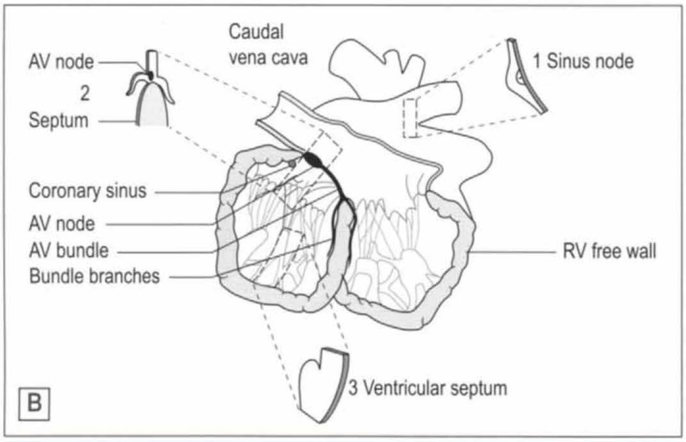

Figure 1.2 B. Tissue sampling from the heart. The cardiac conduction system can be assessed via **block 1**, in which the *sinus node* is located subepicardially in the terminal groove at the junction of cranial vena cava and right atrial appendage, and **block 2**, in which the *atrioventricular node* is located subendocardially on the right side of the interatrial septum, just cranial to the coronary sinus; serial sections through this block will reveal the AV node, the common bundle, and the origins of the bundle branches. A block through the *left ventricular free wall including papillary muscle*, or **block 3** through the ventricular septum, is the minimal representative sample to take from a grossly normal heart.

Table 1.1 Heart weight:body weight (HW/BW) ratios and left ventricular free wall plus septum:right ventricular free wall [(LV + S)/RV] ratios in necropsy accessions of cattle without significant cardiovascular disease

Age	HW/BW (%) (*n*)	(LV + S)/RV (*n*)
<7 days	0.91 (5)	1.69 (5)
7–30 days	0.90 (6)	2.13 (6)
3–365 days	0.48 (9)	2.78 (10)
>1 year	0.48 (11)	2.78 (15)

- The heart may be detached from the lungs if anomalies are absent, but it is usually better left attached to allow careful examination of vessels, e.g., pulmonary artery for thrombi.
- Examine the atria, ventricles, and coronary arteries externally, and confirm normal relationships.
- *When opening the heart, always inspect structures before cutting, and try to preserve a stenotic or dilated valve or vessel.*
- Transect the ventricles in their lower third perpendicular to the long axis of the heart, and check for hypertrophy and/or dilation, myodegeneration or necrosis, mineralization, fibrosis, and mural thrombosis. The apex may remain hinged to the remaining heart. Do not transect the apex if an apical ventricular septal defect is suspected.
- Open the *right atrium*, from the caudal vena cava to the tip of the atrial appendage. Note any thrombus, and check the tricuspid valve and the foramen ovale/fossa ovalis. Leave the cranial vena cava unopened, as a block of tissue to include the *sinus node* may be taken at the junction of the cranial vena cava and the right auricle. Examine the right atrioventricular valve (RAV, tricuspid valve) before cutting.
- Open the lateral side of the *right ventricle* adjacent to the ventricular septum. Examine the RAV and chordae tendineae. The septal leaflet of the RAV is normally thicker than the free leaflets. Transect the moderator band (trabecula septomarginalis).
- Cut through the rostral wall of the right ventricle, and open the *pulmonic valve* if there is no stenosis. Check the pulmonary arteries for thrombi, especially in animals with indwelling jugular catheters. Note the patency or closure of the ductus arteriosus (bear to the right when opening the pulmonary artery in neonates to avoid cutting through a patent ductus arteriosus and creating a false anomaly).
- Open the *left atrium* by cutting into the atrial appendage and then parallel to the ventricular groove. Examine the interatrial septum, foramen ovale/fossa ovalis, and the left atrioventricular valve (LAV, mitral valve).
- Open the *left ventricle* by cutting along the caudal border of the left ventricle adjacent to the ventricular septum, examining the LAV before cutting it. Chordae tendineae should be carefully examined before opening the LAV to ensure that pre-existing ruptures of the chordae are detected.
- Continue to follow the blood flow by cutting through the *aortic valve* and cutting along the aorta – note that the pulmonary artery will be transected by this action.
- The circumference of the four cardiac valves may be measured at this time with a flexible ruler. Normal LAV/RAV valve ratio for dogs is 0.66.

The right ventricle is responsible for systemic circulation in the fetus. Hence, in neonatal hearts, the wall thickness of the left and right ventricles is approximately equal; it is not until a month or more after birth that the mature proportions are attained. Ventricular wall thickness is poorly correlated with ventricular mass, and heart weights provide more valid information about ventricular hypertrophy than do thickness measurements, especially in cases of dilation and eccentric hypertrophy. *To accurately assess cardiac mass, the heart should be weighed and the weights compared to body weight.* After removing the pericardial sac and post-mortem blood clots, weigh the whole heart, right ventricular free wall, and left ventricular free wall plus septum.

- The ratio of normal heart weight to body weight (HW:BW) ranges from 0.5 to 1.0%, depending on age and species (Tables 1.1 and 1.2).
- The HW:BW ratio is higher in neonates than in adults; the more athletic species (horses, dogs) have higher HW:BW ratios; HW:BW ratio is increased by training or exercise; and males typically have greater HW:BW ratios than do females of the same species.
- The ratio of the weight of the left ventricle plus septum divided by the weight of right ventricular free wall [(LV +S)/RV] is 2.8–4.0 in mature animals; (LV +S)/RV >4.0 indicates *left ventricular hypertrophy*; (LV +S)/RV <2.8 is consistent with *right ventricular hypertrophy*.

The usual tissue block taken for routine **histology** is of left ventricular papillary muscle, as this area is one of the most susceptible to damage and most representative in cases of generalized disease. Detailed examination of the heart, including the conduction system, requires collection of tissue blocks (Fig. 1.2B) from the junction of the cranial vena cava and right auricle (sinus node), both atria, the interatrial septum/dorsum of the ventricular septum at

Table 1.2 Reference values for heart weight:body weight (HW/BW) ratio and ventricular ratio [(LV + S)/RV] in normal mature animals at necropsy

the base of the heart just cranial to the coronary sinus (atrioventricular node), right ventricular free wall and AV valve, ventricular septum, left ventricular free wall/papillary muscle and AV valve, great vessels, plus any grossly evident lesions.

The selection of sections to study the **specialized conduction system** should include the sinus node, the atrioventricular node, the common bundle (bundle of His), left and right crura (bundle branches), and conducting fibers. The **sinus node** lies subepicardially in the terminal groove (sulcus terminalis) at the junction of the cranial vena cava and the right atrium. Sections should include either side of that site, to incorporate tissue in the sulcus terminalis region. The **atrioventricular node** is obtained by removing a block of tissue from the coronary sinus to the cranial edge of the septal leaflet of the right AV valve. The block includes interatrial septum and dorsal ventricular septum, and will then contain the atrioventricular node, which is located subendocardially on the right side of the interatrial septum, the common bundle, and the left and right crura. The specimen should be serially sectioned into samples 3 mm thick, and all samples should be processed.

In routine cases, there are no special requirements for fixation. Stains of particular use are hematoxylin and eosin, Masson's trichrome, phosphotungstic acid hematoxylin, Luxol fast blue, and Gomori's aldehyde fuchsin.

Note that *rigor mortis* begins earlier in myocardial than in skeletal musculature, and reaches greater development in the more powerful left ventricle. Rigor should completely express the blood from the left ventricle; rigor of the right ventricle is less efficient, and emptying is incomplete. The presence of some clotted blood in the right ventricle is normal, whereas if present in the left ventricle it is indicative of incomplete rigor and therefore perhaps of severe myocardial degeneration. The presence of unclotted blood in the left ventricle some hours after death is more difficult to interpret. Unclotted blood – the result of fibrinolysis – may flow back into the ventricle when rigor passes.

Blood usually clots slowly after death and permits erythrocytes to sediment. Where blood is present in volume, as in the heart and arterial trunks, this process of sedimentation and subsequent clotting leads to the formation of "currant jelly" and "*chicken fat*" *clots*, the former containing erythrocytes, and the latter largely devoid of them. "Chicken fat" clots are to be expected in horses, which normally have a rapid erythrocyte sedimentation rate, and are in relative excess in anemia. Postmortem **clots** are to be distinguished from **thrombi**; clots are not attached to the endocardium.

Biopsy of the heart in not commonly undertaken in vivo, but is possible via transvenous **endomyocardial biopsy**. Multiple biopsy samples of the right ventricular myocardium may be obtained by this means, and may be used, for example, to monitor the cardiotoxic effects of anthracycline therapy.

CONGENITAL ABNORMALITIES OF THE HEART AND LARGE VESSELS

In the transition from fetal to neonatal life, substantial adjustments occur within the cardiovascular system: there are alterations in the pressures in cardiac chambers and great vessels, the pattern of blood flow, and the volume of blood flow. Because of these changes, the retention postnatally of fetal vascular communications, such as the ductus arteriosus, may place an excessive load on the heart in the postnatal period and beyond. There are also congenital heart defects, such as pulmonic stenosis, which compromise the fetus, the newborn, and the adult. It is typically only those defects that allow adequate in utero development and a reasonably successful perinatal life that are recognized; anomalies sufficiently severe to cause death in utero, or in the neonatal period, often are not.

As with most diseases, there is a spectrum of change. *The variation in severity of a particular lesion may be wide and will necessarily influence whether clinical signs are observed.* As such, there is a higher incidence of congenital heart disease than is recognized clinically. There is also a group of congenital heart diseases that do not produce clinical signs of heart failure, but which are manifested by upper alimentary dysfunction. Although little is known of the causes of many cardiac malformations in domestic mammals, there is no doubt that, especially in dogs, *some are genetically determined.* The demonstration that some congenital heart diseases are genetically determined arose from the observation that the incidence of defects was higher in purebred populations. It has been thought that both patent ductus arteriosus and conotruncal defects have a polygenic inheritance pattern, where the full expression of these diseases depends on the inheritance of a number of genes from different loci. However, studies on Keeshonds with conotruncal defects indicate that the inheritance pattern is most compatible with a single autosomal locus. The data suggest the presence of a mutant allele that is partially penetrant in heterozygotes and fully penetrant in homozygotes. Congenital subaortic stenosis in the Newfoundland dog is also genetically determined; it may either be polygenic or a single dominant gene that is variably expressed. Table 1.3 outlines the breed-specific predisposition to congenital heart disease in the dog.

There may be other as yet undefined factors that contribute to the development of congenital heart disease in domestic animals. In humans, cardiac and vascular anomalies are common features of several syndromes produced by chromosomal abnormalities and viral infections such as rubella. There is little evidence to suggest the presence of similar abnormalities or infections associated with congenital heart disease in domestic animals.

Table 1.3 Breed-specific predispositions to congenital heart disease in dogs

Defect	Breed
Patent ductus arteriosus	Bichon Frise, Chihuahua, Cocker Spaniel, Collie, English Springer Spaniel, German Shepherd, Keeshond, Kerry Blue Terrier, Maltese Terrier, Pomeranian, Poodle, Shetland Sheepdog, Yorkshire Terrier
Pulmonic stenosis	Airedale Terrier, Beagle, Chihuahua, English Bulldog, Fox Terrier, Mastiff, Miniature Schnauzer, Samoyed, Scottish Terrier, West Highland White Terrier
Subaortic stenosis	Boxer, English Bulldog, German Shepherd, German Shorthaired Pointer, Golden Retriever, Great Dane, Newfoundland, Rottweiler, Samoyed
Persistent right aortic arch	German Shepherd, Great Dane, Irish Setter
Tetralogy of Fallot	English Bulldog, Keeshond
Atrial septal defect	Doberman Pinscher, Samoyed
Ventricular septal defect	English Bulldog
Tricuspid insufficiency or dysplasia	German Shepherd, Golden Retriever, Great Dane, Labrador Retriever, Weimaraner
Mitral insufficiency or dysplasia	Bull Terrier, English Bulldog, Chihuahua, German Shepherd, Great Dane

The pattern and incidence of congenital cardiac disease varies with the species examined. In **dogs**, patent ductus arteriosus, pulmonic stenosis, and subaortic stenosis are common (Table 1.4). In **cattle**, atrial and ventricular septal defects and transpositions of the main vessels are most frequently diagnosed. Subaortic stenosis and endocardial cushion defects are the most frequent anomalies in **pigs**. In **cats**, endocardial cushion defects and congenital mitral insufficiency appear to be common. Congenital cardiovascular disease is quite uncommon in **horses**.

In cases of suspected cardiac abnormality, it is essential to examine the heart and large vessels in situ because relations are difficult to trace once the organ is removed. Some animals are born with hearts that, although of normal arrangement, are very small. In the majority of cases of cardiac abnormality, the anomaly is reflected in gross enlargement of the organ and in alteration of the size or disposition of the large vessels. Cardiac malformations are extremely variable, and their analysis can be perplexing if it is not remembered that they do follow fairly simple basic patterns. The recognition of the primary abnormality is an essential first step. This then assists in the recognition of secondary abnormalities, which develop as adjustments to allow blood to circulate through the heart. An understanding of the mechanics of abnormal development is necessarily based on an understanding of the normal development of the organ, for which reference should be made to a standard text of embryology.

There is no completely satisfactory system for classifying congenital heart defects, as defects may be complex or may overlap as

Table 1.4 Proportions (%) of canine congenital cardiac anomalies in four surveys

[b] *Includes tetralogy of Fallot.*

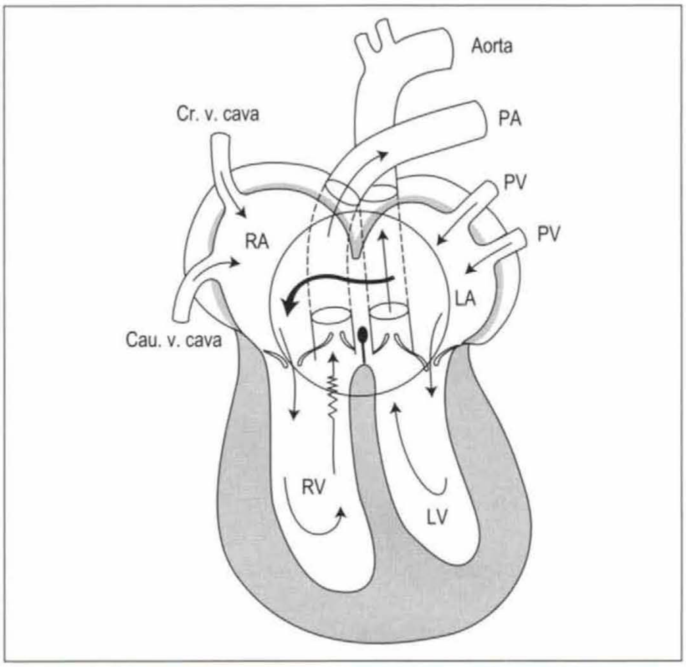

Figure 1.3 Atrial septal defect. Blood flows through the defect from the left atrium to the right atrium. The right ventricle dilates and hypertrophies under increased preload. A relative pulmonic stenosis is induced because of the increased volume in the right ventricle. Both atria also dilate following increased volume loads. Reverse shunts may occur with blood flowing from the right to the left atrium. (Figures 1.3, 1.5, 1.6, 1.7, 1.8, 1.10 from Robinson WF, Huxtable CRR, eds. Clinicopathologic Principles for Veterinary Medicine. Cambridge: Cambridge University Press, 1988, with permission. Abbreviations in these figures: LV, left ventricle; RV, right ventricle; LA, left atrium; RA, right atrium; PA, pulmonary artery; PV, pulmonary veins; Cr. v. cava, cranial vena cava; Cau. v. cava, caudal vena cava.)

part of a spectrum. Based on a combination of anatomical defects and functional effects, they may be classified as:

- malformations causing systemic to pulmonary (left-to-right) shunting,
- malformations of cardiac valves,
- transposition complexes,
- miscellaneous cardiac anomalies, and
- vascular anomalies.

Malformations causing systemic to pulmonary (left-to-right) shunting

In the development of the heart, there are three major arteriovenous communications: between the atria, the ventricles, and the great vessels. These connections are necessary for shunting of blood in the fetus. The atrial and ventricular septa close in utero; the foramen ovale and the ductus arteriosus close early in the neonatal period. Failure of closure results in *atrial septal defect, ventricular septal defect, or patent ductus arteriosus*, three of the more common congenital cardiac defects in domestic animals. Less common defects in this group include *atrioventricular septal defect, persistent truncus arteriosus, aorticopulmonary window*, and *anomalous pulmonary venous return*.

Atrial septal defect

In the fetus, separation of the left and right atria commences with the downgrowth of the *septum primum*, which grows toward the atrioventricular junction, where the developing endocardial cushions begin to form the atrioventricular valves and separate the ventricles. The septum fuses with the endocardial cushions, obliterating the *ostium primum*, and then begins to fenestrate in its middle. The fenestration is destined to become the *ostium secundum*. A second septum (*septum secundum*) develops downward and to the right of the septum primum. With its semilunar edge, the septum secundum and the remains of the septum primum form the **foramen ovale**. Within the left atrium, the septum primum forms the flap valve of the foramen ovale that allows blood flow from right atrium to left atrium in the fetus. In the majority of animals, anatomic closure of the foramen ovale follows functional closure postnatally. A *probe-patent foramen ovale* postnatally is not an atrial septal defect, for although the foramen ovale may not be anatomically closed, it is functionally closed (*valvular competent*) because left atrial pressure exceeds right atrial pressure.

An atrial septal defect can result from:

- defects of the septum between the right upper pulmonary veins and the cranial vena cava (**sinus venosus defect**),
- failure of fusion of septum primum with the endocardial cushions (**ostium primum defect**, low in the atrial septum adjacent to the atrioventricular valves, a form of atrioventricular septal defect), or
- an excessively large ostium secundum or inadequate development of the septum secundum (**ostium secundum defect**, in midseptum at the site of the fossa ovalis, the most common type).

The consequence of an atrial septal defect in the neonate is excessive flow from the left to right atrium, with resultant volume overload on the right ventricle and elevated central venous pressure (Fig. 1.3). In some cases, following the development of pulmonary hypertension, the flow through the defect is reversed, leading to cyanosis.

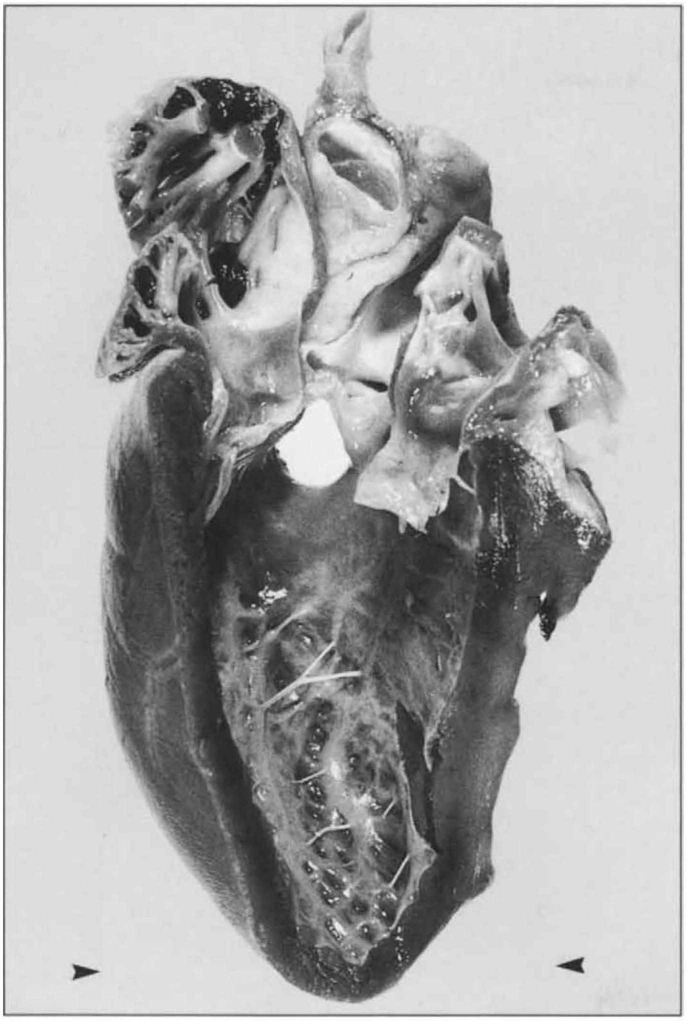

Figure 1.4 Ventricular septal defect in a goat. The defect is just below the aortic valve and the left ventricle is dilated. (5 cm between arrows.)

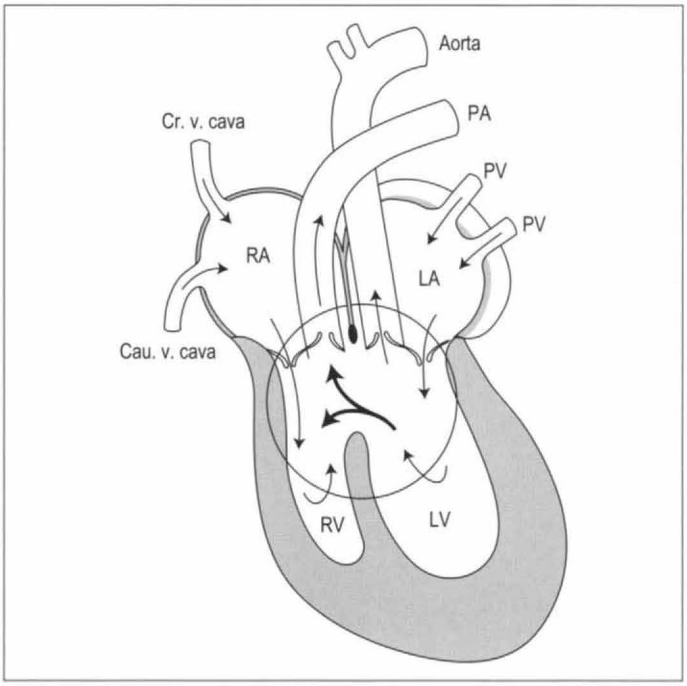

Figure 1.5 Ventricular septal defect. Both increased preload and afterload are imposed on the right ventricle by a VSD. The increased volume of blood returning from the pulmonary circuit also places increased preload on the left atrium and ventricle.

Atrioventricular (AV) septal defect

Also known as *endocardial cushion defects* or *atrioventricular canal defects*, these malformations arise from deficiency of the AV septum that separates the left ventricular inlet from the right atrium. The atrial septum primum must fuse with the endocardial cushions, which in turn contribute to the development of the atrial and ventricular septa, and to the medial leaflets of the left and right atrioventricular valves. Anomalous development may result in a range of anatomic defects, including *ostium primum defect (partial AV canal), ventricular septal defect with a cleft in the tricuspid valve*, or *common atrioventricular canal*. The common or complete AV septal defect consists of an ostium primum defect, a ventricular septal defect, and a common AV orifice.

Defects of the atrioventricular canal are among the most common defects in the pig. In the largest series examined, 40% of pigs with congenital heart disease had this defect. It is also a frequent finding in *cats*.

Ventricular septal defect

Ventricular septal defect (VSD) is one of the most common defects encountered in domestic animals. The separation of the left and right ventricles is completed by three parts of the embryonic heart: the muscular portion of the septum, the downward growth of the conotruncal ridges, and the membranous portion of the septum derived from the endocardial cushions. Defects can be related to defective development of any of the three parts. VSDs are usually single (Fig. 1.4), but may be multiple, and *most commonly involve the membranous septum*. This type of VSD is termed *paramembranous* or *perimembranous*, as they exceed the bounds of the membranous septum and involve a muscular defect at their periphery; they may also be referred to as subaortic or infracristal. Less common sites of VSD are *subpulmonary* (infundibular, conal, supracristal), *below the septal leaflet of the tricuspid valve*, or *in the muscular portion of the ventricular septum* towards the apex of the heart. While occurring most commonly as an isolated defect, VSD is also seen as part of a number of other defects, such as tetralogy of Fallot or persistent truncus arteriosus. There appears to be a high incidence of *spontaneous postnatal closure* of small VSDs in humans, and a similar phenomenon has been reported in dogs.

The presence of a VSD has no deleterious effect on the fetus because left and right ventricular pressures are equal and there is therefore little flow across the defect. *Postnatally, the effects of VSDs are related to the size of the defect and the level of pulmonic vascular resistance relative to the systemic resistance.* Pulmonary vascular resistance normally drops postnatally, leading to a *left-to-right shunt*. Left ventricular output is maintained by an increase in end-diastolic volume and augmentation of contractility by the Frank–Starling mechanism. Since right ventricular pressure equals left ventricular pressure, the right ventricle is confronted with a large systolic and diastolic load. *Both ventricles undergo hypertrophy*, the left being more obviously eccentric in nature (Figs 1.4 and 1.5).

Eventually, pulmonary hypertension can lead to shunt reversal (right-to-left), cyanosis, and death. The term **Eisenmenger complex** is applied to VSD cases in which, instead of the usual left-to-right shunt, flow has been reversed to a right-to-left shunt through the VSD as a consequence of severe pulmonary hypertension that is in turn due to high pulmonary vascular resistance. The more general term of **Eisenmenger syndrome** is applied to any anomalous circulatory communication (e.g., ASD, VSD, PDA) that leads to obliterative pulmonary vascular disease, with resulting reversal of the left-to-right shunt across the pulmonary-systemic communication.

Patent ductus arteriosus

Patent ductus arteriosus (PDA) is one of the more common defects, and it is recorded in all species. In the dog it has a polygenic inheritance pattern, and PDA may result from hypoplasia or asymmetry of ductal smooth muscle plus aorta-like elastic tissue in the ductus wall. The ductus develops from the sixth left branchial arch, and functions in the fetus to divert a major portion of blood from the pulmonary artery to the aorta. The flow from venous to arterial side is a consequence of the presence of the high vascular resistance of the fetal pulmonary bed. The structure of the normal ductus differs from the adjacent pulmonary artery or aorta. In contrast to the large elastic arteries, the media of the ductus has a dense layer of smooth muscle, which is responsive to a number of compounds. Among the most powerful are epinephrine, norepinephrine, and angiotensin; less effective ones include oxygen, acetylcholine, bradykinin, and indomethacin, a prostaglandin inhibitor. Prostaglandin E_2 keeps the ductus in a dilated state. Of the compounds mentioned, oxygen and acetylcholine are probably the most important in vivo in causing constriction.

With contraction of the medial smooth muscle, the ductus becomes functionally closed in the first few hours after birth. There are exceptions. The ductus in some foals may remain patent for up to 5 days, and a continuous murmur is detectable up to that time. A ductus arteriosus that remains patent beyond this time is considered to be abnormal. They are minimally responsive, or nonresponsive, to oxygen and other compounds that constrict the normal ductus.

Continued patency results in a number of sequelae that are dependent on the size of the PDA and the relationship between the pulmonary and systemic vascular resistance. In uncomplicated cases, the blood flow is from the aorta to the pulmonary artery *(left-to-right shunt)* during both systole and diastole. Depending upon the ensuing rise of pulmonary arterial pressure, there may be left-to-right flow only during systole. In severe cases, the shunt is reversed and flow from the pulmonary artery to the aorta *(right-to-left shunt)* occurs. If the ductus is of sufficient size, there is volume overload of the left ventricle and pressure overload of the right ventricle, resulting in compensatory hypertrophy of both ventricles. There is also left atrial dilation resulting from increased pulmonary blood flow (Fig. 1.6). The ascending aorta and pulmonary artery are dilated, probably resulting from a combination of turbulent flow and altered pressure relationships. The development of congestive heart failure with a large PDA is not only related to pulmonary vascular resistance, but also to the ability of the left ventricle to handle volume overload. In dogs where aorticopulmonary shunts were created experimentally, a communication of 3 mm or less in diameter may lead to the slow development of left ventricular hypertrophy, but it is otherwise well tolerated. A window of 5 mm in diameter may lead to pulmonary hypertension, with degenerative changes in pulmonary vessels and congestive heart failure.

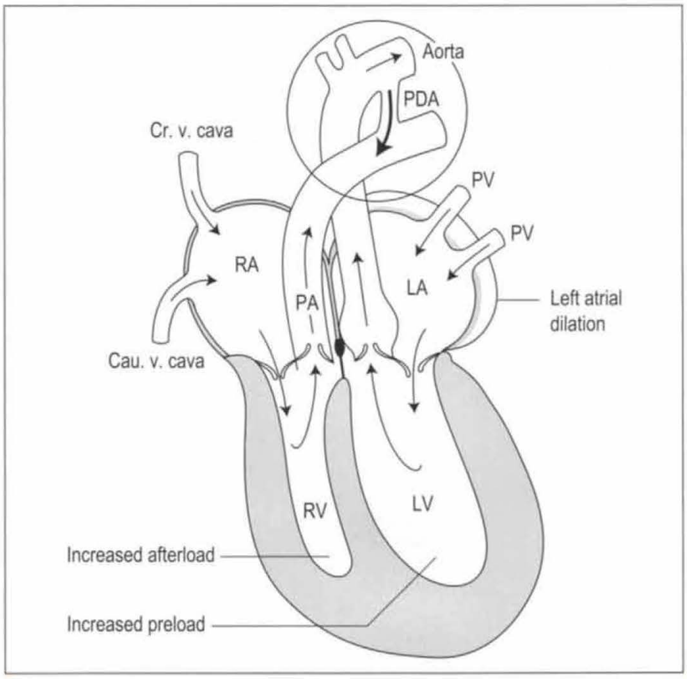

Figure 1.6 Patent ductus arteriosus. In most cases, blood flow through the PDA occurs during both systole and diastole from the aorta to the pulmonary artery. The right ventricle hypertrophies concentrically because of the increased afterload (increased pulmonary hypertension). The left atrium and ventricle hypertrophy eccentrically because of the increased preload (increased volume of blood returning from the pulmonary circuit). LV, left ventricle; RV, right ventricle; LA, left atrium; RA, right atrium; PA, pulmonary artery; PV, pulmonary veins; Cr.v.cava, cranial vena cava; Cau.v.cava, caudal vena cava.

As a consequence of turbulent flow, a PDA is predisposed to thrombosis, which is referred to as *endocarditis of the ductus*. The anatomic appearance of the PDA ranges from a *ductus diverticulum*, which is a blind funnel-shaped outpouching of the aorta at the site of the ductus, to a ductus that approaches the diameter of the aorta. The length of the patent ductus may also vary. In some cases there is virtually no ductus, but, instead, an opening between the aorta and pulmonary artery, which are closely approximated. Hypoplasia and asymmetry of ductus-specific smooth muscle and the presence of aorta-like elastic tissue in the ductus wall, as has been observed in some cases, may cause patency. In dogs, as the number of genes that determine its presence increases, the histologic appearance of the PDA more closely resembles the aorta, and the severity of the defect increases.

Malformation of semilunar or atrioventricular valves

Failure of adequate development of the semilunar valves usually results in valvular or subvalvular stenosis. Anomalous atrioventricular valves may be insufficient or stenotic or both.

Pulmonic stenosis

Pulmonic stenosis is a relatively common congenital anomaly in dogs, but an unusual finding in other domestic species. It is inherited in Beagles, and is suspected to be so in English Bulldogs, Bull Mastiffs, Chihuahuas, and terrier types. *The term pulmonic stenosis encompasses*

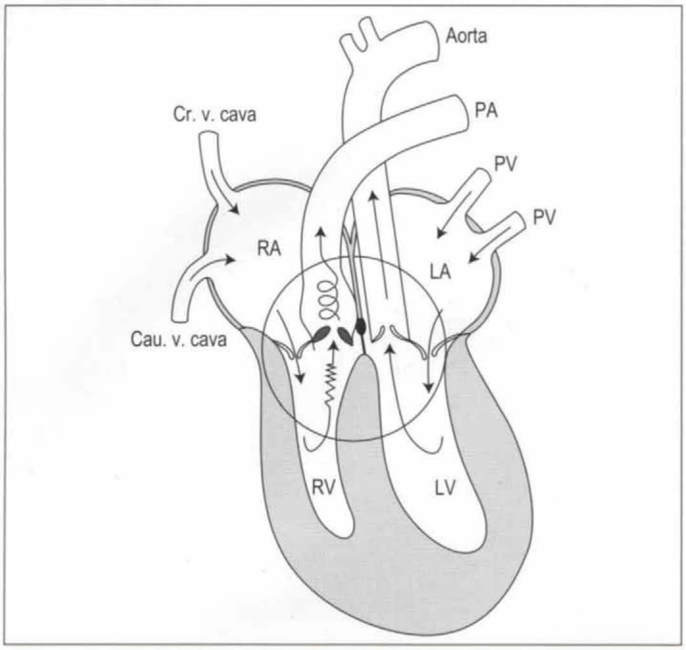

Figure 1.7 Pulmonic stenosis. The stenosis is almost always valvular and places increased afterload on the right ventricle, which undergoes concentric hypertrophy. There is also poststenotic dilation of the pulmonary artery.

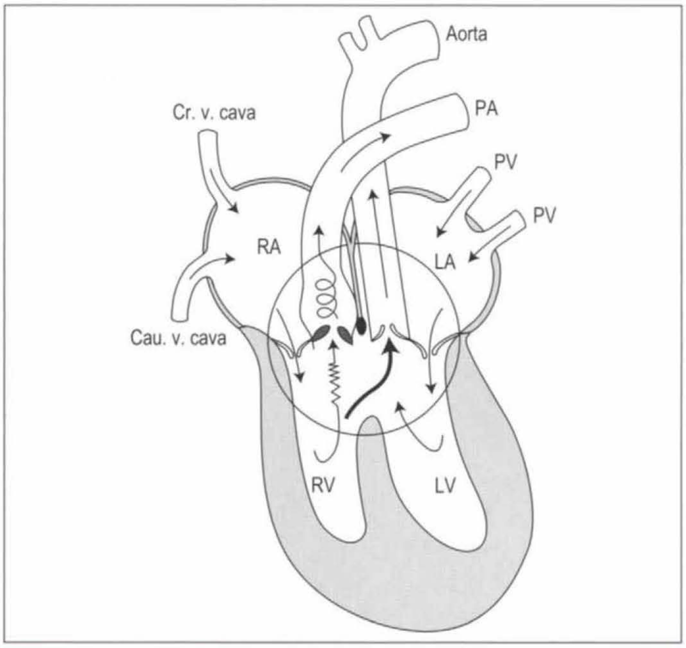

Figure 1.8 Tetralogy of Fallot. The severity of the pulmonic stenosis determines the predominant direction of blood flow. If severe, a proportion of the blood in the right ventricle flows into the aorta via the VSD. The right ventricle hypertrophies concentrically because of the increased afterload placed on it.

three anatomic variations: supravalvular, valvular, and subvalvular or infundibular stenosis. **Valvular stenosis**, the most common form in dogs, is probably due to disordered fusion of the valve cushions and their failure to hollow out properly. The valve, which is then more or less dome-shaped with an irregular central perforation, is surrounded by three recognizable sinuses of Valsalva that are small and irregular in form. **Subvalvular or infundibular stenosis** is produced by a ring of connective tissue that encircles the upper portion of the outflow tract of the right ventricle, or by hypertrophy of the crista supraventricularis muscle ridge. With each form, the pulmonary trunk is dilated and thin walled (Fig. 1.7). This is probably due to a combination of turbulent flow and a drop in pressure, creating a venturi effect in the pulmonary artery. *Concentric right ventricular hypertrophy* is always present because of the *increased afterload* placed on the right ventricle.

The primary lesion in **tetralogy of Fallot** is *obstruction to right ventricular outflow* either through pulmonic stenosis or infundibular stenosis that results from abnormal conotruncal partitioning. The other lesions in the tetrad are *ventricular septal defect, overriding aorta,* and *secondary right ventricular hypertrophy.* Tetralogy is one of the congenital heart diseases that invariably results in clinical signs. *Affected animals fatigue easily and are usually cyanotic and polycythemic.* The latter is a response to hypoxia. Growth rate is usually retarded. At least in Keeshonds, the condition is *inherited as a defect at a single autosomal locus* in which there is partial penetrance in heterozygotes and complete penetrance in homozygotes. Analysis of affected Keeshonds has revealed *various grades of malformation.* The spectrum of anomalies included: subclinical defects of the crista supraventricularis, ventricular septal defect, pulmonic stenosis with abnormal non-patent interventricular septum, and tetralogy of Fallot. Closure of the interventricular septum is contributed to by the conotruncal septum. The flow of blood from the right ventricle into the dextroposed aorta does not depend on the degree of overriding, but on the severity of the pulmonic stenosis (Fig. 1.8).

In English Bulldogs, the breed most commonly affected by pulmonic stenosis, the stenosis is frequently caused by a *circumpulmonary left coronary artery* that originates from a single right coronary artery. The cause of this syndrome appears to be malformation of the left aortic sinus of Valsalva and inversion of the proximal segment of the left main coronary artery.

Aortic and subaortic stenosis

Isolated congenital *aortic valvular stenosis* is distinctly uncommon. **Subvalvular aortic (subaortic) stenosis** is, in contrast, a common defect in pigs and is associated with what has been termed *endocardiosis of the left atrioventricular valve.* In one study of 321 pigs that had left atrioventricular valvular abnormalities (endocardiosis), 258 had accompanying subaortic stenosis. *Subaortic stenosis is among the more frequently encountered anomalies in dogs,* and it is often seen in association with left atrioventricular valvular disease. Dog breeds commonly affected include the German Shepherd Dog, Weimaraner, Golden Retriever, German Shorthaired Pointer, Saint Bernard, Newfoundland, and English Bull Terrier.

The *anatomic appearance of the subvalvular lesion* ranges from a number of small fibrous plaques on the endocardial surface of the interventricular septum, to a completely encircling fibrous band just below the aortic valve (Fig. 1.9A, B). There may also be involvement of the aortic valve. The subendocardial thickenings are composed of connective tissue in irregular arrangements, intermixed with abundant mucinous ground substance. The change is sometimes fibrocartilaginous in nature. Where there is an accompanying mitral valvular defect, it composed of a thickened, ridged and larger anterior leaflet, which forms part of the left ventricular outflow tract. The anterior leaflet forms about one-third of the cylinder that is the left

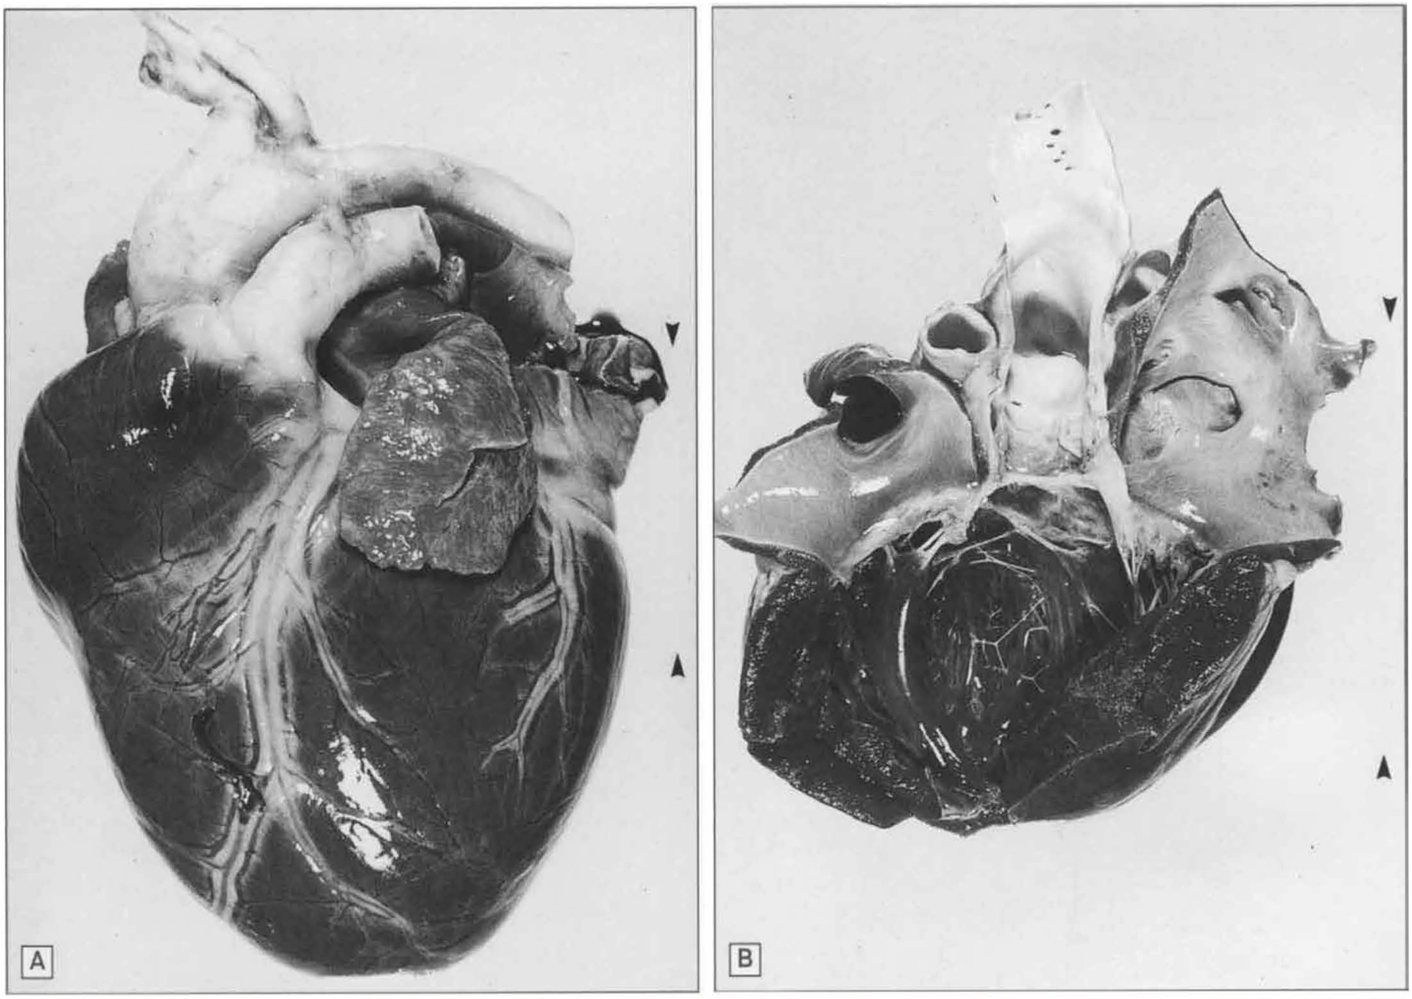

Figure 1.9 A. Subaortic stenosis in a dog. **A.** The left ventricle occupies most of the ventricular mass and the ascending aorta is dilated. (5 cm between arrows.) **B.** The opened left ventricle is concentrically hypertrophied and thick fibrous bands encircle the subaortic area. (10 cm between arrows.)

ventricular outflow tract and when abnormal completes the stenosing subaortic ring.

As with pulmonary outflow tract obstruction, *increased afterload on the left ventricle and turbulent post-stenotic flow produce compensatory concentric hypertrophy of the involved ventricle and post-stenotic dilation of the aorta* (Fig. 1.10). Intimal proliferation of collagen and deposition of glycosaminoglycans in the intramural coronary arteries is common. This may well explain the presence of multifocal myocardial necrosis and fibrosis, and the relatively common clinical finding of sudden death, presumably due to the generation of ventricular dysrhythmias following myocardial necrosis.

The *heritability* of this anomaly in dogs is either polygenic or involves a major dominant gene with modifiers. There is some question as to whether it is a true congenital lesion. In one experimental study, no dog exhibited the typical lesion before 25 days of age. There is also some evidence that the severity of the condition increases with age.

Dysplasia of the tricuspid valve

Dysplasia of the tricuspid valve appears to be one of the more common defects observed in the cat, but is uncommon in other domestic species. The anatomic characteristics of tricuspid dysplasia are focal or diffuse thickening of the leaflets, some of which may be absent, or short chordae tendineae and papillary muscles, and direct fusion of portions of the affected valve with the ventricular wall. In tricuspid dysplasia, *the valve is insufficient, the right atrium is enlarged, and the right ventricle is eccentrically hypertrophied.* The anomaly may be associated with malformation of the mitral valve complex or ventricular septal defect. In **Ebstein's anomaly** of the tricuspid valve, there is downward displacement of the basal portions of the valve into the right ventricle. The morphologically similar *canine tricuspid valve malformation* has been mapped to a susceptibility locus on chromosome 9 in several kindreds of purebred Labrador Retriever dogs. **Tricuspid atresia** – absence of the tricuspid orifice – is accompanied by an interatrial communication, right ventricular hypoplasia, and usually a VSD.

Mitral valvular insufficiency or stenosis

A mixed-frequency holosystolic murmur, with its point of maximum intensity on the left caudal sternal border, is indicative of mitral insufficiency. Commonly heard in old dogs with endocardiosis, it may also be associated with moderate to severe left-sided

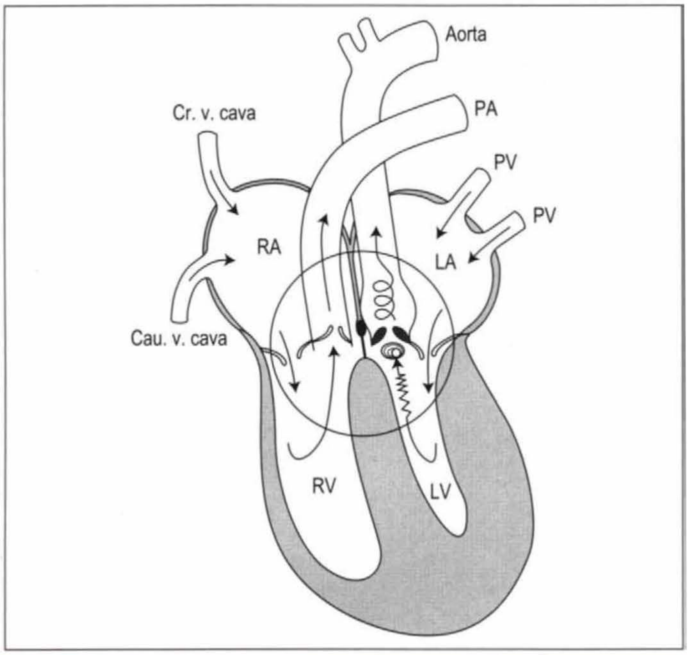

Figure 1.10 Aortic and subaortic stenosis. The left ventricle hypertrophies because of the increased afterload, and the aorta dilates distal to the stenosis.

failure in young dogs and cats. *Malformation of the mitral valve complex is probably the most common congenital cardiac anomaly in the cat.* The lesion has a relatively wide spectrum of severity, and *may result in either an insufficient or a stenotic valve.* Anatomically, there is an enlarged annulus, short thick leaflets, short thickened chordae tendineae, upward malposition of atrophic or hypertrophic papillary muscles, and enlargement of the left atrium and ventricle. There is also diffuse endocardial fibrosis. In dogs, the lesion has been most commonly seen in Great Danes, English Bull Terriers, and, to a lesser extent, German Shepherds.

Transposition complexes

Some of the more severe cardiac anomalies are a combination of defects of the aorta and pulmonary artery. Malposition or **transposition of arterial trunks** is a condition in which the aorta lies in relation to the pulmonary artery such that it receives blood from the right ventricle, the basic defect being *dextroposition of the aorta. There are four degrees, or types, of this anomaly:*

- *overriding aorta* – (the most common type), the aorta straddles the septum, which is defective, and receives blood from both ventricles, and the pulmonary artery leaves the right ventricle;
- *partial transposition* – both vessels leave the right ventricle;
- *overriding pulmonary artery* – the pulmonary artery straddles a defective ventricular septum and the aorta emerges from the right ventricle;
- *complete transposition* – the aorta emerges from the right ventricle and the pulmonary artery emerges from the left (Fig. 1.11).

It is usual in these transposition complexes for either the pulmonary artery or the aorta to be *hypoplastic.*

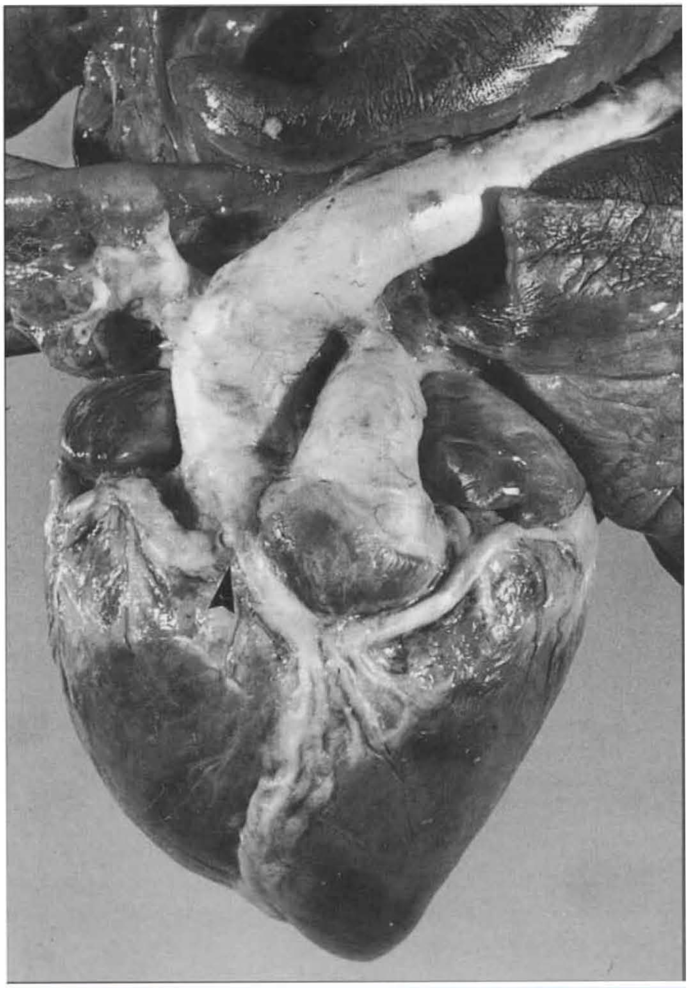

Figure 1.11 Complete transposition of aorta and pulmonary artery in a foal. Coronary arteries arise from a common trunk (arrowhead).

Miscellaneous cardiac anomalies

Congenital hematomas *(hemocysts) on the margins of the atrioventricular valves are common, especially in calves,* but appear to be of little consequence. These are usually blood-filled cysts lined by endothelium; they originate in the clefts normally present in the substance of the valves in intrauterine life. The cysts may measure up to 1.0 cm in diameter and be multiple. There is some question as to whether the cysts involute within a few months of birth, or whether they persist for a year or more, by which time the content is changed to serous fluid. A similar process, termed *valvular telangiectasis* in the septal cusp of the tricuspid valve in Beagles, has been reported to progress from telangiectasis through scarring and osseous metaplasia.

Primary endocardial fibroelastosis is characterized by diffuse endocardial thickening by collagen and elastic fibers, and left ventricular hypertrophy and dilation in the absence of any associated cardiac malformation. The fact that diffuse endocardial thickening occurs when any chamber of the heart remains dilated for a prolonged period has probably led to the confusion that exists about endocardial fibroelastosis. There have been reports in the literature describing the existence of this condition in a number of species, but the primary disease has only been well documented in cats and, to a lesser extent, dogs. The disease in affected Burmese kittens commences with localized endocardial lymphedema. This is detectable microscopically, but not grossly, at 1 day of age. Progressive deposition of endocardial collagen and elastin follows and allows macroscopic detection from 20 days of age. The left atrium is dilated, and the left ventricle is hypertrophied and dilated. The endocardial fibrosis progressively involves cardiac conducting fibers, which exhibit some degenerative change. Although not definitely established, there appears to be little doubt of the inherited nature of the disease.

False tendons are thin, often branching, structures that *traverse the cavity of the left ventricle* and are not connected to the valve cusps; they are common in domestic mammals. They are composed of cardiac muscle, blood vessels, fibrous tissue, and Purkinje cells. False tendons are of debatable significance, but may play a role in innocent murmurs and cardiac dysrhythmia.

Cor triatriatum (triple atria) is a rare lesion in cats and dogs resulting from failure of incorporation of the common pulmonary vein into the left atrium. A membrane separates the left atrium into two compartments, which can impede pulmonary drainage and lead to pulmonary edema. **Cor triatriatum dexter** (right atrium) can cause ascites.

Epithelial inclusions are found occasionally in ventricular myocardium in well-defined areas of discoloration or sponginess. The inclusions are present as acinar or ductular structures lined by a simple layer of cuboidal epithelial cells on a basement membrane. The inclusions are possibly of endodermal origin from the foregut and represent displacements arising very early in embryogenesis, when the heart rudiment is adjacent to the developing foregut.

Myocardial bridges are anatomical variants that are superficial myocardial bands that run across short segments of a coronary artery located epicardially in the dog, cat, goat, sheep, and human. The bridges appear to be of little functional significance.

Congenital absence of the pericardium occurs in dogs. Affected animals are usually asymptomatic.

Variations in the position of the heart are not cardiac malformations but, instead, malformations of adjacent structures:

- In **ectopia cordis**, the heart may lie in *extrathoracic, presternal, or intra-abdominal positions* (Fig. 1.12). Dislocations within the thorax are the result of asymmetric pressure, as for example, in congenital diaphragmatic hernia or pleural effusion.
- In **peritoneopericardial diaphragmatic hernia**, which occurs in dogs and cats, intestine and/or liver are present in the pericardial sac.
- **Dextrocardia** is a rare condition in dogs in which the apex of the heart, which normally points to the left (levocardia), points to the right. Dextrocardia may be part of *situs inversus*, in which the heart and other internal organs are transposed in a mirror-image fashion. *Kartagener's syndrome*, a rare condition in dogs, includes dextrocardia, sinusitis, and bronchiectasis, the last two features as a result of ciliary dyskinesia.

Vascular anomalies

Persistence of the right aortic arch is a well-known anomaly in dogs and has been observed in cattle. *It is due to persistence of the right fourth aortic arch instead of, as is normal, the left fourth aortic arch.* A right aorta descends to the right of the midline, arches over the origin of the right bronchus, and descends either to the left or right of the vertebral column. With the aorta in this position, the ductus arteriosus (ligamentum arteriosum), passing from the aorta to the pulmonary artery, *encloses the esophagus and compresses it against the trachea.* Obstruction of the esophagus at this point leads to dysphagia and, shortly, to dilation of the cervical portion of the esophagus (Fig. 1.13).

A **double aortic arch** is a variation of the foregoing in which *the left arch persists as well as the right.* Both arches arise from the ascending aorta. The right arch, which is usually the larger of the two, follows the course given above. It is joined above the esophagus by the small left arch. The significant end result is *constriction of the esophagus.*

Aorticopulmonary septal defect, or *window*, is a rare defect in dogs that results from incomplete division of the truncus arteriosus. Pulmonary hypertension develops, leading to right-to-left shunting of blood.

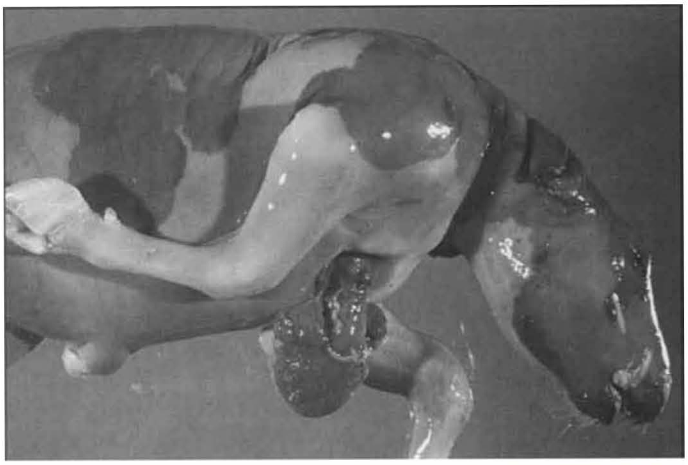

Figure 1.12 Ectopia cordis in a bovine fetus.

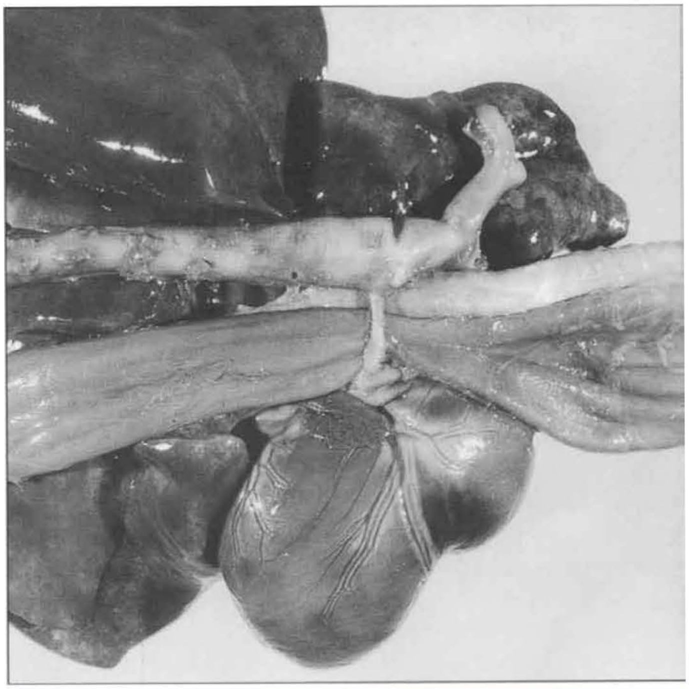

Figure 1.13 Persistent right aortic arch in a dog. The esophagus is constricted by aorta, trachea, and ligamentum arteriosus.

Coarctation of the aorta is another rare defect in dogs, and is seen as narrowing of the aorta adjacent to the ductus arteriosus/ligamentum arteriosum. Left ventricular pressure overload can result in left heart failure. Additional malformations of the aorta reported in dogs include *interruption of the aorta* and *tubular hypoplasia of the ascending aorta*.

Congenital aneurysm of the aorta or of the pulmonary artery, involves, for either vessel, the trunk and arch, but may not extend beyond the insertion of the ligamentum arteriosum. Aortic aneurysm may be associated with aneurysm of one or more of the aortic sinuses of Valsalva.

PERICARDIAL DISEASE

Primary disease confined to the pericardium is rare, but the close anatomic relationship of the pericardium to the heart, lungs, and pleura sometimes results in the extension of disease processes from the latter organs to the pericardium. Somewhat paradoxically, the pericardium is not needed for normal life, but pericardial disease can be life threatening. The pericardial sac may be removed surgically for relief of pericardial constriction.

The pericardial cavity may communicate with the peritoneal cavity through clefts in the diaphragm; hence herniated intestine may be found surrounding the heart as a result of congenital *peritoneopericardial diaphragmatic hernia.* Partial or complete *congenital absence of the pericardial sac* is without clinical effect. *Pericardial cysts* are rare congenital anomalies that occur in one of the costophrenic angles.

Epicardial fibrous fronds occur on the atria of Beagle dogs as an occasional incidental finding at necropsy.

Noninflammatory lesions of the pericardium

Hydropericardium

The pericardial sac normally contains a very small quantity of clear, serous fluid. *Any excess in the volume of fluid is referred to as hydropericardium.* A small increase in volume occurs by transudation after death, and it is soon reddened by postmortem hemolysis.

Hydropericardium is often part of *generalized anasarca* and is thus seen in many cachectic illnesses, perhaps as the result of hypoalbuminemia, and in *congestive heart failure* (Fig. 1.14). It may also be the product of local events such as implanted metastases of *neoplasms* on the pericardium, and lymphomatous infiltrations of the myocardium; primary tumors about the base of the heart and in the cranial mediastinum are rather common causes of hydropericardium. Hydropericardium may also accompany congenital and acquired *peritoneopericardial hernias* and *uremia. Infectious processes* of the pleura, especially granulomatous inflammations, may cause irritation of the pericardium sufficient to provoke a sterile serous effusion; the infection may eventually extend to the pericardial sac. If drainage of the thoracic duct is disrupted, for example by a cardiac neoplasm, then the fluid may be chylous (*chylopericardium*).

In hydropericardium, the serosal surfaces remain smooth and glistening, but if the fluid persists for a long time, it may produce slight fibrous thickening and opacity of the pericardial and epicardial surfaces. It is usually about the base of the ventricles, and small villus proliferations of the serosa may rupture and result in a blood-stained effusion. Neoplastic involvement of the pericardium characteristically has this result.

The pericardial fluid is clear or light yellow, without floccules, and with low content of protein. Fluid rich in protein, including fibrinogen, is often found in acute toxemias of clostridial (gas-gangrene group) origin. Clotting occurs soon after exposure to air. In such cases, exudation is due to direct injury to the endothelium by circulating toxins. Fluid that is copious and gels on exposure also is characteristic of African horse sickness and of heartwater. In pigs with edema disease or mulberry heart disease, fibrin is often formed antemortem. The presence of protein, especially fibrin, in pericardial fluid is only an index of the degree of endothelial injury and increased permeability and is not a precise point of distinction between an exudate and a transudate. **Inflammatory exudates** can be differentiated from **transudates** on the basis of the higher content of protein and cells in exudates and histologic evidence of inflammation involving the pericardium and epicardium.

The volume of fluid that accumulates is quite variable and of lesser significance than the rate at which it accumulates. When fluid accumulates rapidly, the pericardium is put under tension, the heart is compressed, and venous blood pools in the splanchnic and systemic circulations due to impaired atrial and ventricular filling (**cardiac tamponade**). When the fluid accumulates slowly, there is time for stretching and adaptation of the pericardium so that very

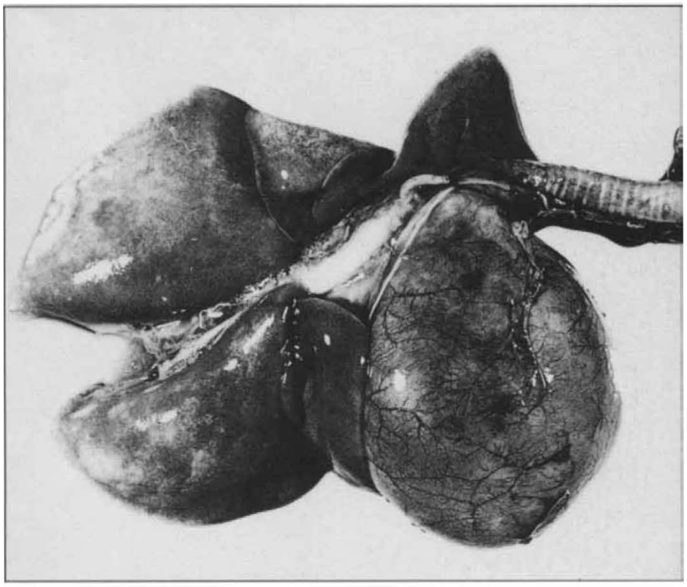

Figure 1.14 Hydropericardium in a cat. Pericardium is distended and pericardial vessels are injected.

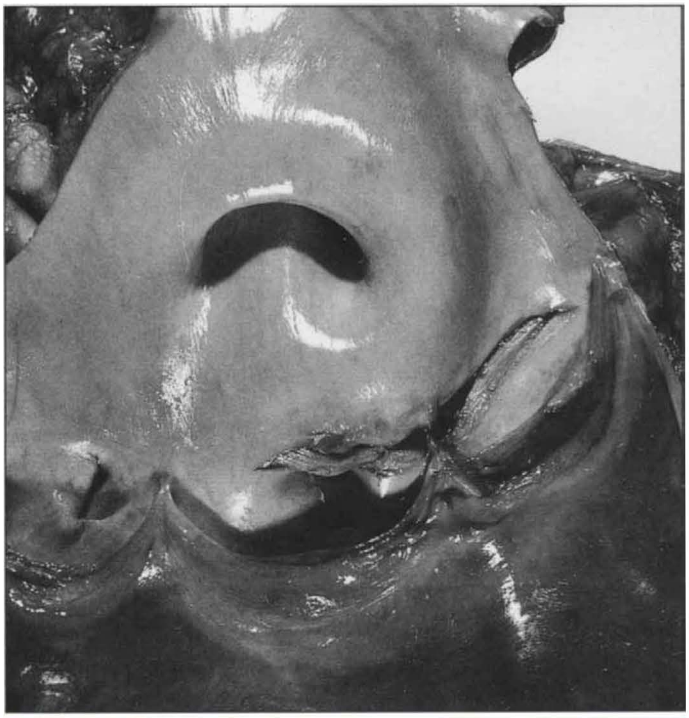

Figure 1.15 Aortic rupture, which caused hemopericardium and sudden death in a horse.

large amounts of fluid can accumulate before there is significant impairment of diastolic filling of the heart.

Hemopericardium

The term hemopericardium is limited to accumulations of pure blood in the pericardial cavity, and should not apply to mixtures of blood and serous fluid. If the blood is clotted, it can be assumed that the process is a true hemopericardium. Death usually supervenes rapidly. It is an unusual lesion, except following cardiac puncture or other direct trauma. It is seen in *horses* in which rupture of the intrapericardial aorta or atria occurs (Figs 1.15, 1.16). In *dogs*, hemopericardium occurs in atrial rupture in endocardiosis, hemorrhage from atrial hemangiosarcoma, in ulcerative atrial endocarditis of renal failure, and rarely, following rupture of a coronary artery or from hemorrhage from a heart base thymic remnant. In young, growing *swine*, rupture of the heart, particularly of an atrium, a coronary artery or the aorta, occurs on rare occasions. These deaths have not been examined specifically with deficiency of copper in mind, but attention is drawn to the remarkable cardiovascular lesions of experimental deficiency, which is discussed with diseases of the arteries.

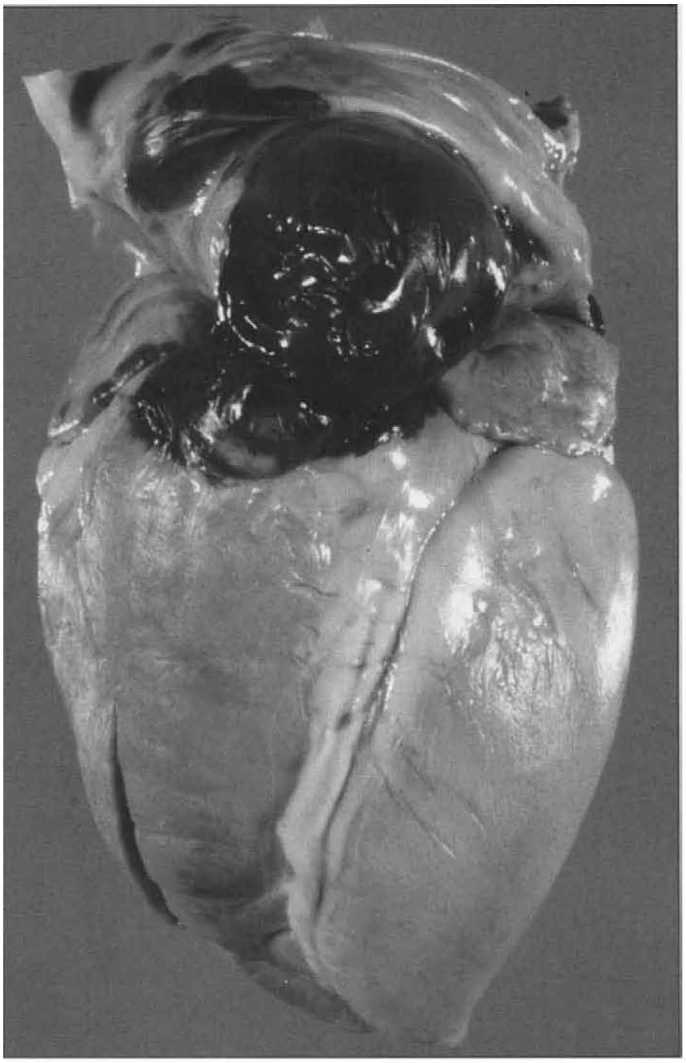

Figure 1.16 Hemorrhage at site of traumatic **right atrial tear** in a 4-day-old foal. Death resulted from hemopericardium and cardiac tamponade.

Idiopathic pericardial hemorrhagic effusion occurs predominantly in large-breed dogs, and is characterized by the presence of both clotted and unclotted blood in the pericardial sac without obvious cause. The clinical presentation is that of slowly developing right-sided heart failure, with some having accompanying left-sided heart failure. The heart sounds are muffled or inaudible on initial presentation with no evidence of dysrhythmias. However, some subsequently develop atrial fibrillation. The clinical course can be prolonged. The slow onset of clinical signs suggests either slow or intermittent bleeding allowing distension without tamponade. Indeed, some dogs may make a full clinical recovery following aspiration of the pericardial fluid.

Serous atrophy of pericardial fat

In cachexia of any cause, and paralleling fairly closely the reduction in body weight, there is progressive mobilization of depot fat, including that beneath the epicardium. As the lipid vacuoles are reduced in size, they are replaced by proteinaceous fluid, and with a concomitant increase in interstitial fluid, the depots are converted to gray, gelatinous masses that may be flecked by small white foci of fat necrosis (Fig. 1.17).

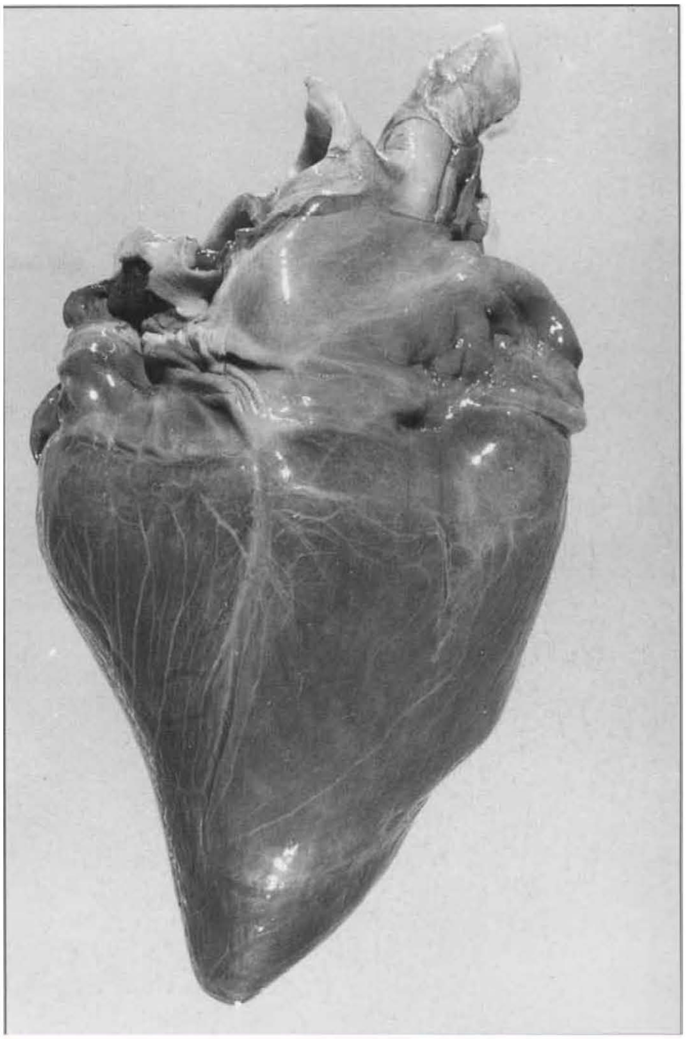

Figure 1.17 Serous atrophy of epicardial fat. The fat is gelatinous and translucent, and the myocardium is dark.

Pericarditis

It is seldom possible by examination of the lesion itself to decide the cause of pericardial inflammation, although a decision on the cause is often possible when the total pathologic picture in the cadaver is noted. For this reason and for descriptive purposes, we employ a morphologic classification of pericarditis.

Fibrinous pericarditis *is usually the result of hematogenous microbial infections*, but it may arise by lymphatic permeation from an inflammatory process in adjacent tissue. In *cattle*, fibrinous pericarditis, with or without some hemorrhage, is commonly part of pasteurellosis, blackleg, sporadic bovine encephalomyelitis, contagious bovine pleuropneumonia, clostridial hemoglobinuria, and some of the neonatal coliform infections that enter via the umbilicus. In *swine*, it is frequently part of the morbid picture of Glasser's disease and pasteurellosis, is a common complication of porcine enzootic pneumonia (infection with *Mycoplasma hyopneumoniae* and other agents), and is occasionally observed in salmonellosis and in streptococcal infection of piglets. Fibrinous pericarditis in adult *sheep* is usually part of pasteurellosis; in lambs, it is usually part of pasteurellosis or caused by streptococci. In *horses*, *Mycoplasma felis* causes pericarditis and pleuritis; streptococcal pericarditis may coexist with polyarthritis. Fibrinous pericarditis in horses may also be associated with the mare reproductive loss syndrome. Pericarditis is rare in *cats*, but it is seen as part of feline infectious peritonitis.

In fibrinous pericarditis, there is seldom significant exudation of fluid, so distension of the pericardial sac is not to be expected. The exudation of fibrin usually begins about the base of the heart and extends from there to cover, more or less completely, both the pericardium and epicardium. The fibrin is gray-white but it may be flecked with blood, or yellow if a large number of leukocytes are added to the exudate. Except for small pools of serum or serous exudate, the pericardium and epicardium are in apposition. When the leaves are drawn apart, the exudate is drawn out into villus-like projections to give an appearance responsible for the names "cor villosum," "shaggy heart," and "bread-and-butter pericarditis" (Fig. 1.18A, B).

The completeness of resolution depends upon how quickly the fibrinous exudate can be removed, which is a function of the amount of fibrin, and how quickly the mesothelium can be regenerated, which is a function of the amount of mesothelium that has been destroyed. *Restorative processes compete with the processes of organization.* Within a week or so, there will be well-formed fibrous tissue in the deepest parts. Immediately superficial to this there will be young granulation tissue and then a stratum of fibroblasts mixed with leukocytes, and on the surface there remains the fibrin clot infiltrated with numerous leukocytes. If the course is prolonged, organization and scarring will result in focal or diffuse fibrous adhesions between the pericardial surfaces, with partial or complete obliteration of the sac.

The *residual lesions of fibrinous pericarditis* occur as more or less distinct variants. Focal, patchy thickenings of the epicardium without adhesions form minimal residue and are usually more distinct on the ventricles than on the atria, where they may be obscured by normal fat. The original scar tissue may undergo fatty metaplasia or be edematous. (The same lesion also occurs covering healed foci of superficial myocarditis.) Focal or diffuse adhesive pericarditis varies in extent from a few "violin strings" across the sac to complete obliteration of the sac. Inclusion cysts lined by mesothelium are often present in fibrous adhesions, and there tends to be excess fluid present in non-obliterated portions of the sac. The pericardium is separable from the epicardium by blunt dissection. As the connective tissue is not dense, there is usually no embarrassment of cardiac function.

Purulent pericarditis *almost invariably denotes the presence of pyogenic bacteria*, either as primary pathogens or as opportunists in fibrinous pericarditis. It occurs almost solely in cattle as a result of traumatic perforation by a foreign body originating in the reticulum (Fig. 1.19), but it is observed in cats and horses in association with empyema (pyothorax). Migrating grass awns ("foxtail," *Hordeum glaucum* and *H. leparinum*) have been identified as causes of suppurative pericarditis in dogs in the western USA.

The suppurative pericardial fluid may appear as thin, cloudy exudate, as frank, creamy pus, or as a mixture of pus and masses of fibrin. The color depends on the organisms present, but usually varies from yellow to green, being irregularly dirty gray when putrefactive bacteria are present. The exudate is usually foul smelling. The volume of exudate varies from a thin layer on the serosal surface to 4 L or more. In the early stages, it can be wiped or washed off to reveal the vascular injection and granularity of the membranes. Soon, the whole of the epicardium is covered with coagulum; the parietal layer of the pericardium is less severely affected, and separation of the two presents a shaggy appearance of the heart (cor villosum).

Microscopically, the subjacent tissues are densely infiltrated with leukocytes, the reaction extending more deeply than in fibrinous pericarditis, the formation of new blood vessels and connective tissue is prominent, and the overlying coagulated exudate is densely infiltrated with leukocytes.

Resolution probably never occurs. Because of the severity of the inflammatory reaction, *healing is by organization*, as is characteristic of all suppurative inflammations. Although the course of suppurative pericarditis may be prolonged, the persistence of the inciting agent, or more usually agents, prevents complete organization. **Constrictive pericarditis** resulting from progressive organization can be so severe and diffuse that it leads to impaired diastolic filling

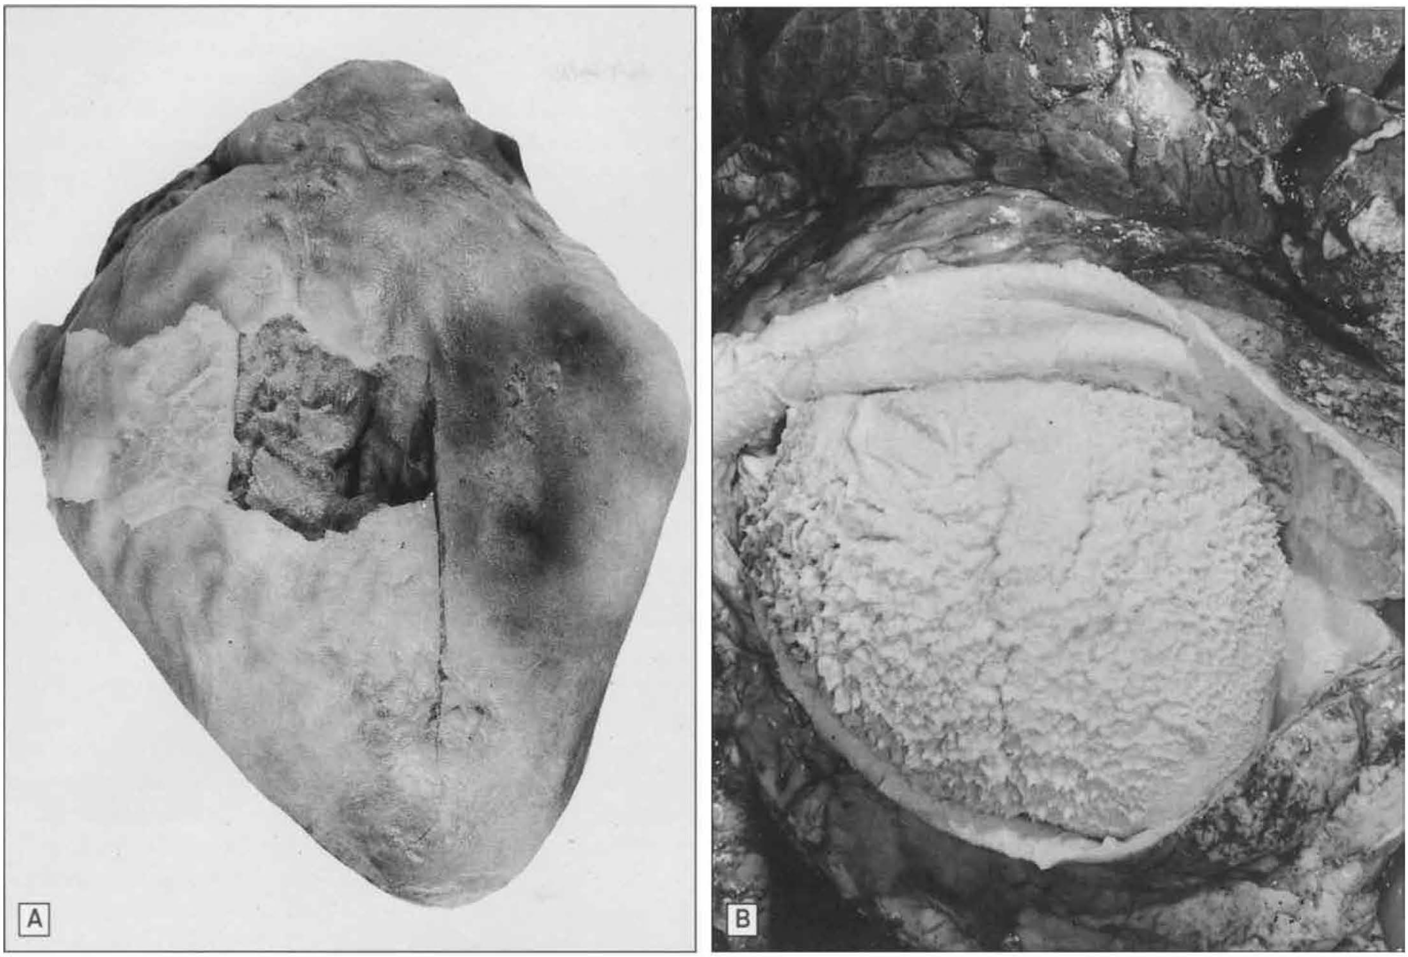

Figure 1.18 A. Fibrinous pericarditis in a pig. There is some blood staining of the exudate, which can be peeled off. **B. Chronic pericarditis** with "bread and butter" exudate in a cow. The reflected pericardium is thickened.

and the development of right-sided heart failure (Fig. 1.20). The adhesions cannot be broken down by blunt dissection and may be mineralized. They obliterate the pericardial cavity, but they may also extend beyond it to involve the mediastinum. The heart, which is confined by scar tissue, may be smaller than normal, or it may be greatly enlarged and hypertrophic, especially when there are also extrapericardial adhesions present. *There is always severe cardiac dysfunction, and death occurs from congestive heart failure.*

ENDOCARDIAL DISEASE

The most clinically significant endocardial lesions affect the heart valves rather than the mural endocardium. Valvular lesions may cause **stenosis**, or **valvular insufficiency**, or both. *Stenosis of a valve, or failure to open completely, impedes the forward flow of blood. Valvular insufficiency, regurgitation, or incompetence results in reversed flow of blood.* Valvular dysfunction may produce abnormal heart sounds that are detectable clinically as *murmurs.* The consequences of valvular disease depend upon the rapidity of onset, type, and duration of the lesion, and may be ameliorated by cardiac compensatory mechanisms. For example: congenital aortic or pulmonic valvular stenosis result in myocardial hypertrophy and *progressive heart failure*; rupture of chordae tendineae causes *acute heart failure*; myxomatous degeneration of the mitral valve in aging dogs causes valvular insufficiency and *congestive heart failure.*

The propensity of **thrombi** to form on the free margins of valves is well known, but the factors leading to it are not. It may be related to the continual movement and the resulting apposition of the surfaces of the free margins of the valves. There are also ill-defined factors, such as intercurrent disease or increased workload, which promote the development of thrombi. The lack of an internal blood supply to the valve may also be a contributing factor, and in common with other vascular structures, injured endothelial cells release inflammatory mediators, such as prostaglandins, and other substances, such as adenosine diphosphate, which are potent stimulators of platelet aggregation. Once the endothelium is removed, the exposed collagen also stimulates the aggregation of platelets. The presence of the initial thrombus leads to further clotting. In contrast to myocytes, endothelial cells have a great capacity for regeneration and for covering any breach in their continuity. If the original insult is removed, which without appropriate treatment is not often, the valve heals by fibrosis, but a shrunken, distorted, insufficient, or stenotic valve may remain.

Little is known of the process leading to the abnormal development of valves in the embryo, or the progressive accumulation of glycosaminoglycans in the degenerative disease, endocardiosis. The various theories are discussed under the appropriate heading. However, both lead to deficiencies of valve function.

Acute rupture of chordae tendineae can occur spontaneously or in association with chronic valvular degeneration or valvular endocarditis. As well, acute rupture of chordae tendineae or papillary muscles, and resultant acute valvular insufficiency and heart failure, and can be caused by blunt trauma to the chest, e.g., falls, hit by motor vehicle.

Degenerative lesions

Myxomatous valvular degeneration ("endocardiosis") in dogs

Myxomatous valvular degeneration, commonly termed *endocardiosis, is the most common cardiovascular lesion in dogs*, and is frequently encountered as an incidental finding at autopsy. Advanced endocardiosis of the left atrioventricular (AV) valve leads to *mitral insufficiency* and regurgitant flow into the left atrium, noted clinically as systolic murmurs, and culminates in left-sided heart failure. The shrunken, distorted AV valves are seen with greatest frequency in toy, small, and medium breeds of dogs, especially in males of breeds such as the Poodle, Pomeranian, Schnauzer, Chihuahua, Doberman Pinscher, Whippet, Fox Terrier, Boston Terrier, Cavalier King Charles Spaniel, Dachshund, and the English Cocker Spaniel. There are significant negative associations for the Labrador Retriever and the German Shepherd Dog. *The prevalence of the disease increases with age*, from 5% at less than 1 year of age to >75% at 16 years of age. Endocardiosis is also reported in the mitral valves of normal market-weight pigs, but appears to be inconsequential.

Endocardiosis affects chiefly the left AV valve (Fig. 1.21A, B). The right AV valve is less severely and less frequently affected. Only occasionally are the aortic and pulmonary semilunar cusps involved. The AV cusps are shortened and thickened. The thickening of the leaflet may be more or less uniform with a rounded edge, or prominent nodular thickenings may affect the free margin. *The valves are opaque and white, but the surface is smooth and glistening, without any evidence of*

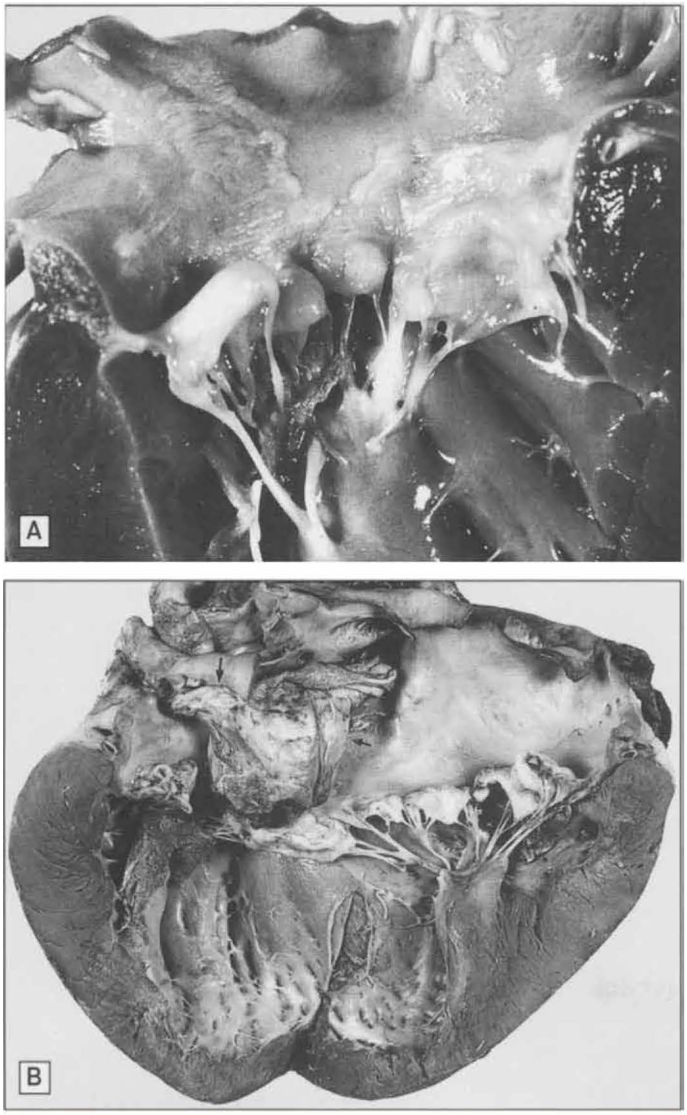

Figure 1.21 Endocardiosis. A. Thickened, distorted left atrioventricular valve with focal endocardial fibrosis ("jet lesions") in the left atrium of a dog. **B.** Endocardiosis of left AV valves and atrial thrombosis (arrows) in a dog.

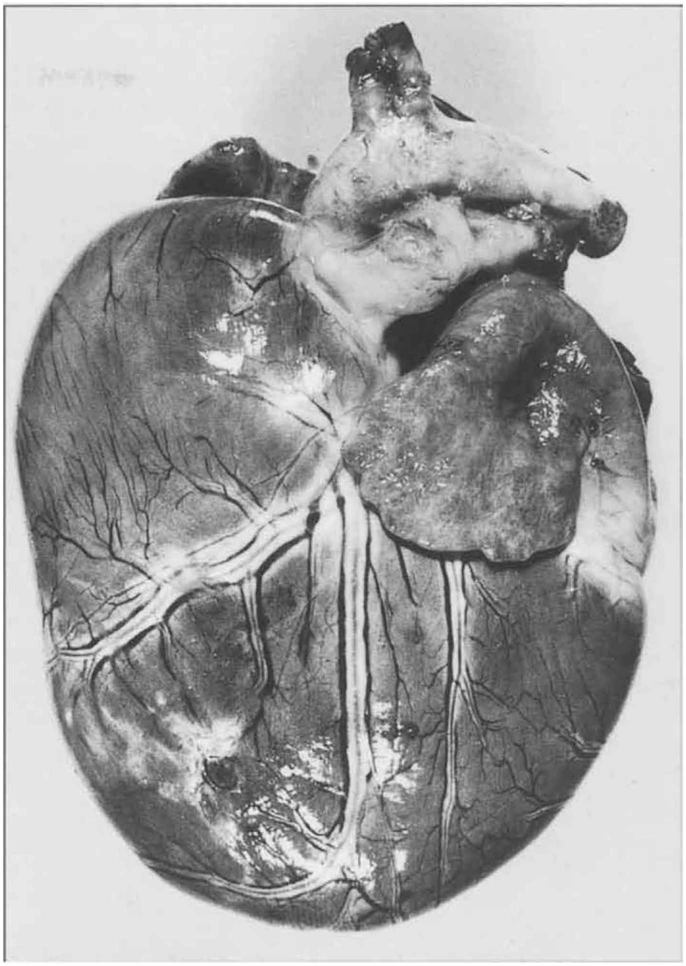

Figure 1.22 Dilated left ventricle and atrium with focal ventricular fibrosis in a dog, the result of **endocardiosis**.

inflammation. The chordae tendineae may also be thickened and occasionally are ruptured, allowing eversion of the leaflet into the atrium and leading to acute ventricular failure. The mitral annulus may be enlarged.

The least severe gross change consists of a few small, discrete nodules at the line of closure of the valve. This progresses to multiple larger nodules that tend to coalesce in the area of contact. There may be irregular areas of opacity in the proximal portions of the leaflet. The nodules may coalesce to form plaque-like deformities in the area of contact. The chordae tendineae are thickened at their points of insertion into the valve, and there are clearly defined areas of opacity on the basal portions of the leaflet. The most severe change is characterized by a gross distortion of the valve by gray-white nodules and elevated plaques. The cusps are contracted, thickened, and irregular. There may also be fixed upward displacement of the free margin of the valve. Enlargement and redundancy of the valve may be seen as doming or hooding of the body of the valve towards the atrium; this prolapse of the body of the redundant left AV valve into the atrium ("*mitral valve prolapse*") may be seen both echocardiographically and at necropsy. Chordae tendineae may be ruptured, in which case the free edge of the valve may prolapse as a *flail leaflet*. Care should be taken in the assessment of the valves, since both the left and right AV valve leaflets thicken with increasing age, and the free margin of the septal leaflet of the right AV valve is normally distinctly thicker than the free leaflets.

Changes secondary to AV valvular insufficiency are *dilation of the atria*, particularly the left atrium, and *dilation of the left ventricle* (Fig. 1.22). In a small majority of cases, the left ventricle is eccentrically hypertrophied. The left atrial and ventricular endocardium may be diffusely thickened by fibrosis following prolonged dilation. There may also be evidence of regurgitation in the form of focal elevated streaks and plaques of subendocardial fibrosis in the atria ("*jet lesions*"). Left atrial tears may also be seen in advanced cases, and these tears may lead to hemopericardium. Mural thrombi can form in the dilated left atrium; dislodgement of the thrombi can result in thromboembolism, e.g., of coronary arteries leading to myocardial infarction.

Microscopically, the earliest changes are present on the atrial side of the valves. There is proliferation of the endothelium, increased numbers of subendothelial fibroblasts and macrophages, and splitting and separation of elastic fibers between the atrialis and spongiosa. However, *it is the thickening of the spongiosa and degeneration of* *the fibrosa that are the most prominent features of endocardiosis.* The spongiosa is greatly thickened by the proliferation of loose fibroblastic tissue and the deposition of the proteoglycans, hyaluronic acid, and chondroitin sulfate. In a few cases, amyloid may be deposited. There is no increase in collagen or elastic tissue in the spongiosa. The changes in the fibrosa are also marked. Collagen bundles become swollen and hyalinized, fragment, and disappear. In advanced cases, only scattered remnants of the fibrosa remain. Similar changes are seen in chordae tendineae. Intramural coronary arteriosclerosis and focal myocardial necrosis and fibrosis are commonly seen in the left ventricular myocardium, especially the papillary muscle, if the ventricle is hypertrophic.

The cause of endocardiosis is not known, but is likely a genetically influenced degeneration of connective tissue. This suggestion is supported by the observation that the most frequently affected breeds are of the chondrodystrophoid type. Endocardiosis is *inherited* in Dachshunds and Cavalier King Charles Spaniels; a polygenic mode of inheritance is suggested. There is a striking similarity of endocardiosis to the *prolapsed mitral valve syndrome* of humans, in which there is deposition of glycosaminoglycans in the spongiosa secondary to an as yet undefined abnormality of collagen metabolism. Mitral valve prolapse in humans occurs in association with connective-tissue disorders such as Marfan's syndrome, Ehlers–Danlos syndrome, osteogenesis imperfecta, and a variety of muscular dystrophies.

Mitral regurgitation also occurs commonly in **horses**, and can result from endocardiosis, endocarditis, flail valve leaflets, rupture of chordae tendineae, and mitral valve prolapse. Clinical signs of exercise intolerance, poor performance, or congestive heart failure result. Dilation of the pulmonary artery may also ensue, indicating pulmonary hypertension, and may presage pulmonary artery rupture.

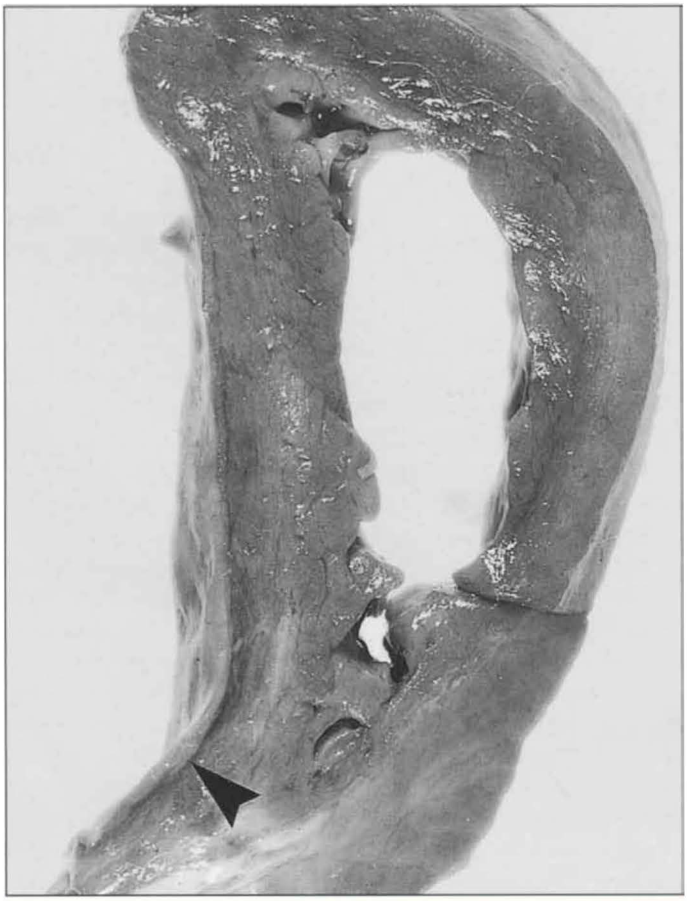

Figure 1.23 Endocardial fibroelastosis (arrowhead) in a calf.

Valvular cysts

Congenital hematomas (hemocysts) on the margins of the atrioventricular valves are common, especially in calves (see above: Miscellaneous cardiac anomalies). *Blood cysts* and *serous cysts* have been reported in the atrioventricular valves in 11% of the hearts in a series of 30 000 slaughter cattle, with a higher incidence in cows than calves. Blood-filled cysts were often present on both atrioventricular valves, while serous cysts occurred more frequently on the left atrioventricular valve. The findings in this study suggest that cysts do not regress with age, indeed their incidence and size may increase with age. The endothelium lining the blood-filled cysts was positive for factor VIII-related antigen. The cysts may represent ectasias of blood vessels and lymphatics.

Subendocardial fibrosis

Subendocardial fibrosis may be diffuse or focal, congenital or acquired (Figs. 1.23 and 1.24). The congenital lesions are discussed

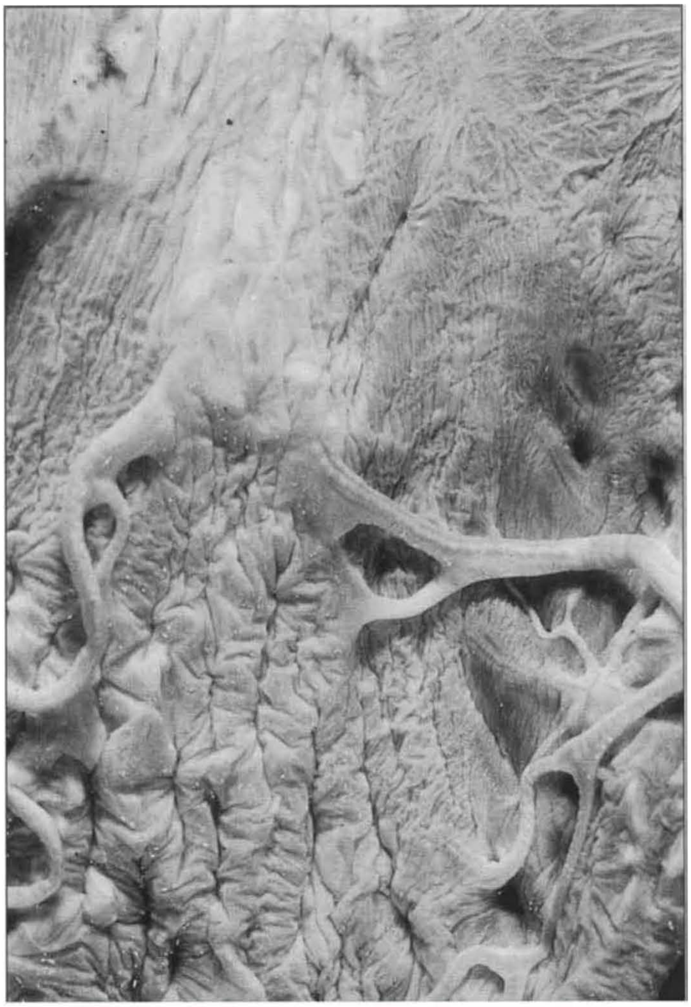

Figure 1.24 Endocardial fibrosis in a cow.

under Congenital abnormalities of the heart and large vessels. *Diffuse subendocardial fibrosis is seen whenever a ventricle or atrium is dilated for a prolonged period.* It is probably best exemplified by the dilated cardiomyopathy of large-breed dogs.

Subendocardial fibrosis in localized areas is observed chiefly in the atria and is regarded as a reaction of the endocardium to abnormal jets of blood or to turbulence following congenital or acquired valvular disorders (Figs. 1.22 and 1.25). They are loosely termed **jet lesions,** but are probably areas subject to increased static pressure in turbulent flow.

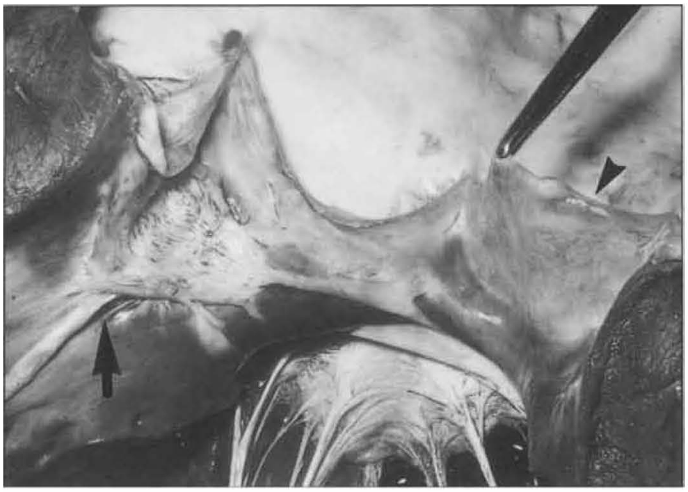

Figure 1.25 Aortic valve fenestrations (arrowhead) causing endocardial "jet lesion" (arrow) in the left ventricle of a horse.

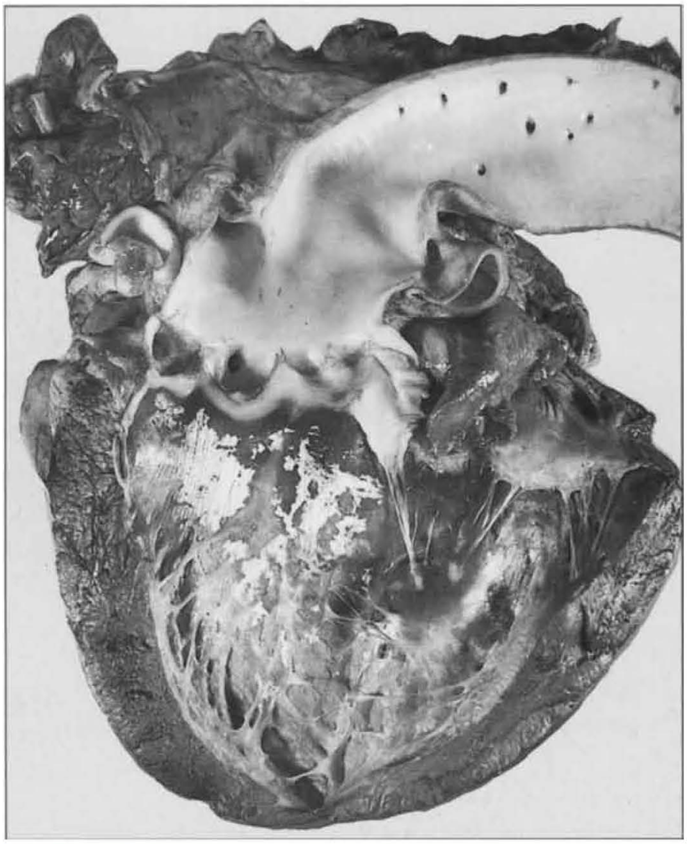

Figure 1.26 White subendocardial plaques of **mineralization** in the left ventricle of a cow.

Subendocardial mineralization

Subendocardial mineralization is associated with a variety of disorders. It occurs commonly in opaque plaques or as small grains in the left atrium, and occasionally in the trunk of the aorta in dogs that have recovered from ulcerative endocarditis of *renal insufficiency* (see below). Prominent white plaques of mineralization also occur beneath the endocardium of the right ventricle in *nutritional myopathy* of lambs. Subendocardial mineralization in the atria and left ventricle may accompany endocardial fibrosis when these cavities are acutely dilated, either as congenital or acquired defects, and in a variety of *prolonged debilitating diseases in cattle* (Fig. 1.26). Calcium and phosphorus are deposited in degenerate subendocardial muscle, but more commonly in fibroelastic tissue. The fibroelastic tissue is modified either by chronic disease or elevated serum levels of calcium and phosphorus, as in *vitamin D intoxication*, or following the ingestion of plants containing vitamin D analogs (see Vol. 3, Endocrine glands). Proprietary *rodenticides* based on calciferols cause this lesion in dogs.

Endocarditis

Endocarditis is one of the more significant of the endocardial alterations. It is *usually bacterial* in cause, the exceptions being occasional *parasitic* or *mycotic* lesions. Any portion of the endocardium may become inflamed, but *the lesions are usually primary on the valves*, from which there may be some encroachment on the adjacent mural

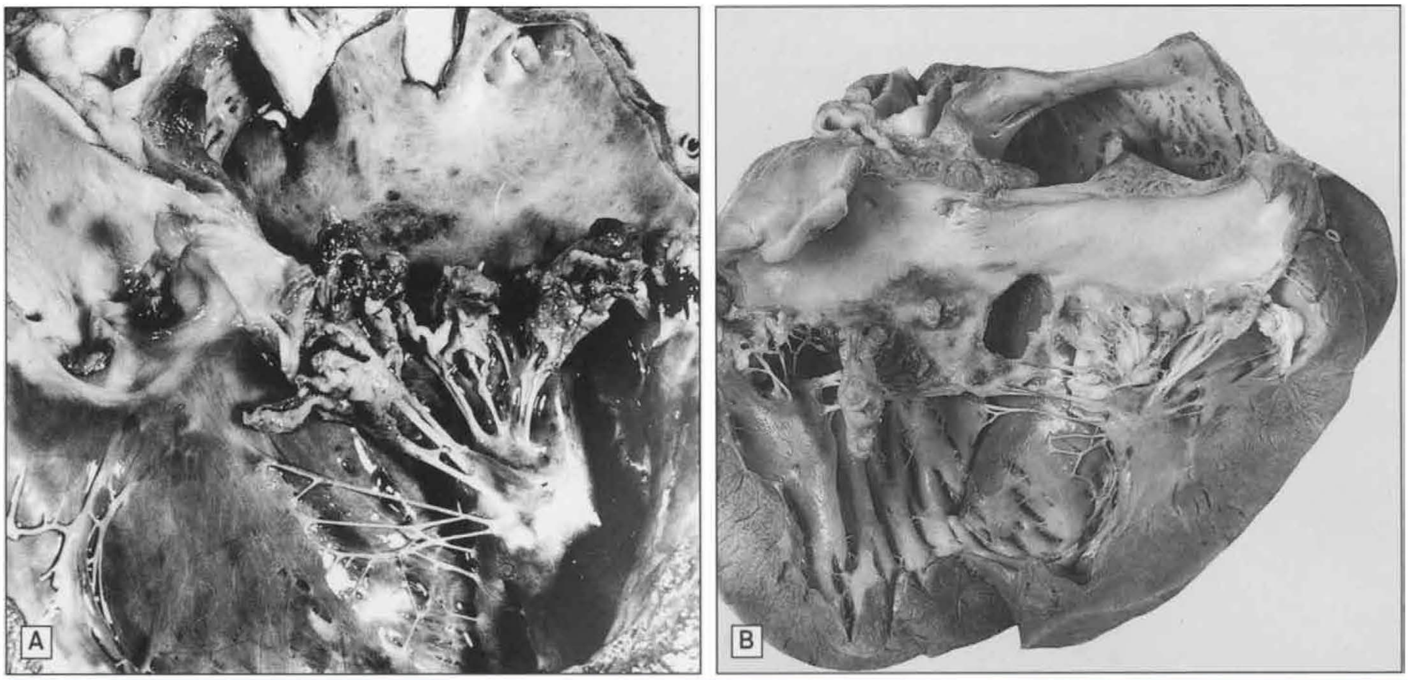

Figure 1.27 Valvular endocarditis. A. Caused by *Escherichia coli* infection in a dog. **B.** Valvular endocarditis with valvular rupture and extension to the ventricular wall in a dog.

endocardium (Fig. 1.27A, B). The mitral valve is most commonly affected in most species, followed by aortic, tricuspid, and pulmonic, except in cattle, in which the tricuspid valve is more commonly affected.

Many bacterial species are capable of causing acute **valvular endocarditis**, and the larger the number of cases examined, the wider the variety of pathogens recognized. In **cattle**, *Arcanobacterium pyogenes* is probably the most common pathogen, and a primary focus of infection can often be found in some other site, such as a traumatic peritoneal abscess, hepatic abscess, metritis, or mastitis. Streptococci of enteric origin are also of some importance in cattle, although the manner of their systemic invasion is not clear. *Erysipelothrix rhusiopathiae* has caused endocarditis in a variety of animals, most commonly in the **pig**; however, streptococci are more commonly isolated from cases of acute bacterial endocarditis of swine. **Horses** seldom develop bacterial endocarditis, but the lesion has been observed in association with *Streptococcus equi, Actinobacillus equuli, Escherichia coli, Pseudomonas aeruginosa*, and *Candida parapsilosis*. A number of cases in horses have originated from septic jugular vein thrombophlebitis. Minor outbreaks of endocarditis occur in **lambs** and are usually caused by *Streptococcus* spp., particularly enterococci; there may be associated polyarthritis. Endocarditis is seldom observed in **dogs**, but can be associated with a variety of organisms, especially *Streptococcus* spp., *Staphylococcus aureus*, and *Escherichia coli*, and less frequently with *Bartonella* spp., *Erysipelothrix rhusiopathiae, Erysipelothrix tonsillarum, Pseudomonas aeruginosa*, or *Pasteurella multocida* (Fig. 1.28). Endocarditis is unusual in **cats**, but has been caused by *Bartonella* spp. and *Streptococcus* spp.

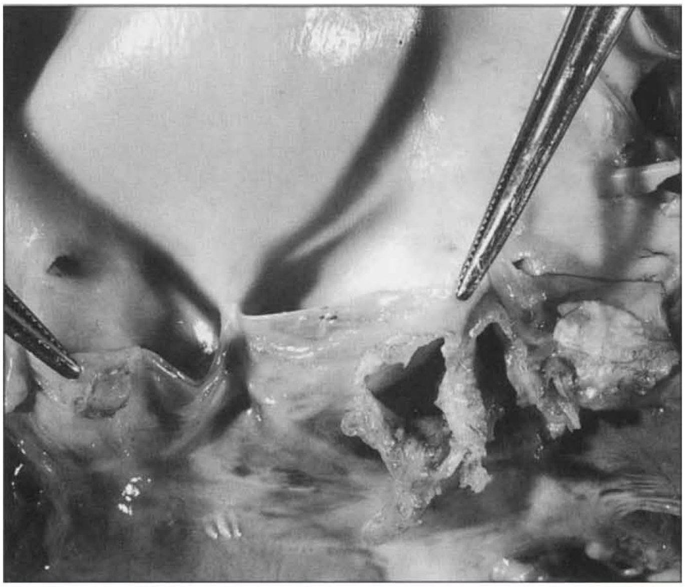

Figure 1.28 Aortic valvular endocarditis in a dog. The valve cusp is perforated.

The manner by which bacteria localize on a valve is not clear, and there is seldom detectable evidence of some separate underlying disease of the leaflet. In probably all cases of active thrombotic valvular endocarditis, bacteria are present in the lesion. Two factors that must be included in any concept of pathogenesis are

1. the tendency for lesions to occur at the *lines of apposition of the valve surfaces* exposed to the forward flow of blood, and
2. the necessity for *sustained or recurrent bacteremia.*

It is possible that simple debilitation of endothelial cells in recurrent bacteremia, aggravated locally on the valves by the trauma of apposition, may alter the adhesiveness of the leaflet endothelium sufficiently for bacterial adhesion to occur. It is of significance that valvular endocarditis can be produced in normal animals by a single intravenous injection of bacteria of suitable type and virulence; the incidence of endocarditis is increased if the hearts of such animals are subjected to increased workloads or the valves are traumatized during the experiments. There is also the possibility that bacterial endocarditis can begin within the valve during septicemia, as has been demonstrated by isolation of bacteria from the spongiosa of pig valves.

Particular strains of *Erysipelothrix rhusiopathiae* can selectively adhere to the valvular endothelium of porcine heart valves in vitro, with greatest numbers at the base of chordae tendineae. The phenomenon of *selective adherence* has been demonstrated for pathogens associated with other organ system disease, notably staphylococci and streptococci in mastitis and enterotoxigenic coliforms in colibacillosis. There is also an immunologic cross-reaction between *E. rhusiopathiae* antigens and valvular and myocardial antigens. Various *Streptococcus* spp. have been shown to adhere to exposed basement membrane of porcine valves.

The lesion of **acute bacterial endocarditis** is usually observed as an *irregular vegetation* on the affected valve. It is quite exceptional to find the earliest lesion, which consists of *irregular ulcerations* on the swollen leaflet. The composition of vegetations is similar to that of thrombi with, however, few platelets. *Numerous bacterial colonies are present in the vegetations*, almost always in pure populations. It is wise to make preliminary identification of the organisms by smears, because although they persist in colonies buried in the vegetations, they may not be cultivable. With the current techniques of molecular biology, such as PCR, it should be possible to identify at least the genus of the non-cultivable organisms embedded in the thrombus. The bacteria that initiate the lesion are enmeshed in the early layers of thrombi and are buried deeply as new layers are formed on the surface. With continued multiplication, many microscopic colonies are formed, and without appropriate antimicrobial treatment, it is their persistence in the protected environment that is the reason healed bacterial endocarditis is seldom seen. Even though the bacteria in the thrombi may lose their vitality, as indicated by lack of cultivability, they are persistently antigenic.

Grossly, the vegetations are yellow-red or yellow-gray and usually covered by a thin clot of blood, which can be easily peeled off. The surface of the vegetation is friable, and small vegetations can be easily removed to leave a granular, eroded surface on the valve. The ulcerations are especially common in the commissures and at the free margins of the valves, imparting to them a rough, serrated appearance. The primary valvular lesion frequently extends to the adjacent mural endocardium and, in the cases of aortic valvular endocarditis, to the adjacent aortic intima in the sinuses of Valsalva; in the latter eventuality, the lesion may involve an orifice of a coronary artery, predisposing to *myocardial embolism*. Endocarditis of the atrioventricular valves tends to spread along the chordae tendineae, causing some of them to rupture. Acute swelling and inflammatory change take place in the substance of the valve itself, often with necrosis, which obscures the line of partition between the valve and its surface vegetation.

Organization of the thrombus proceeds from the base by the usual process of granulation, which is likely to be impeded or destroyed by bacterial growth. Early scarification in the deepest layers separates the thrombus from the underlying myocardium and is frequently accompanied by mineralization.

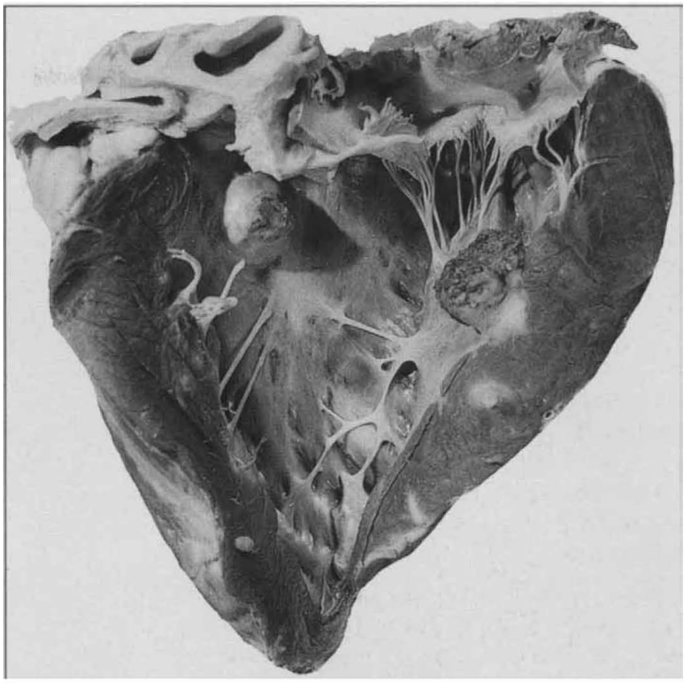

Figure 1.29 Myocardial abscessation and scarring. There is extension of inflammation to the mural endocardium with thrombus development.

Valvular endocarditis is commonly fatal, although resolution may be complete if lesions are only minor. Clinical signs in animals with endocarditis may only be detected late in the disease, with the most common being *pyrexia, lameness, and cardiac murmurs.* The frequency with which clinical signs are observed is dependent on the husbandry conditions under which the animal is kept. Other sequelae are those resulting from valvular damage or embolism. Portions of the vegetations may become detached and carried as **emboli**, to become impacted in the vessels of other organs. Such emboli may be either *bland*, that is, consist of thrombotic material only, or *septic*. Emboli arising in the right heart may produce pulmonary abscesses or pulmonary thrombosis. These latter do not produce pulmonary infarcts in the absence of preexisting pulmonary congestion. Emboli arising in the left heart produce their most obvious effects in the kidney and spleen as septic or aseptic infarcts and embolic glomerulitis, and in the myocardium as myocardial abscesses or interstitial myocarditis. Arthritis is commonly observed in association with endocarditis in the dog. Cerebral embolism is rare in animals. Unless the valvular lesions are very slight, there is, with healing, some degree of permanent damage, especially if the inflammation is recurrent. Shrinkage or adhesion of leaflets may cause narrowing of the orifice (stenosis), or insufficiency as a result of failure of the distorted valves to close the orifice. Stenosis and insufficiency may coexist. The usual outcome is *congestive heart failure.*

Mural endocarditis may be merely an extension to the walls of the cardiac chambers of a process originating on the valves. This is almost invariably true of endocarditis caused by *Arcanobacterium pyogenes*. Small foci of mural endocarditis may be found adjacent to foci of myocarditis, especially myocardial abscesses (Fig. 1.29). There are some additional occurrences of mural endocarditis worthy of mention.

Parasitic endocarditis caused by the larvae of *Strongylus vulgaris* occurs in horses acutely in the form of vegetative valvular endocarditis (Fig. 1.30), and chronically as caseous and calcareous nodules attached to the endocardium at various sites, including the apex of the left ventricle and protruding into the cavity. There is, in the same cases, parasitic aortitis of the bulb. With the advent of effective anthelmintics, parasitic endocarditis in horses is rare.

An acute form of **ulcerative mural endocarditis** occurs in cattle dying from *blackleg*, as red thrombotic masses attached to the free wall of the right ventricle and, less often and less extensively, on the right atrial and valvular endocardium.

Various unique **intracardiac fistulae or shunts** have been reported a sequelae to endocarditis in dogs, including: extension of aortic valvulitis into the right coronary artery and fistulation into the right atrium; perforation of the membranous interventricular septum leading to a left ventricular outflow tract–right atrial shunt (*Gerbode defect*) in a dog with severe mural endocarditis due to a *Bordetella*-like organism; and a fistula between the left ventricular outflow tract and the left atrium adjacent to the mitral valve annulus in a dog with *Staphylococcus intermedius* endocarditis.

One of the more common forms of mural endocarditis occurs in **renal failure** in dogs. The lesion is confined, within the heart, to the left atrium, but similar lesions occur in the large elastic arteries, being more frequent in the pulmonary and aortic trunks immediately proximal to the valves, and less frequent in the descending aorta and its major branches. (The vascular lesions associated with renal failure are discussed under Diseases of the vascular system.) The endocardial and major-arterial lesions are more common in acute than in chronic renal failure, insofar as these syndromes are distinguishable.

The *ulcerative atrial lesion*, which is identical to the arterial lesion, begins as a swelling of the interstitial spaces of the subendocardium or intima of the arteries, with deposition of glycosaminoglycans. Initially, the endothelium is intact, and when viewed grossly in this stage the endothelial surface is seen to be raised slightly, finely wrinkled, and slightly opaque but still shiny. The lesion may not progress farther than this but, instead, heals with some fibrosis, which leaves areas of uneven opacity. More usually, however, there is progression to necrosis involving the cellular elements as well as collagen, elastic, and reticulin fibers. The necrotic tissue ulcerates, and the margin is densely infiltrated by leukocytes. The ulcerations may perforate the wall of the atrium. Thrombus, in greater or lesser amounts, forms on the ulcerated surface. Heavy deposits of calcium salts often form in the degenerate tissue. If renal sufficiency is reestablished, the endocardial lesion may heal leaving irregular patches of fibrosis with an intact endothelium, often covering persistent white plaques of mineralization. Other extrarenal lesions of uremia are considered in Vol. 2, Urinary system.

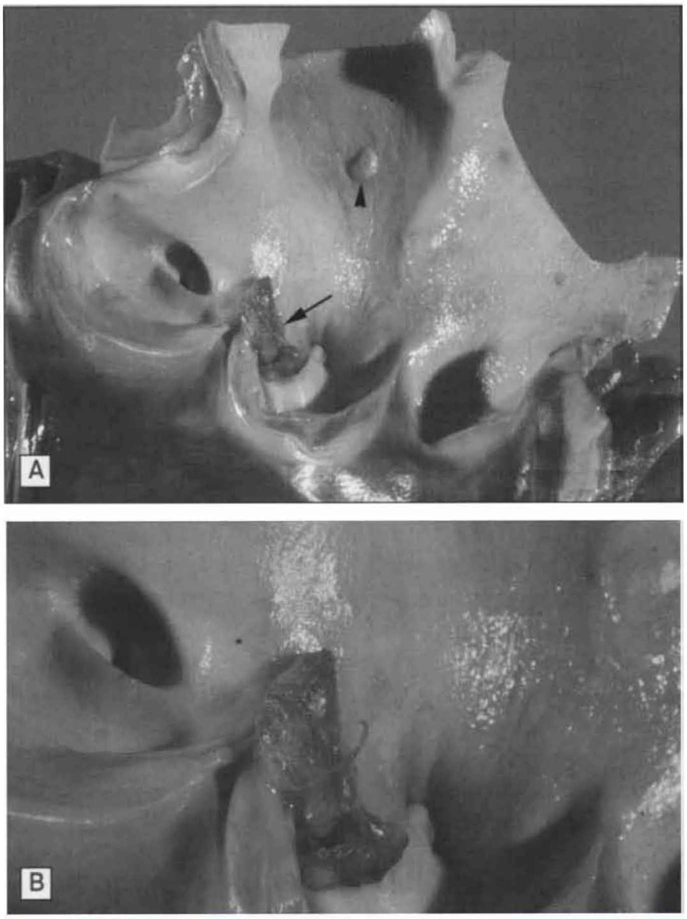

Figure 1.30 A. Vegetative aortic **valvular endocarditis** (arrow) and calcareous aortic intimal nodule (arrowhead) caused by *Strongylus vulgaris* infection in a horse. **B.** A strongyle larva was present in the aortic valvular vegetation.

MYOCARDIAL DISEASE

Myocardial dysfunction can be the product of a wide variety of agents and conditions (Table 1.5). We will deal in this section with the range of myocardial disease, from the more-or-less specific myocardial conditions of *degeneration, necrosis, hemorrhage, and myocarditis, through idiopathic myocardial disease (cardiomyopathy). The reaction of myocardium to insults is limited*, and includes the usual expressions of degeneration, necrosis, inflammation, and healing. Acute changes, such as necrosis and hemorrhage, will be discussed first. Given time to adapt to an insult, a diseased heart may grossly take one of two conformations: dilated or hypertrophic. This classification is useful conceptually, but is somewhat arbitrary, and individual cases will often have features of more than one form, e.g., the heart in a cat with hyperthyroidism will hypertrophy, but it may eventually dilate and fail.

Hemorrhage of the heart and its membranes

Petechial and larger hemorrhages beneath the epicardium are so common in *horses* that die naturally that they are almost to be regarded as normal. The incidence of hemorrhages in sheep and cattle is somewhat lower; they are seldom seen in dogs and cats. *Subepicardial hemorrhages are common in instances of asphyxia or death in anoxia, and in many acute infectious fevers.* Larger ecchymotic hemorrhages that may involve most of the epicardium occur in the *hemorrhagic diatheses*.

Subendocardial hemorrhages have the same pathogenesis but are considerably less common. Ecchymotic hemorrhages beneath the endocardium of the left ventricle occur in instances of *acute cerebral injury* and are useful as a diagnostic indication of *clostridial enterotoxemia* in lambs and calves, being present in a considerable proportion of cases.

Small interstitial capillary hemorrhages *within the myocardium* accompany those within the subserosa. Deep myocardial hemorrhages that do not extend to the serosa are commonly present in pigs that die of *asphyxia*; they are distributed in the wall of the right ventricle in the vicinity of the descending coronary grooves. A remarkable degree of myocardial hemorrhage occurs in *mulberry heart disease of swine* (see below).

Table 1.5 Causes of myocardial dysfunction in domestic animals

Infectious	Viruses, chlamydia, rickettsia, bacteria, fungi, protozoa, helminths
Toxic	Ionophores (monensin, salinomycin, maduramicin), catecholamines, antineoplastics (cyclophosphamide, doxorubicin, daunorubicin), doxycycline, gossypol, saccharated iron, thallium, toxic plants (many), insects (blister beetle (*Epicauta*))
Metabolic	Hyperthyroidism, hypocalcemia
Nutritional deficiency	Vitamin E–selenium, taurine (cats), copper, thiamine
Genetic	Porcine stress syndrome
Neuromuscular	Muscular dystrophy
Storage disorders, other depositions	Glycogen storage disease, amyloidosis
Infiltrative	Neoplasia (lymphosarcoma, hemangiosarcoma)
Idiopathic	Cardiomyopathy

Myocardial degeneration

Cardiac muscle is structurally similar to skeletal muscle and is subject to the same anatomic types of degeneration. There is, however, a greater liability for cardiac muscle to undergo degeneration as a response to many nonspecific causes, probably related to its continuous activity. *Diffuse nonspecific myocardial degeneration* occurs secondarily in a variety of systemic diseases, especially infectious fevers, anemia, and toxemia.

Hydropic change, *or vacuolar degeneration*, of the myocardium is characterized grossly by a dull gray appearance and increased friability so that the myocardium is easily torn. On cut surface, the muscle is smoother than normal, the outlines of individual muscle bundles obscured. **Fatty change** – the appearance of lipid vacuoles in myocyte cytoplasm – is a more severe event than hydropic change, and may be recognized as uneven patches of pale yellow myocardium. The process of fatty change is not uniform, and it is sometimes possible to recognize, beneath the endocardium, alternating bundles of fibers or strips of myocardium more yellow than the remainder ("thrush-breast heart"). Both hydropic change and fatty change are reversible forms of cellular injury.

Atrophy *of the heart occurs in chronic wasting diseases and malnutrition*. In some cases, the atrophy is accompanied by dark pigmentation, and it is then called "*brown atrophy*." It should be recognized, however, that atrophy can occur without pigmentation, and pigmentation can occur without atrophy. Ruminants are principally affected by atrophy, brown or not, and rarely does the atrophic heart produce clinical disturbance. The epicardial fat may be gelatinous, the endocardium wrinkled, and myocardium brown and friable. Histologically, the muscle fibers are thin, the nuclei small and dark, and masses of brown pigment granules are present within secondary lysosomes at the nuclear poles. The pigment is *lipofuscin*, an oxidation product of unsaturated lipids.

Mineralization *occurs quite commonly in the myocardium*, and is to be expected whenever there is necrosis of fibers. Calcium salts are selectively deposited in the Purkinje network in organomercurial poisoning in cattle, in which the mineralization is preceded by hyaline necrosis of the Purkinje fibers and is followed by surrounding fibrosis.

Xanthosis (xanthomatosis) refers to the *abnormal brown pigmentation* of the myocardium and skeletal muscles seen in cattle, particularly mature Ayrshire cows (see Vol. 1, Muscle and tendon). The pigment is *lipofuscin*, and is present near the nuclear poles in cardiac myocytes. Microscopically, lipofuscin ("wear-and-tear pigment") is commonly seen at the nuclear poles of cardiac myocytes in aged dogs and cats.

Myocardial necrosis

Focal to massive myocardial necrosis, or residual scars thereof, is a common lesion in necropsy material. The causes are quite varied and part of a number of disease syndromes described elsewhere in these volumes.

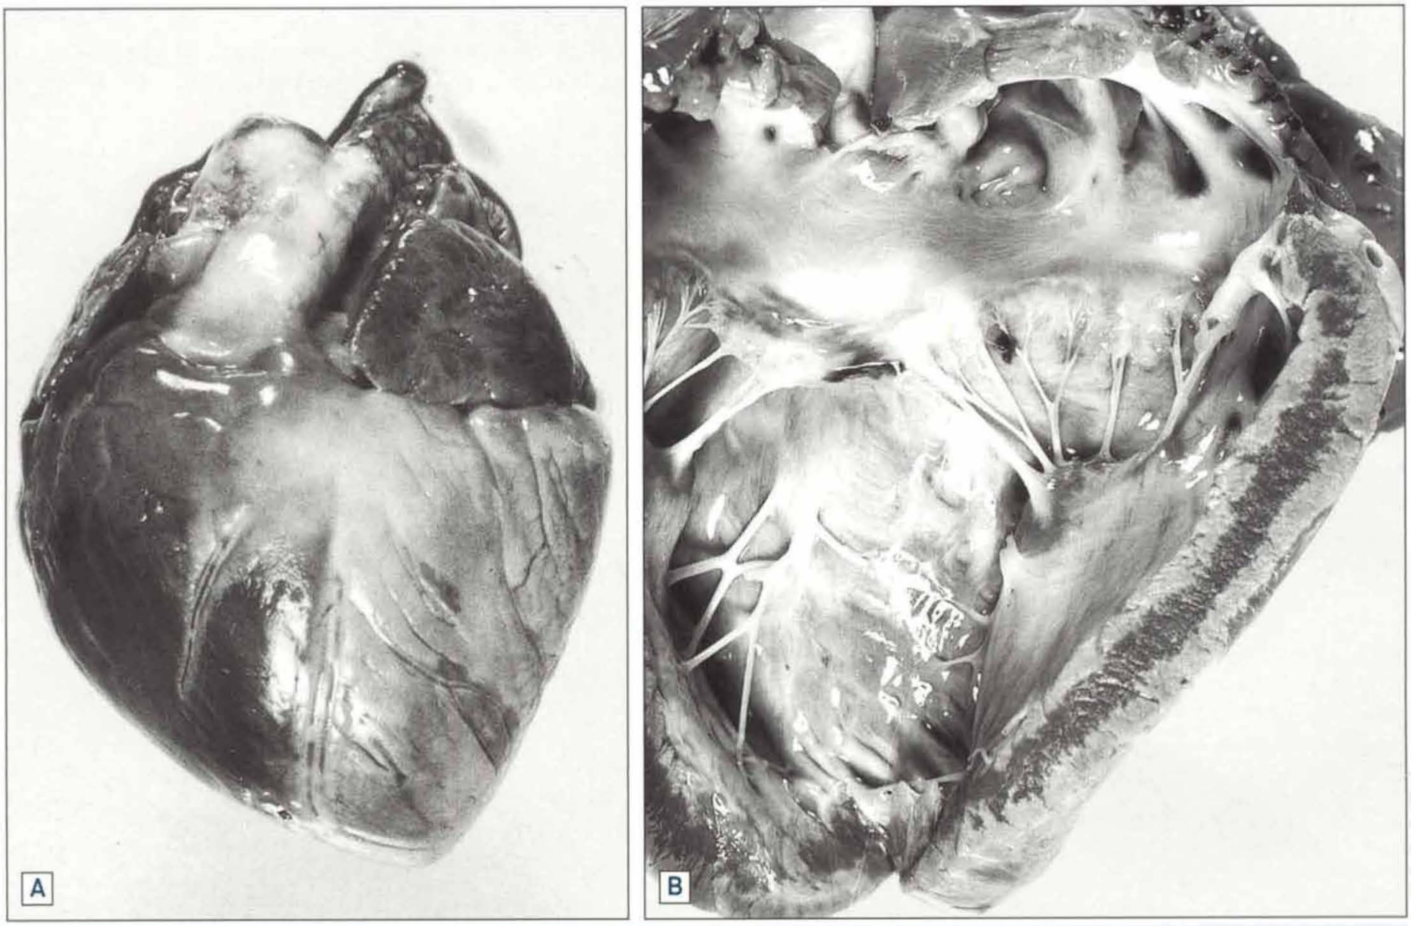

Figure 1.31 Nutritional myopathy in a calf. **A.** Marked pallor of left ventricle due to myodegeneration. **B.** Cut surface of left ventricle showing subepicardial and subendocardial myodegeneration.

In infectious disease, the distinction between myocardial necrosis and myocarditis with myofiber necrosis is somewhat arbitrary – inflammatory cells will invade necrotic myocardium; in acute myocarditis, inflammatory cells should be intimately associated with necrotic myocardial cells and adjacent myocytes may appear normal. Necrosis predominates in highly fatal foot-and-mouth disease in neonatal lambs, piglets, and calves, whereas the residual lesions in older cattle qualify as myocarditis with a significant inflammatory response. Fulminating infection by *Canine distemper virus* in young puppies is purely degenerative, whereas **parvoviral** and **herpesviral** infections in the same age group contain elements of an inflammatory response. Of the bacterial diseases, and excepting blackleg, *Histophilus somni* appears to be responsible for a residual syndrome of sudden death in cattle with myocardial necrosis or infarction, although in some cases myocardial abscesses may be present.

Severe, often fatal, myocardial necrosis is typically part of the important **vitamin E and selenium-responsive syndromes** of nutritional myopathy of lambs, calves (Fig. 1.31A, B), swine, and horses, and in mulberry heart disease of swine. It may also be seen as part of equine rhabdomyolysis and of capture myopathy and other exertional syndromes. (See Vol. 1, Muscle and tendon.)

Deficiency disease, additional to those that respond to vitamin E and selenium, may include myocardial necrosis. It occurs, although not invariably, in **thiamine deficiency** in carnivores, always as a single acute episode. Falling disease of cattle in Australia and Florida is a syndrome of sudden death believed to result from prolonged **copper deficiency**. Myocardial scars accompany acute lesions suggesting repetitive episodes and resembling the lesions of fluoroacetate poisoning in cattle eating the gigee plant, *Acacia georginae*. In cats, **taurine deficiency** causes myocardial failure.

Toxic myocardial degeneration is common, and although some examples are accompanied by degeneration of skeletal muscle they are described here. Injectable **saccharated iron** compounds, by virtue of the capacity of iron to generate free radicals in ferric/ferrous translations, cause fatal myocardial necrosis in piglets. **Monensin**, an ionophore that is widely used as a coccidiostat and growth promotant in ruminants, may contaminate compounded feeds for simple-stomached animals and is cardiotoxic for horses and pigs (see Vol. 1, Muscle and tendon for details of toxicity in other species). Also, ruminants fed dried poultry litter containing **maduramicin** or **salinomycin** develop severe myocardiocyte atrophy and interstitial fibrosis sufficient to result in clinical signs of congestive heart failure. Myocardial necrosis occurs in dogs ingesting rodenticides that contain **thallium** – these have been widely replaced by warfarin analogues and calciferols.

Galenia africana is a bushy plant that is toxic to sheep and goats in South Africa. The toxin has not been identified. Hepatotoxicity appears to develop first, advancing from dilation of central veins and sinusoids to centrilobular and bridging fibrosis, with areas of coagulation necrosis. Myocardial changes begin with myocyte hypertrophy and progress to patchy degeneration and necrosis of myofibers and light fibrosis.

Plants that contain **cardiac glycosides** of both the bufadienolide and cardenolide types are of worldwide distribution. Poisoning by **bufadienolide glycoside-containing plants** is the most important plant-associated poisoning of livestock in southern Africa, and may be acute or chronic. **Acute poisoning** is caused by plants of the family Iridaceae ("tulp"), e.g., *Homeria pallida* (the cape tulip), *H. miniata*, *Moraea polystachya*, *M. bipartita*; family Liliaceae ("slangkop"), e.g., *Urginea sanguinea*; and family Santalaceae, e.g., *Thesium lineatum* ("witstorm"). As well, several species of *Bryophyllum* that occur in southern and eastern Africa, and Australia, e.g., *B. tubiflorum* and *B. pinnatum*, contain bufadienolides (bryotoxins A, B, C, or bryophyllins). In acute poisoning, death occurs within a few hours of ingesting the plant. Affected animals show cardiovascular (tachycardia, arrhythmia, heart block), gastrointestinal, respiratory, and neuromuscular signs. Some cases may live for a few days and exhibit scattered foci of myocardial necrosis, but usually a diagnosis must be based on circumstantial evidence and the presence of plant parts in the ingesta. The cardiac glycosides are inhibitors of the sodium–potassium ATPase pump, which is responsible for maintaining membrane ion concentrations and the membrane potential of cardiac muscle fibers.

Chronic cardiac glycoside poisoning ("krimpsiekte") is a botulism-like, paretic condition of small stock that is caused by members of the family Crassulaceae ("plakkies") that contain cumulative bufadienolides, e.g., *Tylecodon wallichii*, *T. ventricosus*, *Cotyledon orbiculata*, *Kalanchoe lanceolata*.

Cardenolide cardiac glycoside-containing plants, e.g., *Nerium oleander* (common pink oleander), *Thevetia peruviana* (yellow oleander), of the family Apocyanaceae, are seldom eaten by livestock and are usually of little veterinary importance. However, when ingested, typically as plant clippings, their positive inotropic effects on the heart can cause tachycardia, arrhythmias, and sudden death. Long-term exposure to oleander can result in degeneration, fibrosis, and mononuclear cell infiltration of the myocardium. Oleandrin, the responsible cardenolide, can be detected in blood or urine by thin-layer chromatography or by high- performance liquid chromatography/mass spectrometry (LC/MS). Summer pheasant's eye (*Adonis aestivalis*), which contains cardenolides similar to oleander and foxglove (*Digitalis* spp.), causes endocardial and epicardial hemorrhage and mild multifocal myocardial necrosis; strophanthidin, the aglycone of several cardenolides in *Adonis*, can be detected by LC/MS/MS in gastrointestinal contents from affected horses.

Not all acute cardiotoxicity of botanical source can be ascribed to glycosides. Whereas chronic ***Phalaris*** toxicity does produce interesting changes in the central nervous system, the acute toxicity is of much greater economic importance as the cause of quick death in animals first exposed to grazing on this pasture species. The acute toxic factor in *Phalaris* appears to be a tryptamine alkaloid, which may interfere with the metabolism and action of serotonin and other catecholamines. The fast death factors of **lupins and algae** still need definition. In sheep, ***Lantana camara*** causes myocardial necrosis that might have an entirely different pathogenesis, possibly dependent on reduced myocardial perfusion as a result of chronic reduction in circulating blood volume. Poisoning by ***Cassia occidentalis*** (coffee senna), ***Karwinskia humboldtiana*** (coyotillo), and ***Cicuta douglassi*** (western water hemlock) causes muscular and myocardial necrosis in livestock. ***Vicia villosa*** (hairy vetch) poisoning involves many organs, including the heart. The lesions are unusual for a poisoning in that there is a substantial chronic eosinophilic granulomatous inflammatory response associated with the necrosis. Young ruminants (before the rumen has developed), pigs, and dogs are susceptible to the cardiotoxic effects of *gossypol*, a toxic alcohol, when **cottonseed meal** is incorporated in their feed as a protein supplement. ***Eupatorium rugosum*** (white snakeroot) causes myocardial and skeletal muscle damage through the action of *tremetol*, another toxic alcohol. High erucic acid **rapeseed oil** can cause myocardial degeneration and necrosis in a variety of species – this effect has been mitigated by the development of canola, which has low erucic acid content.

Ingestion of **locoweeds** (certain species of *Astragalus* and *Oxytropis*) increases the severity and rapidity of onset of high-mountain disease in cattle grazing at high altitudes. The locoweed toxin is swainsonine, an indolizidine alkaloid. Another indolizidine alkaloid, castanospermine, is found in the seeds of the Moreton Bay chestnut tree (*Castanospermum australe*); this toxic legume causes myocardial degeneration when eaten by horses or cattle.

Cantharidin, the toxic principle in **blister beetles** (*Epicauta* spp.), is thought to be the cause of gastric lesions, hemorrhagic cystitis, enterocolitis, and myocardial necrosis in horses that ingest the beetles in baled alfalfa hay.

Focal myocardial necrosis is also frequently observed as an incidental finding on microscopic examination in many diseases, and its immediate pathogenesis can seldom be ascertained, but *the lesions are thought to have an ischemic basis*. Ischemic myocardial necrosis occurs in thrombotic disease such as disseminated intravascular coagulation, in the microangiopathy of vitamin E/selenium deficiency, and in inflammatory vascular disease such as periarteritis nodosa. Poor myocardial perfusion may be the cause of the multifocal myocardial necrosis seen occasionally in hypocalcemic parturient dairy cows. The subendocardial necrosis seen following acute brain injury (the "*brain-heart syndrome*") may result from coronary arterial spasm and/or catecholamine excess. Another example of **catecholamine-induced myocardial necrosis** is that seen in cases of functional pheochromocytoma. The exact mechanism(s) of catecholamine toxicity is unknown, but may involve free radical damage of myocyte membranes.

Coronary embolism is a relatively common cause of focal myocardial necrosis, the emboli originating from vegetations of left-sided endocarditis; septic emboli may result in myocardial abscesses. In granulocytopenic diseases, bacterial embolism may result in multiple minute myocardial infarcts, the best examples being seen in bracken fern (*Pteridium aquilinum*) poisoning in cattle. Myocardial infarction may occur in polyarteritis (periarteritis nodosa and allied lesions).

Arteriosclerosis, although common in animals, is very seldom severe enough to be responsible for ischemia of the myocardium. In aged dogs, some degree of *hyalinosis of the intramural coronary arteries* is frequently seen (Fig. 1.32) and may be associated with, and presumably the cause of, myocardial infarcts. This condition is called **multifocal intramural myocardial infarction** (discussed with Degeneration of arteries). Hearts that are dilated or hypertrophic are susceptible to focal necrosis of apparently random distribution, although larger lesions are more obvious in the subendocardium of the left ventricle and papillary muscles.

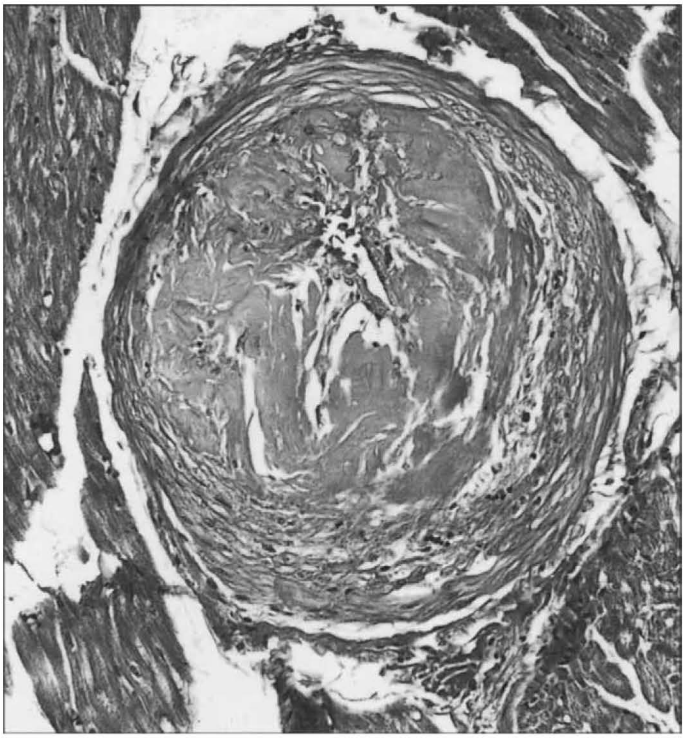

Figure 1.32 Marked **hyalinosis** of an intramural coronary artery.

The gross and microscopic appearance of myocardial necrosis is dependent on the interval between the initial insult and death. **Gross changes** of necrosis are not readily apparent until 12 hours after injury. By 18 to 24 hours, the affected area, in which calcium salts may be deposited, is paler and gray-brown. The overlying serous membrane is usually normal. *Myocardial degeneration, mineralization, and necrosis are most common in the subendocardial myocardium.* This area undergoes the greatest intramyocardial tension during systole and is the most likely to be ischemic. However, proliferative or thrombotic lesions completely occluding vessels in these areas are rarely observed even with careful technique. The common small foci of myocardial necrosis may not be visible from the serous surface, and perhaps may be recognizable only microscopically. The necrosis resulting from infarction will, if sufficiently large, involve the serosal surfaces and produce fibrinohemorrhagic thickening of the pericardium that may neatly overlie and indicate the infarcted area. In cases dying within 24 hours, the pericardial reaction may be the only indication grossly of infarction, the necrotic muscle at this stage not being clearly altered or merely pale. The necrotic area becomes more sharply defined by hyperemia by the second to fourth days. By the tenth day there is beginning replacement of the necrotic zone by fibrous ingrowth. Replacement fibrosis is well established by the end of the sixth week (Figs. 1.33 and 1.34). A substantial, often transmural loss of myocardium and replacement by fibrous tissue may lead to the development of aneurysms of the ventricular wall.

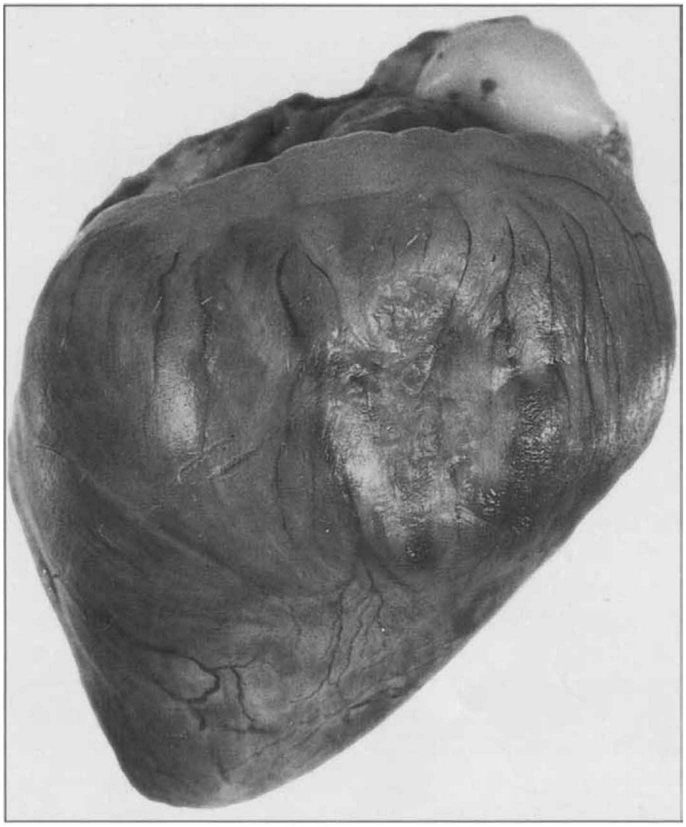

Figure 1.33 Healed, scarified **infarct** in wall of right ventricle of a dog.

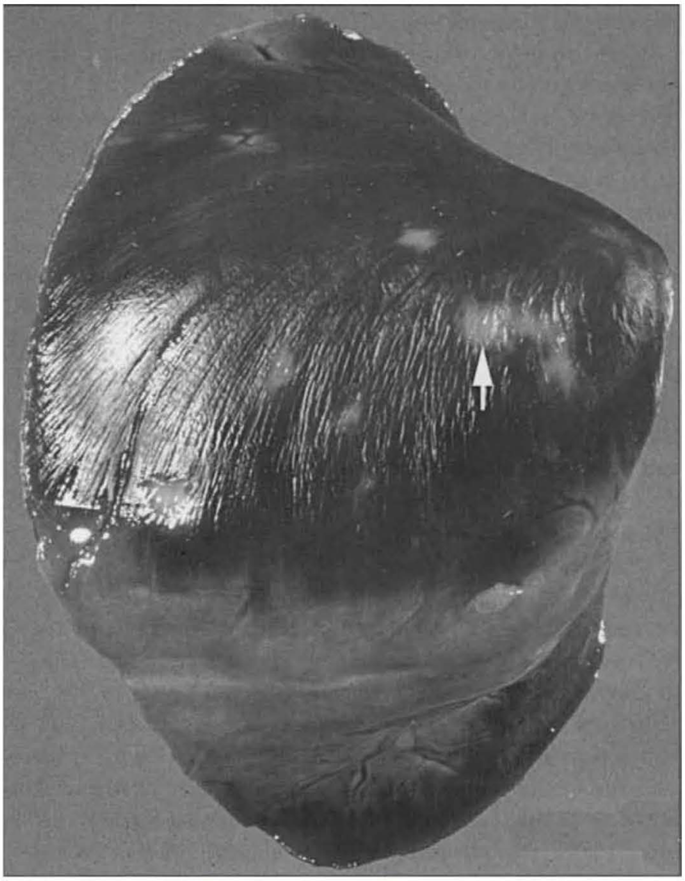

Figure 1.34 Myocardial scar near the apex of the left ventricle of the heart of a horse with vegetative aortic valvular endocarditis caused by *Strongylus vulgaris* infection.

Microscopically, lesions are not usually detectable for the first 6 to 12 hours. However, ultrastructural changes are observed within 1 hour. Recognition as early as 2 hours may be possible using special stains such as hematoxylin-basic fuchsin-picric acid. Necrosis becomes apparent by routine stains after 12 hours. Subsequently, neutrophils infiltrate the affected area and the nuclei of the myocytes become pyknotic. At this stage, macrophages are evident. Granulation tissue appears at the periphery of the lesion toward the end of the first week and usually predominates by the end of the sixth week.

There are variations in the microscopic appearance of myocyte necrosis and some attempt has been made to associate the differing microscopic patterns with particular causes, but these associations are not definitive. The first variant is **coagulative necrosis** characterized by cellular swelling, nuclear hyperchromasia, early loss of striations, and a "granular" appearance of the myocyte. This type of change is observed primarily in ischemic states. **Coagulative myocytolysis** is typified by the presence of thick, irregular, eosinophilic bands, with an accompanying loss of striations and lightly staining granular areas in myocytes. The bands are hypercontracted sarcomeres ("*contraction bands*") (Fig. 1.35) and the light granular areas are mitochondria. Evidence from experimental models suggests that the alteration is the result of the *excessive release of endogenous catecholamines*. However, this change may be observed in normal myocardium if it is fixed immediately after death. **Colliquative myocytolysis** appears as a loss of striations, and homogeneous, weakly eosinophilic cytoplasm. The ultrastructural appearance is characterized by intracellular edema, with disintegration of fibrils and other organelles. *Waviness of myocardial fibers* is claimed by some to be one of the earliest changes observed in myocardial infarction in humans. The affected fibers are not necrotic, but are thinner and undulating in appearance. It is thought that the waviness is due to irreversible stretching followed by compression of ischemic fibers by the surrounding viable myocardium. Attenuated wavy fibers ($<6\ \mu m$ diameter, wavy appearance) have been noted to be common in the myocardium of dogs with dilated cardiomyopathy.

Anichkov cells, also known as "*caterpillar cells*," have been observed in myocarditis and a variety of naturally occurring and experimentally induced myocardial necroses. They are also seen in rheumatic fever in humans in association with Aschoff bodies. Anichkov cells appear as large mononuclear cells in which the nuclear chromatin is present in an undulating wavy ribbon with slender processes radiating from it (Fig. 1.36). The origin of these cells is in dispute. Suggestions include a fibroblastic, pericytic, endothelial, or myocytic origin. Depending on the theory accepted, the function is either that of a macrophage or an abortive attempt at myocyte regeneration.

A few of the more interesting examples of myocardial degeneration and necrosis are described below.

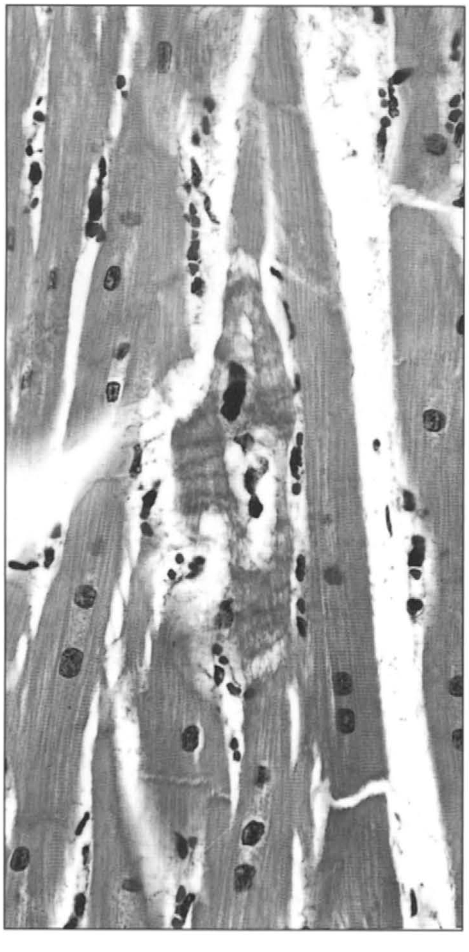

Figure 1.35 Hypercontracted sarcomeres in porcine stress syndrome. (Courtesy of AL Metz.)

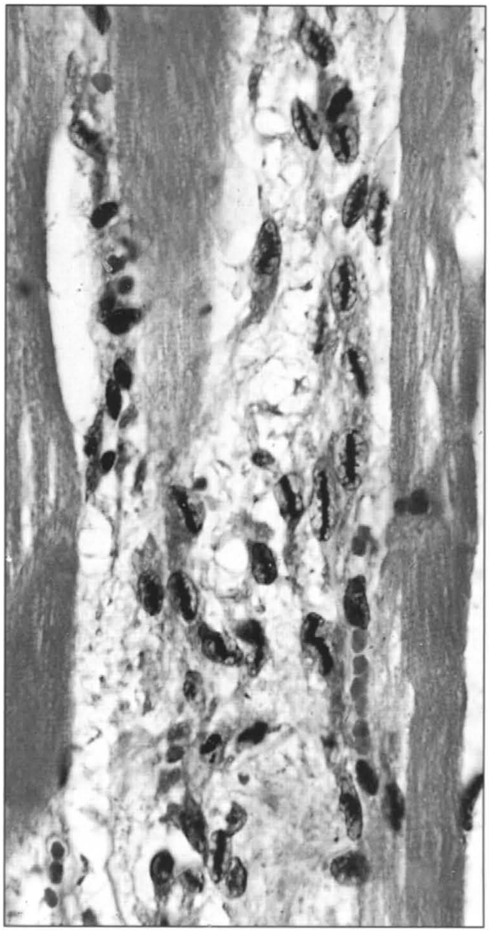

Figure 1.36 Anichkov cells ("caterpillar cells") in interstitium of sheep heart with multifocal myocardial degeneration.

Fluoroacetate poisoning

Sodium fluoroacetate (compound 1080) is used extensively in some parts of the world as a *rodenticide*. It is also highly toxic for most domestic mammals. The median lethal dose for most species is about 0.25–1.00 mg/kg of body weight. Fluoroacetate is not directly toxic, but becomes so when converted to fluoroacetyl-coenzyme A. This compound is then combined with oxaloacetic acid to form fluorocitrate. The citric acid cycle enzymes cis-aconitase and succinic dehydrogenase are inhibited by fluorocitrate, effectively inhibiting the production of adequate amounts of ATP. Accidental poisoning by fluoroacetate occurs either by direct ingestion of the poison, or indirectly, as when dogs eat poisoned rabbits.

Fluoroacetate of **plant origin** is responsible for sometimes devastatingly large episodes of poisoning of ruminants. Horses apparently are not affected, perhaps because they do not eat the responsible plants in adequate amounts and perhaps because, like humans, birds, and some native animals, they are considerably more resistant to the poison than most other species. Plants known to accumulate fluoroacetate in lethal quantities for ruminants are *Gastrolobium, Oxylobium*, and *Acacia georginae* in Australia, *Dichapetalum cymosum* (gibflaar) in South Africa, and *Palicourea marcgravii* in Brazil. Whether fluoroacetate has any role in the physiologic economy of the plants is not known, but in the case of *A. georginae*, there are differences in the development of toxicity in the species. In *D. cymosum*, there are seasonal differences, toxicity being greater in spring and autumn, and especially in young leaves. Young leaves, including sucker growth, and pods and seeds are more toxic than the mature leaves of *A. georginae*.

The syndromes of intoxication vary with the species affected but are either chiefly *neurologic*, as in dogs, which become extremely excited and convulsive, or chiefly *cardiac*, as in ruminants. Sheep may collapse suddenly and die within a few minutes. Those less severely affected may develop cardiorespiratory distress and weakness if driven, with death supervening shortly thereafter. Some showing these signs, if left undisturbed, may recover to appear normal until again forced to exercise. The syndrome in cattle is the same as in sheep, death occurring with cardiac failure, fibrillation, cyanosis, dyspnea, and terminal convulsions. Exercise, excitement, or a large drink of water may precipitate clinical signs.

The necropsy findings in ruminants are referable to *myocardial injury*. This may or may not be conspicuous, depending on the size of the dose and the opportunity for repeated episodes of poisoning. The concentration of fluoroacetate in *D. cymosum* is large, and histologic evidence of acute myocardial injury is seen. In *A. georginae* poisoning, both acute and chronic myocardial changes may be seen. There is some flabbiness of the myocardium, with prominent hemorrhages beneath the cardiac serosa. In acute cases there are irregular areas of myocardial pallor and mottling sometimes associated with older scars. There is multifocal myocytolysis or hyaline degeneration of the myocardial fibers, with intense infiltration of mononuclear cells. Loss of sarcoplasm leaves an open meshwork of reticulum and vessels, which eventually condenses and scar.

Gousiekte

Gousiekte ("quick" disease) is a plant poisoning of ruminants in southern Africa that is of great economic importance in that region. The disease is characterized by acute heart failure 5–8 weeks after the ingestion of certain rubiaceous plants. Clinical signs are seldom seen in natural cases; animals are usually found dead. A number of rubiaceous plants can cause the disease including *Pachystigma pygmaeum*, *P. thamnus*, *P. latifolium*, *Fadogia homblei*, *Pavetta harborii*, and *Pavetta schumanniana*. Pavetamine is the water-soluble, heat-stable toxin responsible for causing gousiekte.

Gross pathologic changes include generalized congestion, ascites, hydropericardium, hydrothorax and pulmonary edema. Ventricular dilation is an inconsistent feature. However, the ventricular walls are thinner and have a tough consistency. In a small proportion of cases the heart is macroscopically normal. Microscopically there is *focal-to-extensive myofiber loss with replacement fibrosis.* The surviving myofibrils may be atrophied, and groups of lymphocytes and macrophages may be present in areas of fibrosis.

Avocado poisoning

Sheep and goats may die following the *ingestion of fresh leaves* from some varieties of the avocado tree (*Persea americana*); the active principle is termed "*persin*." Animals may die suddenly after ingesting comparatively few leaves, whereas others may show few ill effects. In those that die, lesions consist of endocardial hemorrhage, especially of the papillary muscles; hydropericardium; pale, flabby heart; ascites; hepatic degeneration; and pale kidneys. Cardiac lesions are those of *myocyte necrosis* and congestion and hemorrhage of variable severity.

Consumption of avocado leaves also results in depression of milk production in lactating goats. The affected mammary glands are edematous and reddened with clots in the large ducts. The Guatemalan, but not the Mexican, variety of avocado induces these changes in the mammary gland.

Taurine deficiency in cats

Taurine-deficiency myocardial failure (TDMF) *in cats is a primary systolic myocardial disorder associated with taurine deficiency*; most cases of feline dilated cardiomyopathy are actually examples of TDMF. Decreased systolic function results in signs associated with decreased cardiac output giving rise to bilateral congestive heart failure. End-diastolic ventricular volume and pressure are increased, as are atrial volume and pressure.

Taurine (2-aminoethane sulfonic acid), an *essential amino acid for cats*, is abundant in fresh meat, but must be supplemented in commercial feline diets to prevent the development of TDMF, central retinal degeneration, and developmental abnormalities in kittens. Taurine is required in myocardium for the modulation of tissue calcium influx through cardiac calcium channels. Taurine supplementation will restore myocardial function to normal in most cats with low plasma taurine levels and echocardiographic evidence of cardiac chamber dilation and myocardial failure. Cats, and other mammals, have an obligatory need to conjugate bile acids with taurine or glycine; cats not only have a limited capacity to synthesize taurine, but are unable to utilize glycine for bile acid conjugation.

Cats are now unlikely to die of TDMF. In cats that do die, gross and histologic cardiac lesions are as described below for feline dilated cardiomyopathy.

Myocardial necrosis secondary to neural injury

The effect of the central nervous system on the myocardium is mediated by the autonomic nervous system, and in particular the sympathetic nervous system. The heart is richly innervated with autonomic fibers, and myocytes, particularly ventricular myocytes, have high concentrations of β receptors. Both the rate and inotropic state of the heart are stimulated by catecholamines. In a number of species, the continuous administration of *norepinephrine* for 1 or 2 weeks results in focal myocardial necrosis. Multifocal myocardial necrosis may develop in dogs with paroxysmal tachycardia due to *functional pheochromocytomas*. Also, experimentally induced *intracranial hemorrhage* produces focal myocardial necrosis, which can be prevented by prior administration of either reserpine, a catecholamine-depleting drug, or propanolol, which blocks β receptors.

Multifocal myocardial necrosis occurs in dogs, horses, cows, sheep, pigs, goats, and wildlife in association with neurologic disease of diverse origin (“**brain-heart syndrome**”), from external trauma to infectious disease. The primary lesion may involve the head, central nervous system, or major nerve plexuses. The microscopic appearance of the myocardial lesions is dependent on the time elapsed between insult and death. It varies from acute myocardial degeneration and necrosis to almost complete resolution by fibrosis. There are, no doubt, a number of cases with no gross or microscopic lesions where insufficient time elapsed between the onset of clinical signs and death. *The findings of multifocal myocardial necrosis on necropsy in any species should alert the pathologist to examine the central nervous system for abnormality.* Secondary multifocal myocardial necrosis also occurs in dogs with *gastric torsion*, and in dogs and cats with acute necrotizing *pancreatitis* and septic peritonitis.

Doxorubicin (Adriamycin) cardiotoxicity

Doxorubicin, an antineoplastic agent of the anthracycline antibiotic group, is used in the treatment of lymphosarcoma and other neoplasia in dogs; *cardiotoxicity is the major factor limiting its use.* Acute cardiotoxicity appears to be mediated by peroxidative injury or expression of cytokines. As well, binding of doxorubicin to nuclear and mitochondrial DNA causes blockage of DNA, RNA, and protein synthesis. Chronic doxorubicin cardiotoxicity, which may be due to decreased protein synthesis as well as altered divalent cation concentration, occurs in dogs given cumulative doses. Congestive heart failure occurs in such dogs; microscopic myocardial changes consist of myocytic vacuolar degeneration (“*adria cells*”), myocytolysis, myofibril atrophy, and fibrosis. The cardiotoxicity of doxorubicin is reduced when administered as a pegylated liposomal form.

Porcine stress syndrome

Porcine stress syndrome (PSS) is primarily a disease of skeletal muscle (see Vol. 1, Muscle and tendon); the PSS gene mutation is not expressed in myocardial muscle. *Death from PSS may occur as a result of peracute heart failure secondary to the metabolic and hormonal sequelae of PSS*, namely acidosis, hyperkalemia, hyperthermia, and *hypercatecholemia*. The latter may produce myocardial necrosis. Sudden death due to cardiac failure also occurs in sows, both with and without association with the PSS gene mutation.

Clinically, affected pigs exhibit muscular tremor, dyspnea, hyperthermia, and cutaneous blanching and erythema. Death quickly ensues. Typical necropsy findings include the rapid development of rigor, pulmonary edema, hydropericardium, and splanchnic congestion. In some, there is epicardial and endocardial hemorrhage with irregular areas of pallor in the left ventricular myocardium. The presence or absence of myocardial necrosis in porcine stress syndrome is a major difference between the European and North American descriptions of the disease. *Myocardial necrosis is a common finding in European cases.* When present, the necrotic areas are prominent in the inner third of the wall and papillary muscles. The microscopic appearance of the necrotic fibers is characterized by loss of the normal striation pattern, the presence of contraction bands, and fine granulation of the sarcoplasm (Figs. 1.35 and 1.37).

Mulberry heart disease of swine

The name “mulberry heart” is vaguely suggested by the *extensive hemorrhages on the surface of the heart* (Fig. 1.38). The disease occurs in pigs only, chiefly those 2–4 months of age and in excellent condition, but it has been observed in animals from 3 weeks to 4 years of age. Among old pigs the incidence is sporadic, but in young pigs it occurs in short, snappy outbreaks. In most cases, typically affected animals are *found dead*. The circumstances of sudden death combined with the gross and microscopic lesions strongly suggest that the affected animals die of acute heart failure following the development of ventricular dysrhythmias.

Raising weanling piglets on a diet deficient in selenium and vitamin E can regularly reproduce the disease. Such animals may develop disease

within two weeks. As discussed in diseases of muscle (in Vol. 1, Muscle and tendon), selenium is an integral part of the membrane enzyme *glutathione peroxidase*, which reduces toxic lipid peroxides to hydroxy acids. *Vitamin E is an antioxidant* and acts synergistically with selenium to protect membranes from high concentrations of lipoperoxides. Field studies, particularly from the Scandinavian countries, have shown that while dietary selenium supplementation markedly reduces the incidence of hepatosis dietetica and nutritional myopathy, the prevalence of mulberry heart disease remains the same. It is also evident that tissue levels of selenium, particularly those in the heart and liver, are within the normal range. *It is now considered that vitamin E deficiency plays a central role in the development of mulberry heart disease.* However, there is not universal agreement on this. While some studies show lower tissue levels of vitamin E in affected pigs, others show no difference. Additionally, it has been suggested that the disease is the result of altered vitamin E metabolism and not a consequence of inadequate dietary vitamin E levels. It may be that mulberry heart disease is precipitated following a lack of bioavailability of vitamin E in tissues, or possibly a greater requirement for vitamin E under certain dietary circumstances, such as diets containing large amounts of unsaturated fat.

Animals dying of mulberry heart disease are always in *excellent body condition*. There may be slight cyanosis of the ears and ventral abdomen, and exophthalmos, the latter due to orbital and palpebral edema. The intermuscular connective tissues are usually wet, and there may be obvious edema, especially in the axillary and inguinal regions and near the xiphoid process. The skeletal muscles are normal.

The principal lesions occur in the thorax. Some 50 mL or more of heavy, straw-colored fluid that clots on exposure to air is invariably present in the pleural cavity. The lungs are edematous and slightly or severely congested, but not severely enough to account for the degree of edema. The pericardium is edematous and opaque and is always acutely distended with fluid transudate. Either heavy strands or a lace of fibrin float in the fluid (Fig. 1.38). The fibrin is not fixed to the serous surface and, from where it is in contact with the epicardium, it can easily be lifted off to reveal a clean, glistening, serous membrane. *Hemorrhages, linear and ecchymotic, are present beneath the epicardium*. They may be few or they may be extensive and involve the epicardium of all chambers, the myocardium, and beneath the endocardium of the papillary muscles and septum (Fig. 1.39). In some, multiple pale streaks and patches of necrosis extend from the epicardial surface into the myocardium. There may be similar lesions visible from the endocardial surface.

The abdominal cavity contains a small volume of clear transudate and some fine unattached strands of fibrin on the intestine. The stomach usually contains a mass of dry feed, and its fundic mucosa is diffusely congested. The small intestine is empty and dry, with serosal vessels congested. The liver is congested, sometimes markedly so, with edema of the wall of the gallbladder. In some animals that survive 24 hours or more, there is *bilaterally symmetric softening of the white matter* forming the cores of the cerebral gyri. The softenings are visible grossly as gray, translucent, depressed areas studded with tiny hemorrhages that are sometimes confluent (Fig. 1.40).

Microscopically in acute deaths, degeneration of myofibers may be minimal or absent. In these cases there is merely subserosal edema, with some plugging of lymphatics by fibrin, and interstitial hemorrhage. In others, which are probably less acute cases, there are *substantial areas of myocardial necrosis*. The extent of mineralization of the necrotic fibers varies, but never appears to be as severe as that seen in lambs or calves with nutritional myopathy.

The second prominent lesion, which is most probably unrelated to the myocardial necrosis, is observed in arterioles of many organs. The change is seen in the heart, kidneys, liver, stomach, intestine, mesentery, skeletal muscle, and skin. There appears to be gradation in the severity of change, from endothelial swelling with increased permeability, to necrosis of smooth muscle cells of the media. *The basic appearance includes the accumulation of fibrinoid in arteriolar walls, formation of hyaline thrombi, disruption of endothelium, and necrosis of smooth muscle cells.*

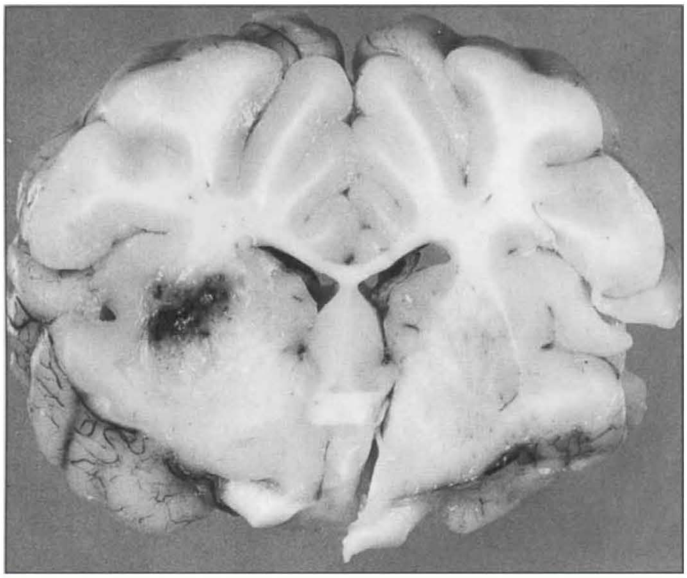

Figure 1.40 Cross-section of brain showing hemorrhage in region of internal capsule in **mulberry heart disease** in a pig.

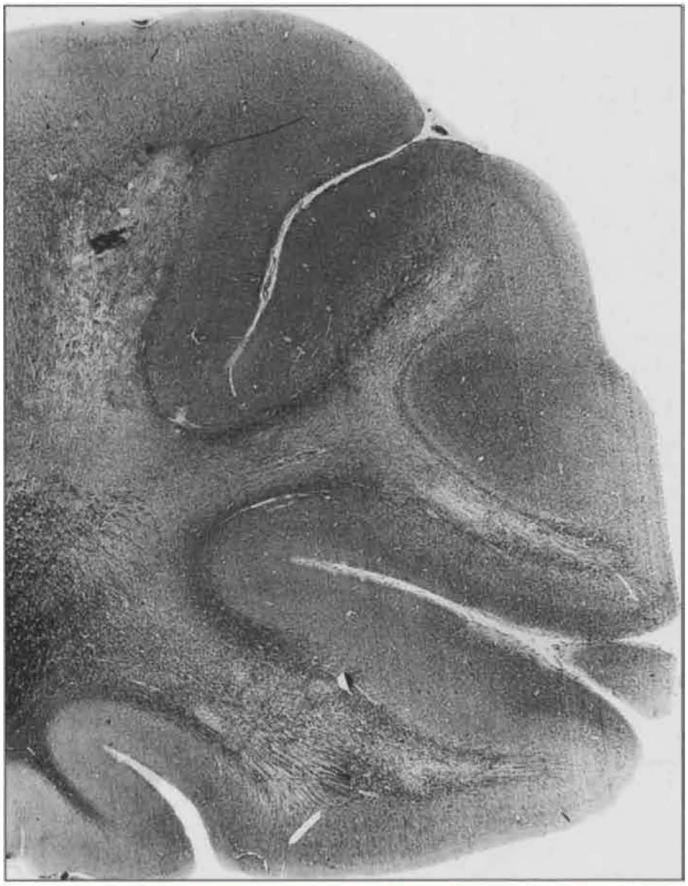

Figure 1.41 Liquefaction of white matter in the cerebrum, sparing corpus medullare and U fibers in **mulberry heart disease** in a pig.

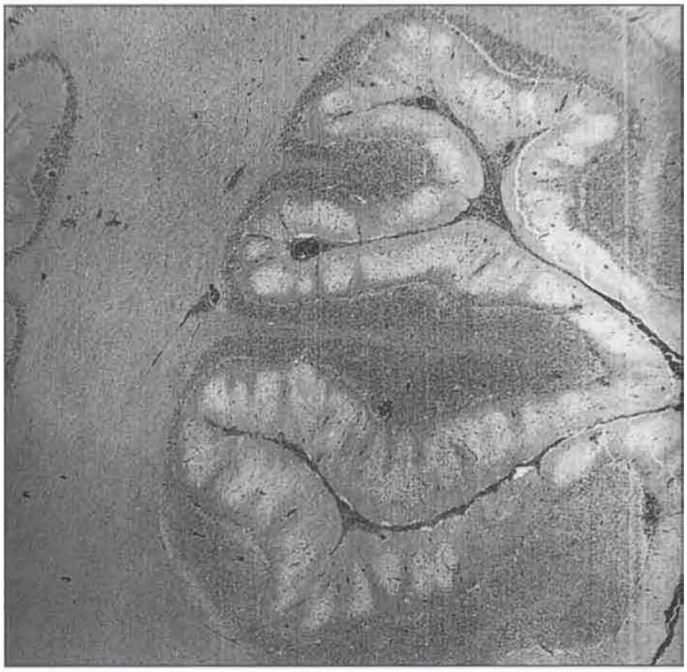

Figure 1.42 Numerous confluent areas of softening in the molecular layer of the cerebellum in **mulberry heart disease** in a pig.

Periodic acid-Schiff (PAS) staining of affected arterioles emphasizes the accumulation of fibrinoid. The lungs show congestion and edema only. There is congestion and edema of the liver, associated in some cases with central necrosis in the lobules. Proteinaceous fluid produces focal detachments of the retina and intercapillary edema of the glomerular tufts.

The development of the *cerebral lesions* can be correlated roughly with the duration of the clinical illness. In the majority of cases, where death occurs suddenly, there is no microscopic change in the brain, or merely some slight venous congestion and edema of the cortical white matter. In pigs that live for some hours, there is edematous separation of the fiber tracts of the white matter of the frontal cortex, with acute swelling and fragmentation of oligodendroglia. The overlying gray matter is edematous. In animals that survive for 24 hours or more, it is usual to find severe lysis of the white matter in the cerebrum, which is more or less extensive but usually avoids the internal capsule, corpus medullare, and association fibers (Fig. 1.41). The cores of the gyri of the frontal lobes are most consistently and severely involved, but in some cases all portions of the cerebrum are involved, and in these there may be similar lesions in the thalamus and brainstem. The vessels, venules especially, in the degenerate areas are severely injured and may be totally necrotic, although more frequently there is only endothelial and adventitial swelling and proliferation. Hyaline thrombi are formed in many vessels, and droplets of similar character form in the perivascular spaces. The overlying gray matter is edematous. The vessels are hypertrophic and cuffed by adventitial cells and a few eosinophils. In a few cases, degenerate foci are also present in the cerebellum; these involve the molecular layer with foci of softening (Fig. 1.42) or narrow sheets of hemorrhage.

The lesions in mulberry heart disease depend on the length of time pigs survive after the initial damage occurs. *Most pigs die from ventricular dysrhythmia*, and those that die immediately no doubt have substantial areas of myofiber death, but there has been insufficient time for the morphologic manifestations of the necrosis to appear. A period of 6–12 hours must elapse before myofiber necrosis can be reliably recognized. After that, the lesions become increasingly evident and progress through stages to replacement fibrosis of the necrotic areas if the pig survives.

In the experimentally induced disease, serum enzyme levels indicative of myocardial damage may be raised for up to 21 days before death. The extent of cardiac damage is related to the length of time the serum enzymes are raised or, alternatively, to a large increase over a shorter period. *The microangiopathy prominent in this disease probably occurs independently of the myofiber necrosis.* It is also nonspecific, as the same change is seen in many porcine viral infections and bacterial toxemias. It is, however, a useful indicator of the presence of mulberry heart disease.

Myocarditis

Myocarditis, or inflammation of the myocardium, is a common lesion found in a wide variety of systemic diseases (Table 1.6), but it is rarely primary. It occurs hematogenously in many infectious diseases, and by direct extension from inflammatory lesions of the endocardium and pericardium. A number of specific parasitic infestations also produce myocarditis. Effectors of the immune and inflammatory responses in myocarditis can have numerous deleterious effects on the myocardium: cytolytic T lymphocytes can produce focal myocyte necrosis; activated lymphocytes and macrophages can release a host of inflammatory cytokines that can lead to altered myocyte metabolism, decreased contractility, and dysrhythmias, and to increased matrix and myocardial fibrosis. Death due to myocarditis may occur acutely due to dysrhythmia; inflammation is often focal and can be missed grossly. Non-fatal cases of myocarditis may progress to congestive heart failure, which ensues subsequent to myocyte loss and fibrosis.

Table 1.6 Causes of myocarditis in domestic animals

Viruses	E.g., *Canine herpesvirus, Canine parvovirus 2, Encephalomyocarditis virus, Equid herpesvirus 1, Foot-and-mouth disease virus, Murid herpesvirus* (murine cytomegalovirus), *Porcine circovirus 2* and/or *Porcine parvovirus* (in PMWS, postweaning multisystemic wasting syndrome), *Pseudorabies virus, West Nile virus*
Bacteria	E.g., *Actinobacillus equuli, Actinobacillus suis, Bartonella vinsonii, Borrelia burgdorferi* (Lyme disease), *Clostridium chauvoei, Histophilus somni, Leptospira* spp., *Streptococcus suis*
Rickettsia	E.g., *Ehrlichia risticii*
Protozoa	E.g., *Neospora caninum, Sarcocystis, Toxoplasma gondii, Trypanosoma* spp.
Helminths	E.g., *Trichinella spiralis*

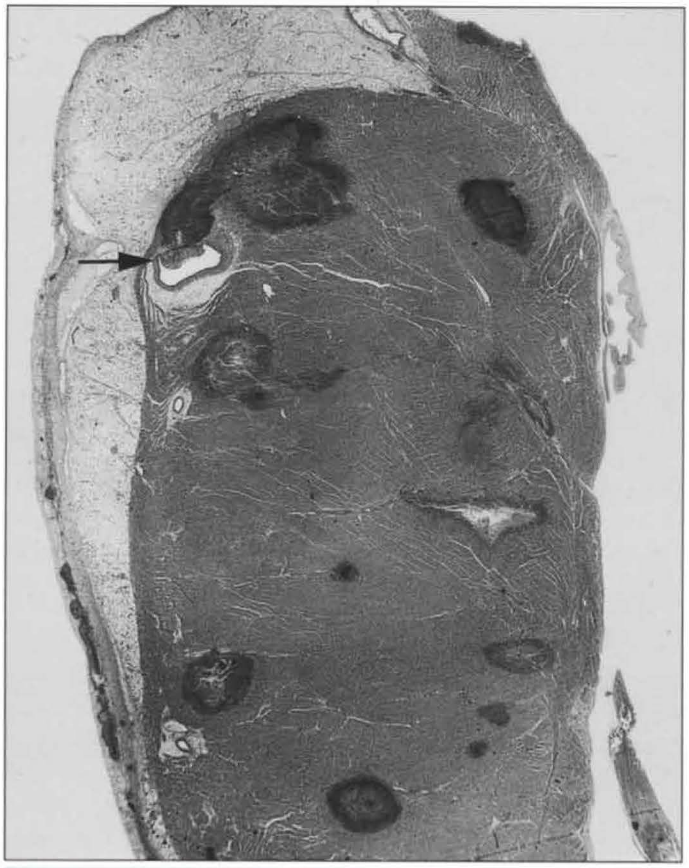

Figure 1.43 Embolic suppurative myocarditis, due to *Arcanobacterium pyogenes*, in a lamb. Multiple abscesses, one of which has encroached upon and caused thrombosis in a coronary artery (arrow).

Pyogenic bacteria, which may originate from any other suppurative focus in the body or, as in the case of *Listeria monocytogenes* and *Actinobacillus equuli*, produce foci of acute **suppurative myocarditis** that may develop into abscesses with inevitable destruction of the involved tissue (Fig. 1.43). In these, it is often possible to demonstrate bacterial emboli. *Clostridium chauvoei* may produce necrotizing myocarditis similar to the typical lesion in skeletal muscle. Tuberculous myocarditis is rare, and when present, the granulomatous reaction is typical of the species. Necrobacillary myocarditis occurs in cattle secondary to extensive necrobacillosis in other tissues; the suppurative reaction is typical for the organism. Other bacterial causes of suppurative myocarditis include *Clostridium piliforme* (*Bacillus piliformis*) and *Citrobacter koseri*. There is also extensive myocarditis in some systemic mycoses, such as *Aspergillus terreus* in the German Shepherd Dog.

Less specific **interstitial myocarditis** *occurs in many infectious diseases and is not detectable by the naked eye.* The basic pattern is usually the same, the reaction being centered on the interstitial and perivascular connective tissues, with edema and infiltration of lymphocytes, plasma cells, macrophages, and some eosinophils. Neutrophils are few. The changes in the myocardial fibers vary widely in extent and in the severity of degeneration. The cause may sometimes be apparent in the histologic nature of the lesion, as, for example, in malignant catarrhal fever of cattle, in which inflammation is centered on the blood vessels. In toxoplasmosis, the degeneration of myocytes predominates over the inflammatory reaction and the organism is identifiable. *In most cases of interstitial myocarditis, however, diagnosis of the cause can only be made by reference to the total pathologic picture.* Only infrequently can death be attributed to the myocardial lesions, and then only when considerable degeneration of the myocardial fibers has occurred, as in foot and mouth disease of young animals. Some other viral infections, such as canine parvovirus infection and encephalomyocarditis virus infection, are exceptions to this general principle.

Myocarditis is seen in **systemic viral infections**, such as canine distemper, canine herpesviral infection, and pseudorabies in piglets and dogs. The myocarditis caused by *Canine parvovirus-2* infection is discussed in Vol. 2, Alimentary system. *Porcine parvovirus* is a common cause of abortion, stillbirth, and mummification (see Vol. 3, Female genital system). However, porcine parvoviral DNA has been detected in suckling piglets by both PCR and to a lesser extent, by in situ hybridization in cases of non-suppurative myocarditis. Myocarditis is a feature of postweaning multisystemic wasting syndrome (PMWS) of weaned pigs – a syndrome experimentally reproduced by co-infection of pigs with *Porcine circovirus-2* and *Porcine parvovirus*. This lesion had formerly been ascribed to infection with *Porcine reproductive and respiratory syndrome virus*.

"**Eosinophilic myocarditis**" is so called because the *reaction to sarcocysts* is predominantly by eosinophils, which produce the typical, small, green to gray-green foci observed occasionally in cattle at routine meat inspection. This syndrome is not to be confused with the eosinophilic myocarditis present in cases of poisoning by ingestion of *hairy vetch* (*Vicia villosa*).

Encephalomyocarditis virus infection

There are three members of the genus *Cardiovirus* in the family Picornaviridae, and the type species is *Encephalomyocarditis virus* (EMCV). All species are antigenically related and by most tests are indistinguishable from each other. EMCV can infect humans and other mammals, principally swine and subhuman primates. *Rodents, in which it appears to be clinically inapparent and behaves as an enterovirus, may act as reservoir hosts*, but infection in laboratory rodents commonly produces fatal encephalitis or myocarditis. The source of infection in outbreaks of myocarditis in swine is thought to be through consumption of feed or water contaminated with virus from rats or other rodents. Ingestion of diseased rodent carcasses is also a likely source of infection. Experimental transmission of disease to swine has been accomplished by feeding the virus, but susceptible pigs kept in close contact with infected pigs did not develop disease.

Sudden death or death following a brief period of excitation and collapse characterizes the clinical disease in the peracute form in swine. In less severe cases, there may be fever, anorexia, and progressive paralysis. The mortality rate is variable. On necropsy there is hydrothorax, hydropericardium, ascites, and pulmonary congestion and edema. In severe cases, there is extreme pallor of the ventricles, with yellow-to-white foci 2–10 mm in diameter throughout the myocardium. In less severe cases, gross lesions are minimal to absent. *Microscopically, the dominant lesions are focal-to-diffuse myocardial necrosis.* Patchy mineralization of necrotic areas is evident, accompanied by a *mononuclear inflammatory reaction* that varies greatly in intensity. Survival allows fibrous scarring to develop. There is little evidence of encephalomyelitis. EMCV infection has also been associated with reproductive failure characterized by mummified fetuses and stillbirth, as well as failure of conception and early embryonic deaths. Fetuses that die toward the end of gestation have multifocal myocardial necrosis.

Experimentally infected swine may die between 2 and 11 days postinoculation. Virus is present in the feces for 7–9 days following oral administration and may be isolated from all organs, with the myocardium exhibiting the highest titer of virus. The virus titer falls rapidly and may not be found in cases that have been infected for 11 days or more. Experimental inoculation of mice regularly produces both encephalitis and myocarditis. Strains of EMCV may be adapted to produce either encephalitis or myocarditis.

Parasitic myocarditis

The parasites that tend to localize in the myocardium are the same as those that have an affinity for skeletal muscle. Parasites without such affinity may also be found in the myocardium in the course of their wanderings, especially if they are migrating in an abnormal host or in unusually large numbers in the normal host.

Of those parasites with an affinity for cardiac and skeletal muscle, the ubiquitous **sarcocysts** are the most common (see Vol. 1, Muscle and tendon). *The finding of myocardial sarcocysts is very common in ruminants.* This increases with the age of the animal and implies a previous acute sarcocystosis in which schizonts are formed in endothelial cells, usually with little effect. The sarcocysts may be found in the cardiac conducting fibers as well as myocardial fibers and normally appear to be harmless. The *multifocal eosinophilic granulomatous reaction* to degenerating ***Sarcocystis cruzi*** cysts may occur alone or in association with similar lesions of eosinophilic myositis in skeletal muscles. Degenerate cysts are occasionally visible within foci of myocarditis. The cyst content is highly toxic, but whether degeneration or rupture of the cyst is primary or is secondary to some other cause of focal myocardial degeneration is unknown.

A rather severe myocarditis in dogs caused by the protozoal parasite ***Neospora caninum*** *is seen in association with myositis and encephalomyelitis.* Affected dogs vary in age from 2 days to 7 years and may be presented with hindlimb paresis or ataxia, skeletal muscle atrophy and in some cases, sudden collapse attributable to dysrhythmias induced by the myocarditis. The differentiation of *Neospora caninum* from *Toxoplasma gondii* in paraffin-embedded tissue is best accomplished by the use of immunohistochemistry. Additionally, *Neospora caninum* is commonly associated with bovine abortion.

The various **cysticerci** of *Taenia ovis*, *T. saginata*, *T. solium*, and hydatid cysts are frequently found in the myocardium, which is one of their sites of predilection (Fig. 1.44A, B). These parasites are described with parasitic diseases of the intestine (in Vol. 2, Alimentary system), which is the habitat of their definitive stage.

Trichinella spiralis is described with diseases of muscle in Vol. 1, Muscle and tendon. However, it is worth noting here that the larvae of this parasite invade the myocardium, but are seldom found there, either because they continue their migration or are

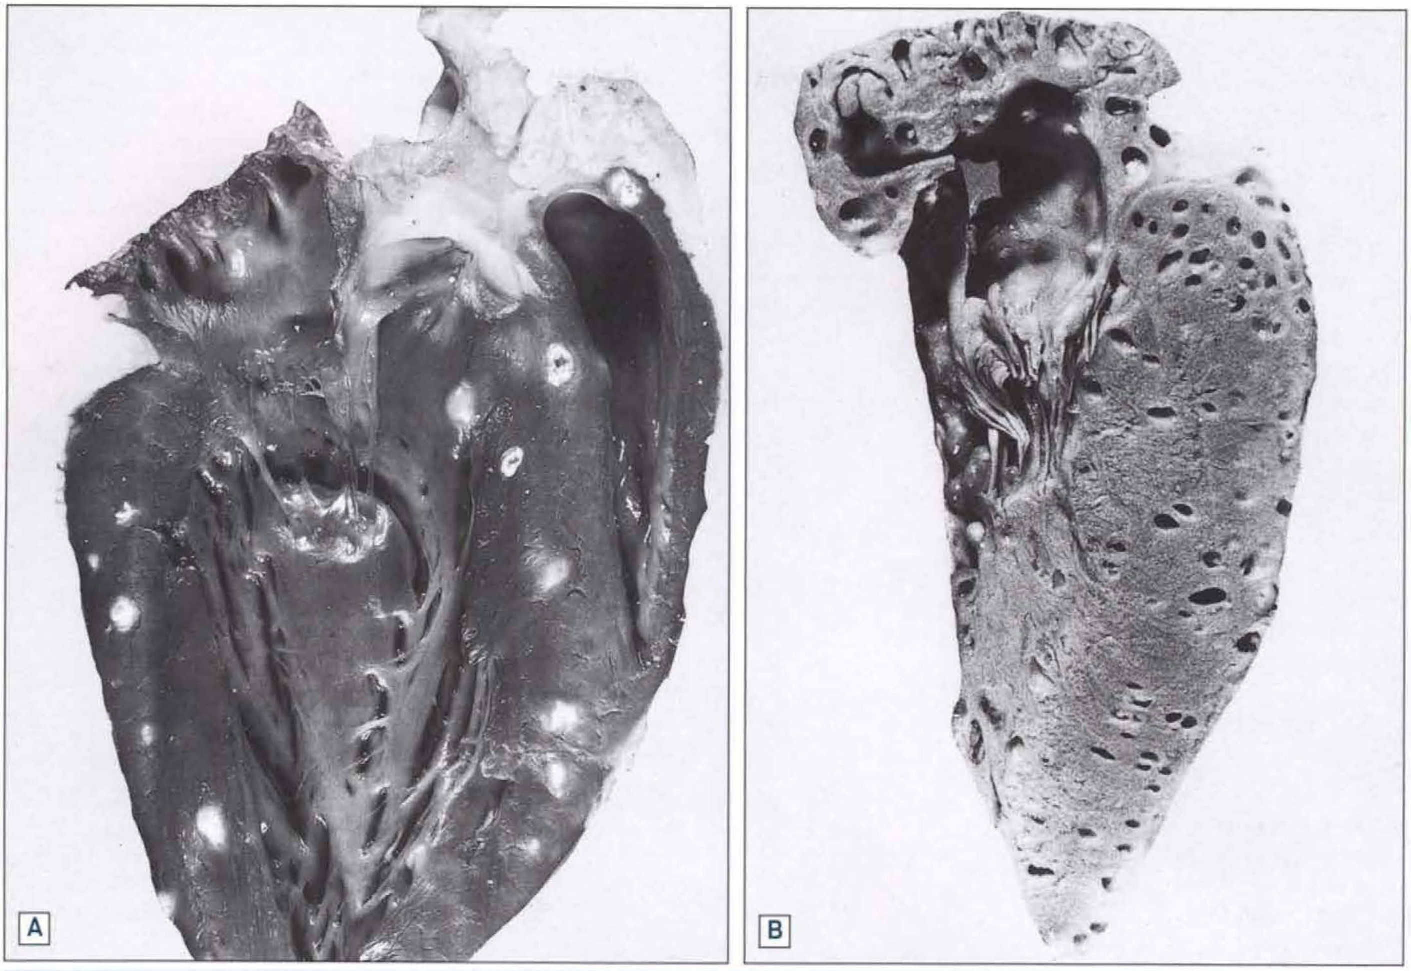

Figure 1.44 Parasitic myocarditis. **A.** Mineralized foci of degenerate ***Cysticercus ovis*** in a lamb. **B.** Cysts of ***Cysticercus cellulosae*** in the myocardium of a pig.

destroyed. The myocardial reaction is a *severe interstitial myocarditis*, with basophilic degeneration and necrosis of fibers in the areas of inflammation.

The *pyogranulomatous myocarditis* caused by ***Trypanosoma cruzi*** (Fig. 1.45) is described in Vol. 3, Hematopoietic system. In Africa, myocarditis can occur in dogs infected with *Trypanosoma brucei*, and in cattle infected with *T. congolense* or *T. vivax*.

Cardiomyopathies

The term **cardiomyopathy** was originally coined for a group of myocardial diseases in humans that were of unknown or obscure cause. It remains essentially a diagnosis by exclusion. In humans, several criteria must be satisfied to establish the diagnosis. They are the absence of

1. significant coronary artery disease or anomaly,
2. vascular disease or anomaly,
3. systemic hypertension, past or present, and
4. shunts inside or outside the heart.

Features usually present are

1. cardiomegaly, due to generalized dilation or hypertrophy,
2. mural thrombosis, usually in the left ventricle, and
3. fibrosis or other lesions in the myocardium indicative of generalized myocardial involvement.

Of these features described for humans that must be absent, coronary arterial disease and systemic hypertension may be disregarded in domestic animals because of their comparative rarity. An additional exclusion, at least for cats, should be that of hyperthyroidism.

Since the original definition, the term cardiomyopathy has been used loosely to describe any abnormality of the myocardium for which an etiology cannot be defined. There has also been some attempt to classify cardiomyopathies into primary (obscure etiology) and secondary (known systemic or etiologic abnormalities) categories. Under such classifications, the list of diseases is seemingly endless. *It is therefore preferable to restrict use of cardiomyopathy to* **idiopathic primary myocardial disease**.

Progress has been made in the understanding of the cardiomyopathies, particularly with one of the forms of feline cardiomyopathy and in hypertrophic cardiomyopathy in people. *Most cases of dilated cardiomyopathy in cats are now recognized as taurine-deficiency myocardial failure (TDMF)*, which is described above with myocardial degeneration/necrosis. Mutations in a number of *genes* coding for contractile proteins promote the development of hypertrophic cardiomyopathy in people. There is also evidence that one of the cardiomyopathies in dogs, and a familial dilated cardiomyopathy in people, are caused by an absolute or metabolic deficiency of *carnitine*. These should properly be no longer regarded as cardiomyopathies because the cause is known. If the understanding of the etiology and pathogenesis of the cardiomyopathies continues to progress, then the term cardiomyopathy will become obsolete. We are, however, not at that stage, and will continue to use the term and discuss these diseases in terms of primary diseases of the cardiac muscle.

Cardiomyopathies generally fall into three forms: **(1) dilated (congestive)**, **(2) hypertrophic**, and **(3) restrictive**. As the clinical and pathologic patterns of the cardiomyopathies were first described in people, a brief discussion of the essential features in this species is warranted.

Dilated (congestive) **cardiomyopathy** (DCM) is the most common form in humans. There is no unifying genetic or metabolic basis for the hypocontracting heart of DCM. It probably represents a common expression of myocardial damage produced by a variety of as yet undefined myocardial insults. Known causes of morphologically similar cardiac chamber dilation and failure include myocarditis, alcohol abuse, cocaine abuse, cobalt toxicity, and genetic influences. *DCM is characterized by dysfunction of the systolic phase of the cardiac cycle*, whereby there is lowered force of contraction and increased ventricular end-diastolic volume. There is enlargement and dilation of both atria and ventricles. The ventricles are hypertrophied, but, because of the dilation, the hypertrophy is not as apparent as in the hypertrophic form of the disease. Microscopically, there is variation in myocyte size, myocyte degeneration and necrosis, and variably severe fibrosis. These changes are, however, disappointingly nonspecific.

Hypertrophic cardiomyopathy (HCM) *is a diastolic rather than a systolic ventricular disorder*. The hypertrophic ventricle is abnormally stiff (less compliant) resulting in impaired ventricular filling. It is inherited as an autosomal dominant characteristic in approximately 50% of human cases, within which there is a high prevalence of subclinical disease. The cause or causes of the remaining 50% of cases is not known. Sudden unexpected death is often the first manifestation of HCM. There is left, and sometimes right, ventricular hypertrophy, reduced size of the ventricular lumen, and dilation and often hypertrophy of the atria. The pattern and extent of the ventricular hypertrophy varies from localized hypertrophy of the ventricular septum (*asymmetric septal hypertrophy*), to the hypertrophy being symmetrical or even apical in nature. Microscopically, *the myocytes are hypertrophied, with many arranged in a whorled or disorganized pattern*. While the disordered myocyte arrangement is not unique to HCM, it is more severe. Fibrosis of variable severity accompanies the hypertrophic process.

Mutations in genes that code for proteins associated with the process of cardiac contraction have been identified in cases of HCM. Understanding of the molecular nature of HCM in people has progressed rapidly, providing insight into cardiomyopathies in domestic species. Genes involved in HCM include the cardiac troponin T gene (cTnT), the myosin heavy chain gene (MyHC), and the cardiac myosin-binding protein C gene (MyBPC3). The mutations in each gene appear not to be singular in nature; for example, at least 7 mutations have been identified in the MyBPC3 gene alone. The inherited form of HCM is therefore a genetically diverse disease, which presents as a common clinical and pathological syndrome. Interestingly, mutations of the cTnT gene can cause both DCM and HCM, and mutation in the same codon in the cardiac troponin I (cTnI) gene causes both HCM and RCM.

Restrictive cardiomyopathy (RCM) *is characterized by impaired ventricular filling due to reduced ventricular compliance, with unimpaired systolic function*. The ventricles are usually of normal size, but both atria are usually dilated. Reduced compliance of one or both ventricles may occur because of interstitial or endomyocardial fibrosis with or without eosinophilia of the ventricles. Restrictive cardiomyopathy may also result from the deposition of *amyloid* or occur in association with the disease *sarcoidosis*. These *infiltrative cardiomyopathies* are, strictly speaking, secondary cardiomyopathies.

The *endomyocardial form* of RCM is subdivided into two major forms: *Loeffler endomyocarditis* occurs predominantly in temperate climates; *endomyocardial fibrosis* is most common in equatorial Africa. Although the end-stage of both forms is pathologically indistinguishable, the natural history and clinical patterns are quite separable. The Loeffler (hypereosinophilic) variant principally affects males and is associated with hypereosinophilia, thromboembolism, and arteritis. In endomyocardial fibrosis, there is no male predominance, and it occurs in younger patients with no accompanying eosinophilia. At least for the Loeffler variant, endomyocardial fibrosis results from release of granules from infiltrating eosinophils in the earlier phase of the disease.

Cardiomyopathies occurring in domestic animals have been similarly classified and have been documented in cats, dogs, cattle, and pigs.

Feline cardiomyopathies

Feline cardiomyopathies constitute a diverse group of morphologic and functional disorders, and are probably the most common and well-recognized cardiomyopathies in domestic animals. Echocardiography is the definitive test used clinically to differentiate and classify feline cardiomyopathies, which include, in decreasing order of prevalence, hypertrophic, restrictive, dilated, unclassified, and excessive left ventricular moderator band cardiomyopathies. Although feline cardiomyopathy was only recognized as an entity in the recent past, a common consequence of cardiomyopathy, *iliac thromboembolism*, was originally described more than 60 years ago. There is a wide range in the age of onset of clinical signs, from 7 months to 24 years. Presenting clinical signs include lethargy, anorexia, dyspnea, tachypnea, and occasionally abdominal distension. Murmurs, most often associated with mitral or tricuspid insufficiency, gallop rhythms, and dysrhythmias of various types are frequently encountered. Approximately one-third of cats with cardiomyopathy develop unilateral or bilateral thromboembolic hindlimb ischemia. The causes of feline cardiomyopathy remain obscure. A possible role for viral infection and inflammation in the pathogenesis of feline cardiomyopathy is suggested by the detection by PCR of *Feline panleukopenia virus* genome in cats with idiopathic hypertrophic, dilated, and restrictive cardiomyopathies and myocarditis.

Hypertrophic cardiomyopathy, the most common form of cardiomyopathy in cats, *is a diastolic disorder*, resulting from ventricular myocardial hypertrophy in the absence of an obvious cause. There is normal or near-normal systolic myocardial function, but diminished capacity to accept diastolic flow from the left atrium. Left ventricular volume is normal or decreased and the papillary muscles are usually greatly enlarged in relation to the volume of the ventricle. The left atrium is usually dilated. A concentrically hypertrophied heart also occurs in cats with *hyperthyroidism* and this should not be confused with hypertrophic cardiomyopathy (see Cardiac hypertrophy, above).

The pathologic features of HCM include an enlarged heart, with comparatively massive *symmetric concentric hypertrophy* of the ventricles in the majority of cases, but especially the left ventricle. The left ventricular lumen is often slit-like. Some cases have *asymmetric hypertrophy of the left ventricle*, with the ventricular septum thicker than the left ventricular free wall. Findings of lesser frequency include atrial thrombi (Fig. 1.46), focal areas of ventricular fibrosis, and fibrosis of the endocardium in the region of the left ventricular outflow tract. Microscopically, myofibers are hypertrophied and contain vesicular nuclei. *Myofiber disarray*, characterized by interweaving of myofibers in the left ventricular free wall and ventricular septum, may be observed. This may also be present in the right ventricle. *Diffuse interstitial fibrosis is also a consistent feature*, especially in the inner two-thirds of the left ventricular free wall. Scattered focal areas of dense replacement fibrosis are seen in a minority of cats. As indicated by increased plasma cTnI concentrations, cats with moderate-to-severe HCM have ongoing myocardial damage, which may be the stimulus for replacement fibrosis. Focal endocardial thickening by fibrosis also occurs commonly. Intramyocardial arteries may have medial hypertrophy, and scattered perivascular accumulations of lymphocytes and monocytes may be present.

Ultrastructurally, the hypertrophied myofibers have large pleomorphic nuclei with undulating surfaces and prominent nucleoli. Dense accumulations of Z-band material are also evident in myocytes, as is the presence of lipofuscin granules. While these changes are seen in normal cat myocytes, the intensity of the changes is greater in cardiomyopathic cases. The cause of feline HCM is unknown; it appears to be inherited as an autosomal dominant trait in Maine Coon cats and American Shorthairs, and is likely heritable in a variety of other breeds.

Restrictive cardiomyopathy is a less common and less well-defined form of cardiomyopathy and is characterized by *impaired diastolic ventricular filling*, which may be due to severe endomyocardial fibrosis. Systolic function is usually normal. Feline RCM has also been termed "*left ventricular endocardial fibrosis*" (LVEF). *Endomyocarditis* may be an antecedent to LVEF. Feline RCM occurs predominantly in older cats with clinical signs of left-sided or bilateral heart failure. Cardiac murmurs and dysrhythmias are common. Pathologic features include *severe endocardial thickening with mural thrombosis*. Left atrial enlargement is marked, the result of the restriction of ventricular filling, and a thrombus may be present. The left ventricle is thickened and the lumen volume may be significantly diminished. Microscopically, the myocardium and endocardium may be replaced by granulation tissue of various ages; adjacent myocardium may be infiltrated by histiocytes, lymphocytes, and plasma cells. *Bartonella* infection has been suggested as a possible cause of feline endomyocarditis. RCM has been reported in cats with hypereosinophilic syndrome.

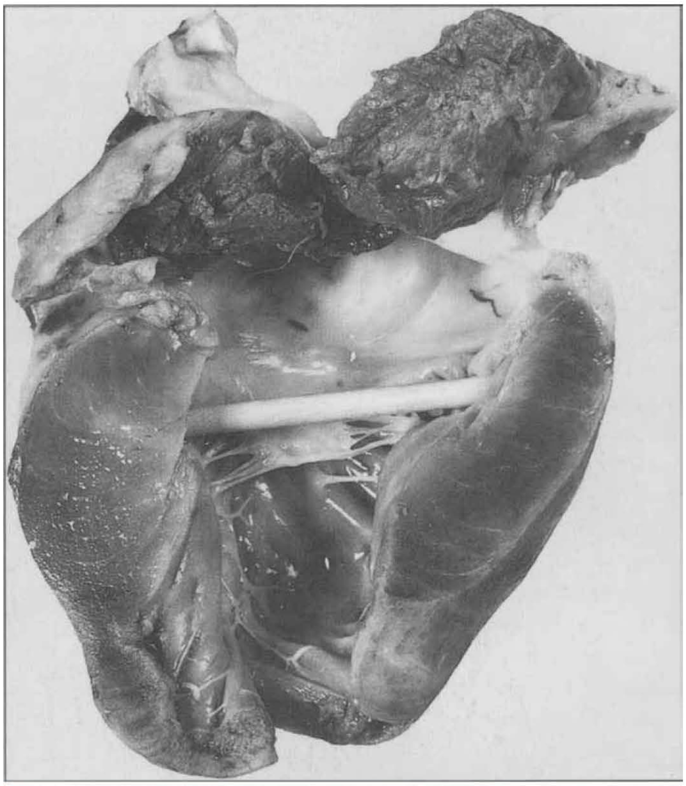

Figure 1.46 Thrombus in left atrium in a cat. The thrombus is red, recent, and attached in the auricle. Aortic embolism caused death.

Dilated cardiomyopathy has decreased markedly in prevalence since the discovery of *taurine-deficiency myocardial failure* in cats. On necropsy, all chambers of the heart are enlarged and the ventricles are dilated and flabby with thinned walls. The endocardium may be pale and slightly thickened by subendocardial fibrosis. The papillary muscles and trabeculae may be atrophied and appear small in relation to the ventricular volume. Often only minor lesions are found on microscopy. Myocardial fibers are moderately hypertrophied, accompanied by areas of mild diffuse interstitial fibrosis. There may also be focal areas of myofiber loss with replacement fibrosis. In some cases, there may be extensive areas of myocardial fibrosis. There is no significant disarray of myofibers. Ultrastructural examination contributes little to the understanding of the pathologic picture.

Excessive moderator bands (*false tendons*) in the left ventricle bridging the ventricular septum and free wall and entangling the papillary muscles are associated with heart failure and death in cats. Although not strictly a cardiomyopathy, it is considered under the heading of cardiomyopathies as the clinical syndrome occurs in mature cats. *In all probability, it is a congenital defect that is only manifest later in life.* Affected cats exhibit a range of clinical signs that are mostly referable to left-sided heart failure. They include lethargy, dyspnea, anorexia, pale mucous membranes, and cardiac murmurs. Radiographic findings include cardiomegaly, hydrothorax, and pulmonary edema. Various conduction disturbances also occur.

Gross changes are dominated by the presence of numerous pink-white bands spanning the left ventricular lumen and papillary muscles. Most commonly, the bands connect the cranial and caudal papillary muscles to the ventricular septum. In others, the bands insert between the ventricular septum and the left ventricular free wall. The left ventricle may be dilated or show increased wall thickness. In neither case is the heart weight significantly different from that of normal cats. The left atrium is enlarged, and pulmonary edema, pleural effusion, hepatic congestion, and aortic thromboembolism may be found. Microscopically, *the abnormal moderator bands consist of Purkinje cells and dense, mature collagen covered by endothelium.* Loose fibrous connective tissue is present between the endothelium and the dense collagen, with the variation in size of the moderator bands the result of more or less mature collagen. Ventricular alterations include myocyte atrophy or hypertrophy, focal fibrosis, and intramural coronary arterial luminal narrowing, intimal thickening, medial hyperplasia, and perivascular fibrosis.

Canine cardiomyopathies

The most commonly recognized is **dilated cardiomyopathy** (DCM), especially in young to middle-aged giant and large-breed dogs, such as the St. Bernard, Irish Wolfhound, and Great Dane, but also afflicting an ever-growing list of other breeds, including Airedale Terriers, Boxers, Doberman Pinschers, English Cocker Spaniels, Newfoundlands, Portuguese Water Dogs, Presa Canario Dogs, and Standard Poodles.

The causes and pathogenesis of canine DCM are unknown. There is a *familial tendency* in the Doberman Pinscher, English Cocker Spaniel, Boxer, Great Dane, Irish Wolfhound, and Newfoundland; DCM may be an X-linked recessive trait in Great Danes. Infantile dilated cardiomyopathy is inherited in Portuguese Water Dogs as an autosomal recessive trait. There is a strong association between the presence of cardiomyopathy and a particular complement C4 phenotype (C4:4) in the English Cocker Spaniel. This is not suggested to be causal, but to indicate a genotype that is predisposed to the development of the disease. It has been suggested that elevated levels of metalloproteinases and neutrophil elastase in the myocardium of Dobermans with cardiomyopathy contribute to the pathogenesis of the disease. A deficiency in the mitochondrial respiratory chain has been demonstrated in Doberman Pinschers, evident by marked impairment of the mitochondrial production of ATP; it is not known whether this is a primary defect or a general manifestation of a failing heart. Nutritional deficiencies may be involved in the pathogenesis of DCM. *Carnitine deficiency* may play a role in some subtypes of cardiomyopathy, although the evidence is not strong. Low blood *taurine* concentrations have been found in dogs with DCM that had been fed certain lamb-rice commercial diets. The DCM in Portuguese Water Dogs can be reversed in some pups by oral taurine supplementation. *Hypothyroidism* has been noted as a reversible cause of myocardial failure in two Great Danes. There is support for the hypothesis that alternative splicing of *cTnT variants* may desynchronize myocardial contraction and contribute to the development of cardiomyopathy and heart failure. *It is likely that a defect or defects at the genomic level underlie DCM in several canine breeds.*

Canine DCM has the *clinical features* of a short history of cough, depression, dyspnea, weight loss, syncope, and polydipsia, or may occur without premonitory signs as sudden death. Clinical signs may be due predominantly to left-sided congestive heart failure and hence pulmonary edema, or may be due to biventricular failure and include ascites. Atrial fibrillation is the most common electrocardiographic abnormality; ventricular tachycardia and ventricular premature contractions are common in most Doberman Pinschers. There is cardiomegaly, with increased end-diastolic volume and poor contractile function. Soft systolic murmurs, indicative of mitral and tricuspid insufficiency, may be heard on auscultation. *The prognosis is poor,* with mean survival times of 6 to 12 months after the onset of treatment.

Necropsy findings in typically affected cases are those of *congestive heart failure.* All chambers, particularly the left ventricle, are markedly dilated and may be hypertrophied. The atrioventricular rings are dilated (Fig. 1.47), the endocardium may be opaque due to subendocardial fibrosis, and there may be atrial thrombosis. There may also be some evidence of infarction in distant organs. The finding, in some cases, of multifocal myocardial degeneration, necrosis, or fibrosis is expected, but unrewarding, with regard to possible causes.

Ultrastructural examination of myocardium from cases of dilated cardiomyopathy shows increases in intermyofibrillar spaces, lipofuscin granules, fat droplets and myelin figures, mitochondrial hyperplasia, disruption of myofibrils, and Z band thickening. These ultrastructural changes are not specific for cardiomyopathy, but are more severe than seen with other causes of congestive heart failure.

There appear to be *two histologically distinct forms of DCM*: (1) the "fatty infiltration-degenerative" type seen in boxers and Doberman pinschers, and (2) the "attenuated wavy fiber" type seen in many giant, large-, and medium-sized breeds, including some Boxers and Doberman Pinschers. This histologic classification of canine DCM may be superior to classification by breed-specific syndromes, since both forms may affect some breeds, such as Boxers and Doberman Pinschers. This postmortem classification does not however assist antemortem etiological diagnosis of DCM, which remains difficult if not impossible.

A variant of DCM is **arrhythmogenic right ventricular cardiomyopathy** (ARVC), a primary familial myocardial disease in humans and in *Boxer dogs* that is associated with cardiovascular morbidity and risk of sudden death. ARVC in Boxers is characterized by various events, alone or in combination, including ventricular arrhythmias of suspected right ventricular (RV) origin, syncope, heart failure, and/or sudden death. Right ventricular dilation or aneurysms are common. Histopathological findings include severe myocyte loss in the RV, with replacement by fatty or fibrofatty tissue. Focal fibrofatty lesions may also be present in both atria and in the left ventricle (LV). Myocarditis may be present in the RV and LV in dogs with sudden death and may be the source of arrhythmias. ARVC is an ion channel defect in humans, with mutations identified at the ryanodine receptor 2 gene and the desmoplakin gene. It is transmitted as an autosomal dominant trait in humans and Boxers.

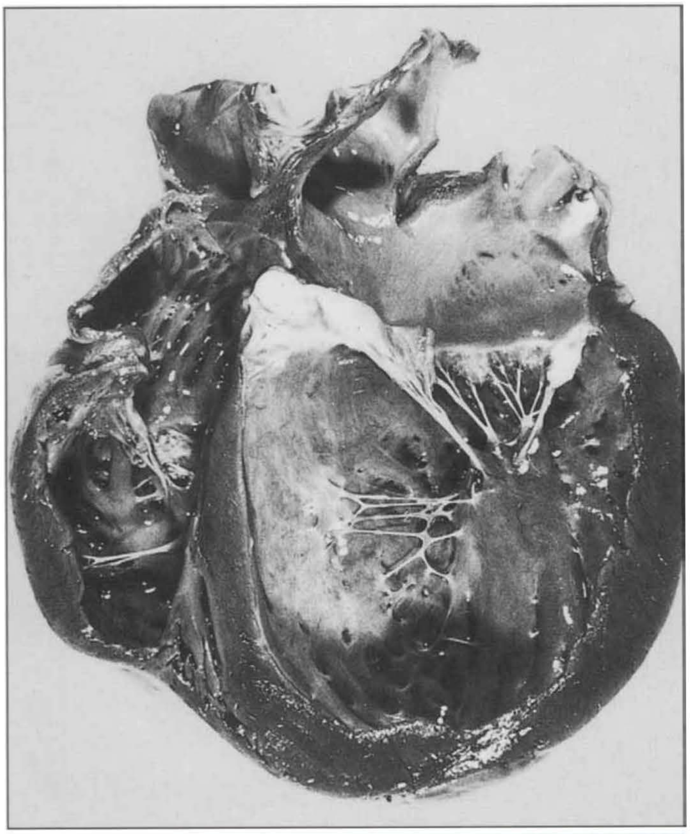

Figure 1.47 Dilated (congestive) **cardiomyopathy** in a dog. The left ventricle is dilated and the endocardium is fibrotic.

Hypertrophic cardiomyopathy is much less common than the dilated form. Associated clinical syndromes include sudden death, death during anesthesia, and congestive heart failure. Disproportionate thickening of the ventricular septum may cause the ratio of the interventricular wall thickness to left ventricular free wall thickness to exceed 1.2:1, and there may be histologic evidence of myofiber disarray in the ventricular septum.

In **canine X-linked muscular dystrophy** in golden retrievers, an animal model for Duchenne muscular dystrophy in humans, affected and carrier dogs develop *Duchenne cardiomyopathy* characterized by myocardial interstitial, especially subendocardial, fibrosis, leading to cardiac insufficiency.

Bovine cardiomyopathies

Several syndromes of cardiomyopathy are recorded in cattle. **Dilated cardiomyopathy** *occurs in* **Holsteins** *in Canada, Australia, and Japan, and in Simmental-Red Holstein crossbreds in Switzerland.* Many of the cases emanate from common sires, and an autosomal recessive mode of inheritance has been suggested. Inappropriate ubiquination of proteins may play a role in pathogenesis. The cardiomyopathy occurs in young adult to mature animals, with the clinical signs particularly referable to right-sided heart failure including dependent subcutaneous edema, hydrothorax, ascites, and severe hepatic congestion. There is no indication of the presence of electrocardiographic abnormalities. The heart is enlarged with dilation of both ventricles. Microscopically there is a mixture of atrophied and hypertrophied myofibers with vacuolation, and there are islands of interstitial and replacement fibrosis, fatty replacement, and ongoing myofiber necrosis.

Dilated cardiomyopathy in Japanese black calves is considered to be inherited as an *autosomal recessive trait.* Sudden death or death after a short period of severe dyspnea occurs in calves younger than 30 days. Lesions found at necropsy include marked cardiac enlargement with left ventricular dilation, hydropericardium, hydrothorax, ascites, pulmonary edema, and hepatic and splenic congestion. Extensive myocardial degeneration and necrosis with fibrosis are present in the left ventricle, particularly affecting the papillary muscles. The right ventricle is similarly but less often involved. The clinical and pathologic pattern is reminiscent of that seen in Hereford calves with cardiomyopathy.

A cardiomyopathy associated with a **tightly curled ("wooly") haircoat** *in both polled and horned Herefords* has also been described. The cardiomyopathy is inherited as an *autosomal recessive trait.* Affected animals are less than 6 months of age and are usually found dead. In some cases detected before death, severe ventricular dysrhythmias are evident. Even in some calves that die at 1 week of age, there are severe lesions in the ventricles consisting of necrosis, mineralization and fibrosis of the myocardium (Fig. 1.48A, B).

Hypertrophic cardiomyopathy has been reported in Holsteins.

Bovine generalized glycogenosis type II (Pompe's disease), although not a primary cardiomyopathy, deserves mention. Most

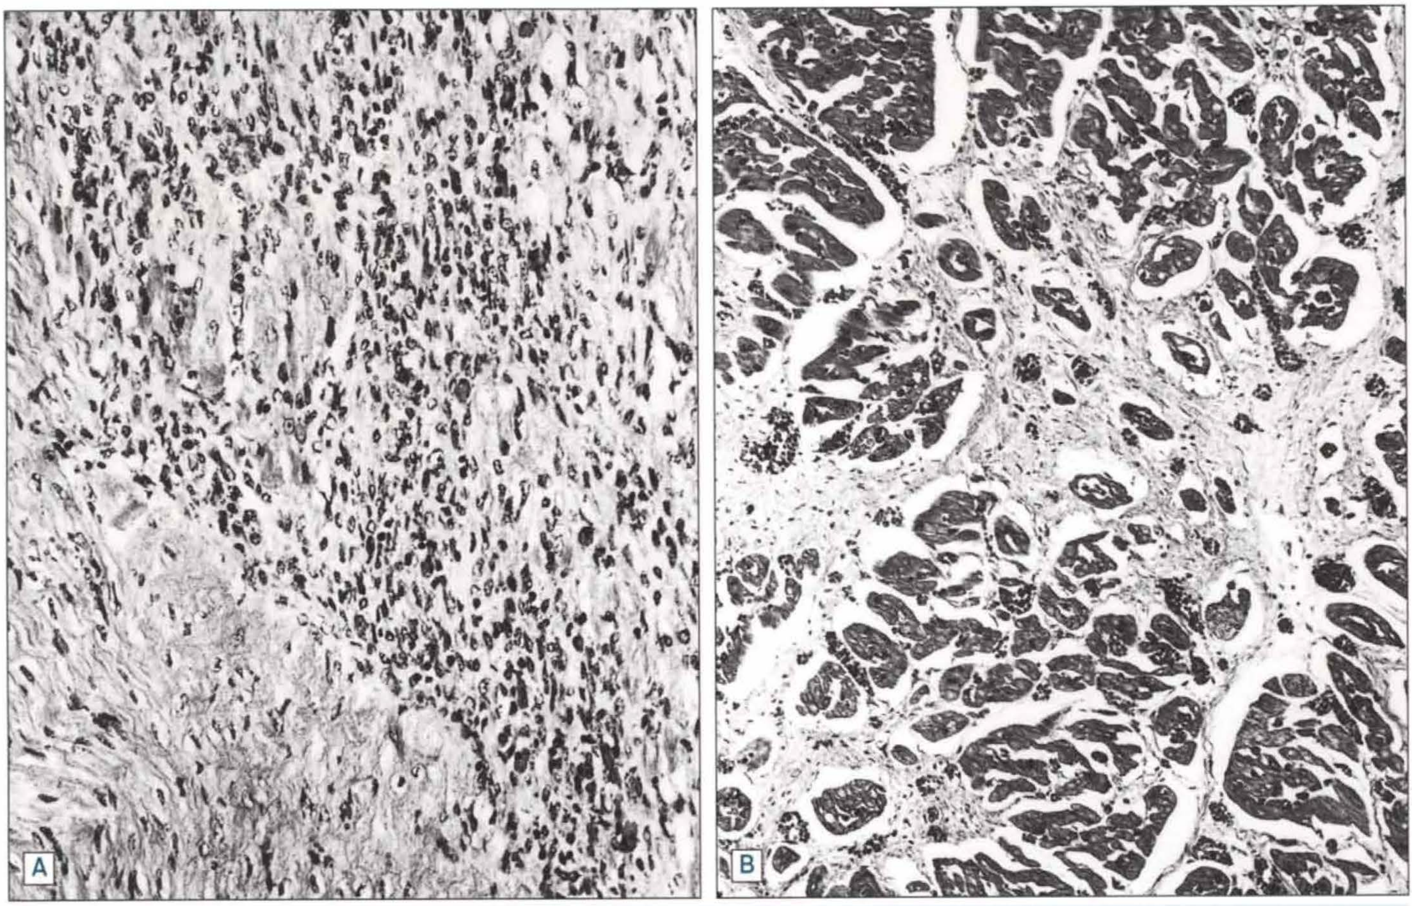

Figure 1.48 Cardiomyopathy in curly-coated poll Hereford calves. A. Degeneration and reparative fibrosis of myocardium, in a 2-week-old calf. **B.** Interstitial fibrosis of myocardium, in a 1-week-old calf.

affected animals have generalized muscle weakness. Occasional cases, however, exhibit clinical signs of left-sided heart failure, and in these the heart is eccentrically hypertrophied.

DISEASES OF THE CONDUCTION SYSTEM

The clinical and electrocardiographic features of primary conduction system disturbances are well documented, but comparatively rare. The clinical signs are primarily intermittent collapse, and sometimes sudden death. Electrocardiography may show a variety of abnormalities, such as sinoatrial arrest, second- or third-degree atrioventricular block, atrioventricular dissociation, left or right bundle branch block, Wolff–Parkinson–White syndrome (rarely), and ventricular tachycardia. It should not be forgotten that *many if not most dysrhythmias are secondary to more or less extensive myocardial degeneration, necrosis, inflammation, or neoplasia*, particularly when in close proximity to the conduction system.

In contrast, *reports on the gross and microscopic examination of cases of primary conduction system disturbances are remarkably sparse*. This may be due in part to negative findings in some cases, or to time and effort required to adequately examine the conduction system. When an abnormality of the conduction system is suspected, tissue samples from the appropriate regions should be collected as part of the necropsy (see Examination of the heart, above). The use of special stains such as Masson's trichrome and PTAH assist in highlighting the presence of excessive fibrosis and the relative paucity of contractile elements in the cells of the conduction system, respectively. For purposes of comparison, it is advisable to have a reference set of blocks of the conduction system from normal animals.
